The mediastinum refers to the central area in the chest between the thoracic inlet and the diaphragm, between the right and left pleural surfaces, and which extends from the inner aspect of the sternum to the vertebral column. It contains the heart, great vessels, trachea and oesophagus and is arbitrarily subdivided into compartments (superior, inferior, anterior, middle and posterior). Many of the regional lymph node chains draining the chest and its organs are also found

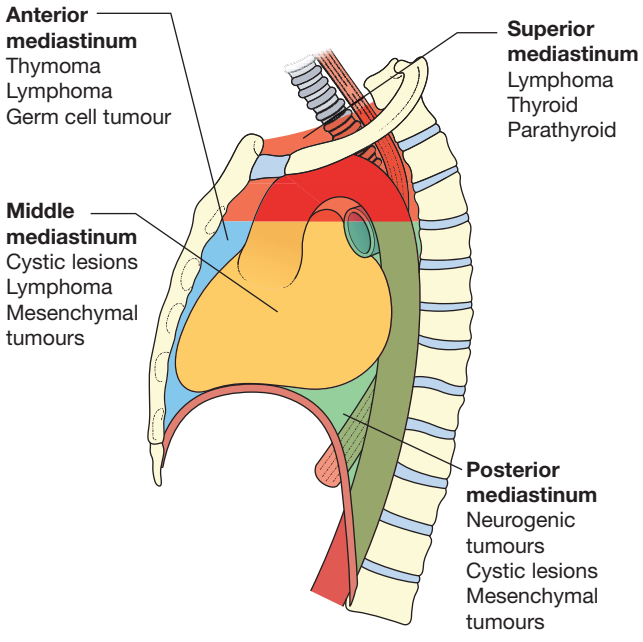

Figure 60.22 Mediastinal pathology. Subdivisions of the mediastinum with the most common mediastinal masses.

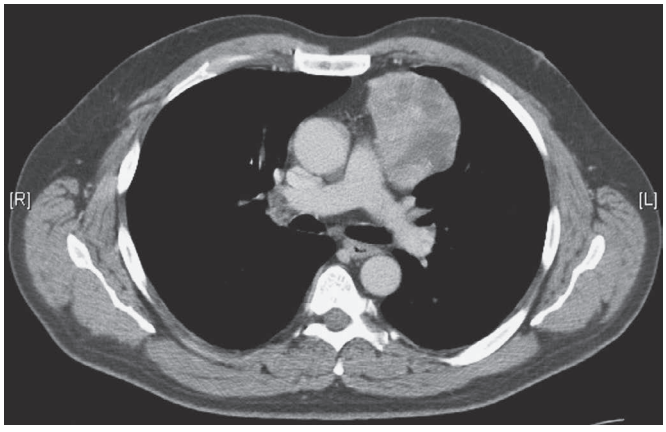

Figure 60.23 Computed tomography scan showing a thymoma presenting as a mediastinal mass.

in the mediastinum. Various surgical procedures to approach structures, and particularly lymph nodes, in the mediastinum are performed, usually as diagnostic procedures. The surgical approach when mediastinal tumours require resection depends on the anatomical location of the tumour (*Figure 60.22*) and includes median sternotomy for anterior mediastinal pathology, thoracotomy or VATS for posterior mediastinal pathology and transcervical (neck incisions) for superior mediastinal pathology. The middle mediastinum can usually be approached through thoracotomy or VATS. Increasingly, a robotic or RATS approach is used, particularly for anterior mediastinal tumours such as thymomas.

Primary tumours of the mediastinum

Thymoma, neurogenic tumours, germ cell tumours and lymphoma are the usual primary tumours of the mediastinum.

- **Thymoma**. This is the most common mediastinal tumour, accounting for 25% of the total, and is derived from the thymus gland (*Figure 60.23*). Thymomas vary in behaviour from benign to aggressively invasive, as reflected in the Masoaka classification system used to stage thymomas and more recently the TNM classification. They are often related to myasthenia gravis, a neuromuscular condition that can have a high associated incidence of thymomas, and interestingly may respond to excision of the thymus gland even when the gland has no associated thymoma present. The only reliable indicator of malignancy is capsular invasion. Diagnosis and treatment are best achieved by complete thymectomy, which for large tumours (>5 cm) or if tumour invasion is suspected a median sternotomy is performed. If the thymoma is small or when the patient has myasthenia gravis and the thymus is being excised as a treatment, various less invasive approaches can be considered, including a VATS approach or a transcervical approach with or without an additional VATS procedure.
- **Germ cell tumour**. The anterior mediastinum is the most common site of extragonadal germ cell tumours. They account for 13% of all mediastinal masses and cysts and contain elements from all three cell types (mesoderm, endoderm and ectoderm). They tend to present in young adults and 75% are benign and cystic, although they may cause compression of neighbouring structures; hence, dermoid cysts are best excised. Malignancy is suspected if elevated levels of serum alpha-fetoprotein, human chorionic gonadotropin and carcinoembryonic antigen are detected. After initial treatment with chemotherapy, a patient with tumour marker normalisation and a persistent mass on CT may be considered for surgical resection. If tumour markers fail to normalise, further chemotherapy is usually offered.
- **Lymphoma**. Lymphoma is a common cause of a mediastinal mass lesion, particularly in the anterior mediastinum, and can lead to superior vena cava obstruction or other symptoms of local compression. The main treatment is chemotherapy, and surgery is rarely required apart from obtaining tissue for diagnosis.
- **Mesenchymal tumours**. Lipomas are common in the anterior mediastinum. Other mesenchymal tumours are very rare.
- **Thyroid**. Ectopic thyroid (and parathyroid) tissue may be found in the anterior mediastinum but usually the mass is an extension of a thyroid lesion (retrosternal goitre). Excision of retrosternal thyroids may be required if there is local airway compression and stridor and can be performed via a transcervical incision, but occasionally median sternotomy may be required.

Akira Masoaka, 1930–2014, Professor of Surgery, Nagoya, Japan.

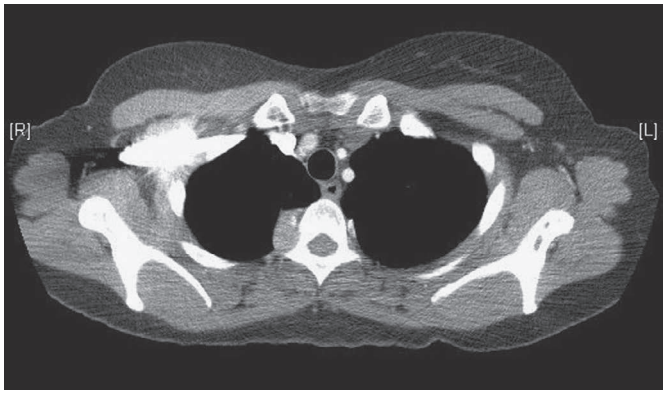

Figure 60.24 Computed tomography scan showing a right-sided paravertebral neurogenic tumour.

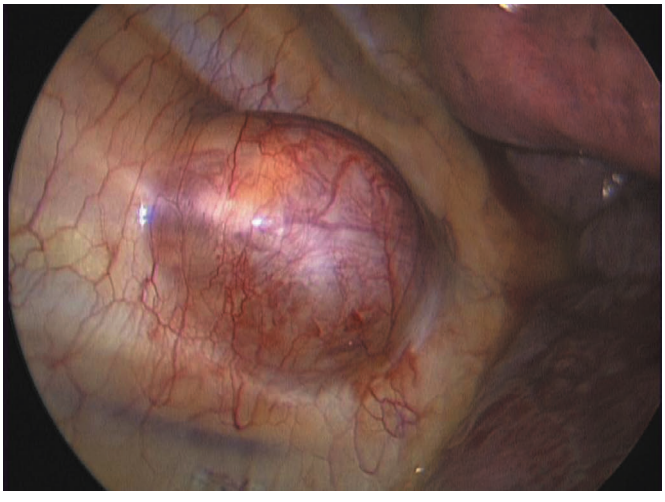

Figure 60.25 Video-assisted thoracoscopic surgery (VATS) image of a neurogenic tumour attached to the posterolateral chest wall prior to excision.

- **Neurogenic tumours**. These may derive from the sympathetic nervous system or the peripheral nerves and are more prevalent in the posterior mediastinum. They may be painful but are more often discovered accidentally on routine chest radiography and can be quite large (*Figure 60.24*). They include neuroblastoma in childhood, and Schwannomas and neurofibromas in adults, which are usually benign. Phaeochromocytoma arises from the sympathetic chain and produces the characteristic endocrine syndrome. Excision of neurogenic tumours is generally recommended, particularly if the patient is developing symptoms. This can be performed through a thoracotomy, though for smaller tumours a VATS approach can be used (*Figure 60.25*).
- Enlarged mediastinal lymph nodes are commonly involved by metastatic tumour, mimicking a primary mediastinal lesion. Symptoms are generally secondary to compression or invasion of a structure within the mediastinum. Surgery such as mediastinoscopy is reserved for diagnosis only.

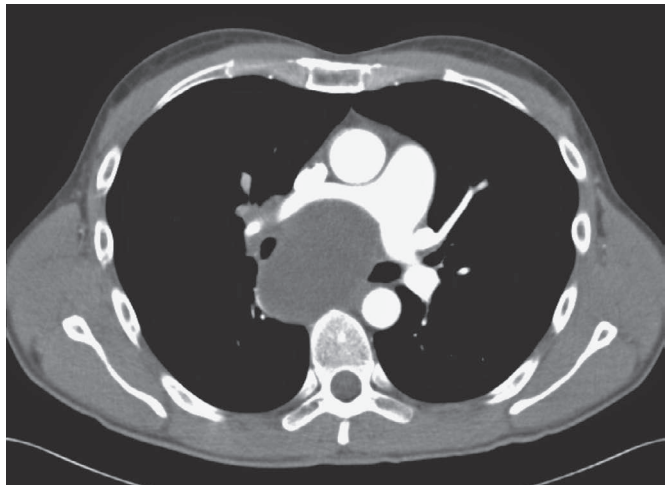

Figure 60.26 Computed tomography scan of the chest showing a bronchogenic cyst splaying the carina.

Other conditions of the mediastinum

Many of the primary tumours such as neurogenic tumours and germ cell tumours can present as cysts or have a cystic quality. In addition, the mediastinum can contain other cysts, often with an embryological aetiology. Thymic, pericardial, bronchogenic and foregut cysts can all present asymptomatically or with local compression (*Figure 60.26*). Surgical excision is recommended if the diagnosis is unclear or the patient has symptoms.

MEDICAL CONDITIONS FOR WHICH SURGERY MAY BE REQUIRED

Bronchiectasis

Bronchiectasis is chronic irreversible dilatation of the medium-sized bronchi, which may occur following a suppurative pneumonia or bronchial obstruction. It is the pathological end stage of a range of conditions. If generalised it is almost never considered for surgical resection. Cases caused by whooping cough and measles are decreasing in frequency in resource-rich countries.

Treatment

Removal of the bronchiectatic part of the lung for bleeding, recurrent infection or copious symptoms can be very effective when the disease is localised.

Lung abscess

The causes of lung abscess are shown in *Table 60.8*. The chest radiograph shows a cavity with a fluid level or in mycetoma a fungal ball. Most acute abscesses resolve with appropriate antibiotic therapy and postural drainage. Surgery is avoided. Small radiologically sited drains are used sometimes in the intensive care unit.

Theodor Schwann, 1810–1882, Professor of Anatomy and Physiology, successively at Louvain (1839–1848) and Liège, Belgium (1849–1888).

TABLE 60.8 Causes of lung abscess.

Specific pneumonia	Streptococcal Staphylococcal Pneumococcal *Klebsiella* spp. Anaerobic
Bronchial obstruction	Carcinoma Carcinoid Foreign body Postoperative atelectasis
Chronic respiratory sepsis	Sinusitis Tonsillitis Dental infection
Septicaemia	
Penetrating lung injury	

Tuberculosis

Surgery is rarely indicated for tuberculosis in resource-rich countries but, when it is, it must be combined with adequate antitubercular chemotherapy or the benefit of surgery will be lost.

Summary box 60.5

Tuberculosis: indications for surgery

- Suspicious lesion on chest radiograph in which neoplasia cannot be excluded
- Chronic tuberculous abscess, resistant to chemotherapy
- Aspergilloma within a tuberculous cavity
- Life-threatening haemoptysis

Diagnosis

Surgical procedures may be necessary to establish the diagnosis if suspected clinically but sputum or pus cultures are persistently negative.

Complications such as an aspergilloma in a chronic cavity causing life-threatening haemoptysis may require lobectomy.

Pulmonary sequestration

This describes a section of non-functional lung separated from the normal bronchial connection with other abnormalities of development, which often include a direct systemic arterial supply from the aorta. Venous return is to the pulmonary veins in the majority of cases. The segment becomes cystic and infected, resulting in the common appearance of a solid lung mass that may be homogeneous or heterogeneous, occasionally with cystic changes on CT scan. Interlobar sequestration occurs within the lung substance. It may present with recurrent chest infections and/or haemoptysis. Patients with extralobar sequestration are usually asymptomatic because air spaces are not present, and therefore it usually presents as an incidental finding.

Lung cysts

Developmental lung cysts have a tendency to become infected. Acquired lung cysts may contain air or fluid and may be single or multiple. Pulmonary hydatid disease is a cause in endemic areas. Air cysts (bullae) may be spontaneous but may be secondary to emphysematous degeneration (***Figure 60.27***).

LUNG TRANSPLANTATION (see ***Chapter 92***)

Lung transplantation is an established therapy for those with end-stage parenchymal or pulmonary vascular disease; it is limited by the number of donor lungs available.

CHEST TRAUMA

The approach to trauma must be methodical and exact because the signs, particularly in the presence of other injury,

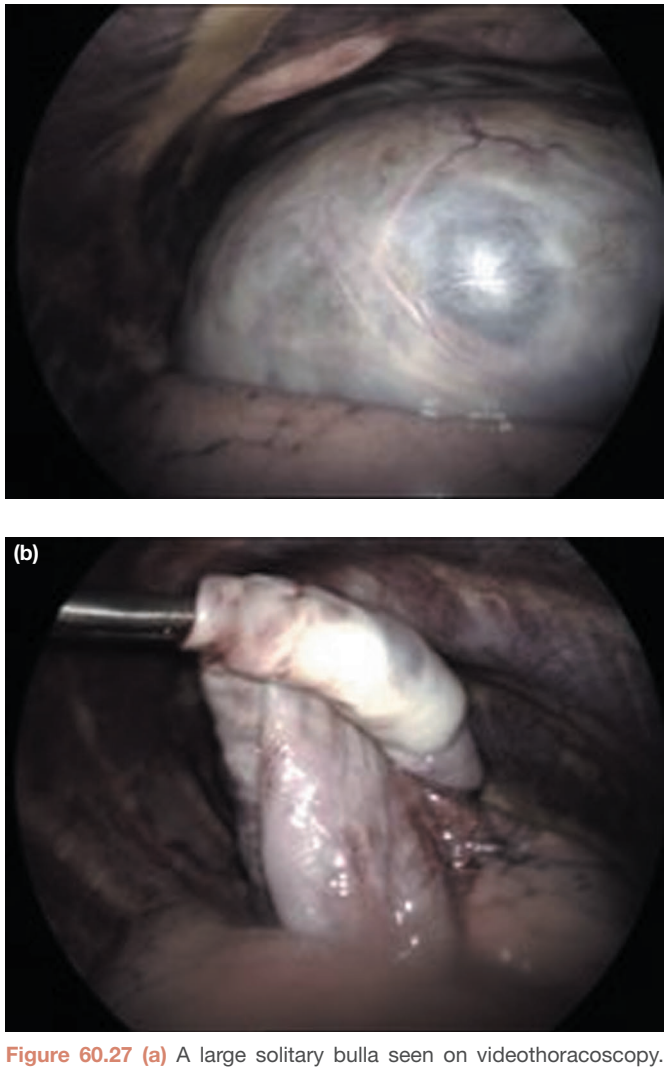

Figure 60.27 (a) A large solitary bulla seen on videothoracoscopy. **(b)** The bulla deflated and rolled in preparation for staple resection.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology, successively at Prague, Czech Republic; Zurich, Switzerland; and The Rush Medical College, Chicago, IL, USA.

may easily be missed. The general principles of resuscitation and ATLS (Advanced Trauma Life Support) must be followed.

Thoracic trauma is responsible for over 70% of all deaths following road traffic accidents. Blunt trauma to the chest in isolation is fatal in 10% of cases, rising to 30% if other injuries are present. The indications for emergency room thoracotomy in blunt chest trauma include massive haemothorax, suspected cardiac tamponade and witnessed cardiac arrest in the resuscitation area. Success rates are low. Penetrating thoracic wounds vary according to the prevalence of civil violence, with a mortality rate of 3% for simple stabbing to 15% for gunshot wounds. The indications for emergency room thoracotomy are similar to those for blunt chest trauma. The standard approach is a left anterior thoracotomy, unless the penetrating injury is in the right chest; however, it may be necessary to extend the incision to bilateral thoracotomies or a clam-shell incision.

THE DIAPHRAGM

The diaphragm is the fibromuscular structure separating the thorax from the abdomen.

Disorders of the diaphragm

Disorders of the diaphragm can be broadly classified as disorders of innervation, leading to paralysis of the diaphragm, with elevation and reduction of thoracic volume leading to breathlessness, and disorders of anatomy, which are further categorised into congenital diaphragmatic hernias or acquired hernias, usually secondary to trauma. There are two well-recognised congenital sites where abdominal viscera can herniate into the chest (***Figure 60.28***).

- The foramen of Morgagni: a hernia in the anterior part of the diaphragm with a defect between the sternal and costal attachments. The most commonly involved viscus is the transverse colon.
- The foramen of Bochdalek: through the dome of the diaphragm posteriorly.

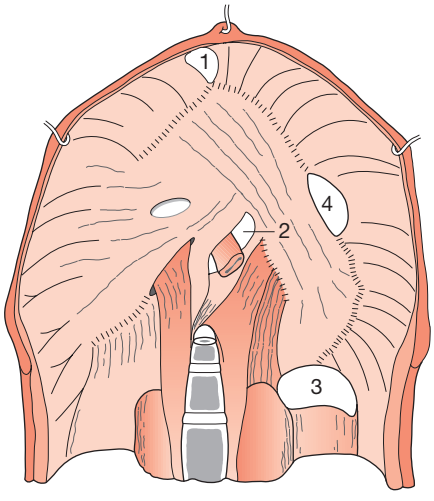

Figure 60.28 Diagram of sites of hernias. The usual sites of congenital diaphragmatic hernia: 1, foramen of Morgagni; 2, oesophageal hiatus; 3, foramen of Bochdalek (pleuroperitoneal hernia); 4, dome.

Traumatic rupture of the diaphragm may occur with blunt trauma. Unless there is severe bleeding or strangulation of the viscera it is best managed after an interval. In a severely injured patient being ventilated it can wait until other injuries are dealt with and weaning from the ventilator is being considered.

When the diaphragm is breached, as in anatomical disorders, repair either with primary closure or with a mesh is usually possible via a thoracotomy. Diaphragmatic paralysis, particularly idiopathic unilateral paralysis, can be treated by plication, returning the diaphragm to a lower position and improving thoracic volume.

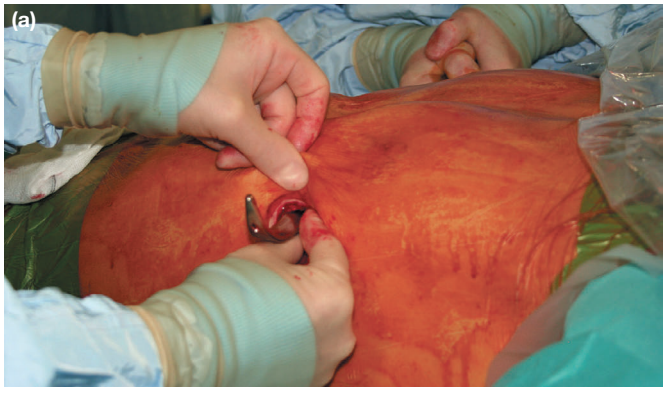
DISORDERS OF THE CHEST WALL

Tumours of the chest wall

These can be tumours of any component of the chest wall, i.e. bone, cartilage and soft tissue. They are treated similarly to those that occur at other sites and require specialist surgical input only if major resection and chest wall reconstruction are contemplated.

Other diseases of the chest wall

Congenital abnormalities are often incidental findings on chest radiography (e.g. bifid rib), but there are some important exceptions.



Cervical rib and thoracic outlet syndrome

This rib is usually represented by a fibrous band originating from the seventh cervical vertebra and inserting onto the first thoracic rib. It may be asymptomatic, but because the subclavian artery and brachial plexus course over it a variety of symptoms may occur. The lower trunk of the plexus (mainly T1) is compressed, leading to wasting of the interossei and altered sensation in the T1 distribution. Compression of the subclavian artery may result in a poststenotic dilatation with thrombus and embolus formation. The diagnosis, assessment and surgery are fraught with uncertainties and are best left to those with a well-developed interest in this problem.

Pectus excavatum

The sternum is depressed, with a dish-shaped deformity of the anterior portions of the ribs on one or both sides. Whether it causes cardiopulmonary issues through compression remains unclear but certainly the disfigurement can lead to significant psychological concerns. It can be repaired either as an open procedure (modified Ravitch procedure), which involves resecting the affected costal cartilages and mobilising the sternum, or

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy, for 59 years, regarded as 'the founder of morbid anatomy'.
Victor Alexander Bochdalek, 1801–1883, Professor of Anatomy, Prague, Czech Republic.
Mark M Ravitch, 1910–1989, paediatric surgeon, University of Pittsburgh, PA, USA.
Donald Nuss, contemporary, paediatric surgeon, Norfolk, VA, USA, described this technique in 1987.

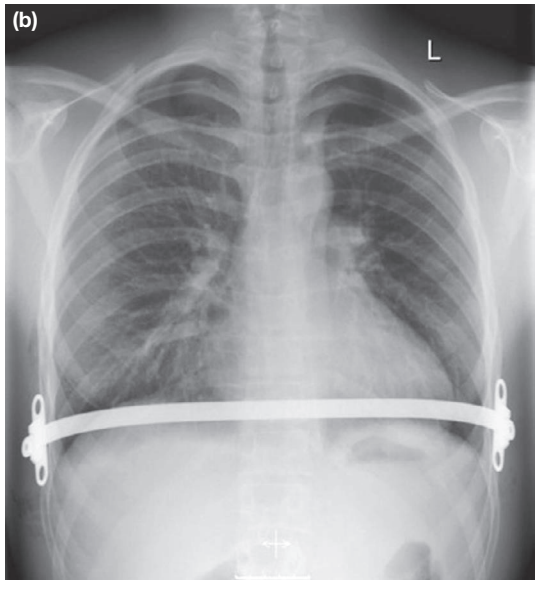


Figure 60.29 (a) Insertion of a preformed bar placed thoracoscopically beneath the pectus excavatum. **(b)** Chest radiograph following insertion of a metal bar bracing the sternum forward (the Nuss procedure).

as a minimally invasive technique, the Nuss procedure. A metal bar is placed behind the sternum to hold this central panel in its new position; the bar has to be removed after a period of time (***Figure 60.29***).

Pectus carinatum (pigeon chest)

In this condition the sternum is elevated above the level of the ribs and treatment is offered for aesthetic reasons. It often comes to light during the growth spurt at adolescence when, of course, the teenager is particularly sensitive about appearance. Most patients are asymptomatic and the only justification for treatment is on cosmetic grounds. Some surgeons make a very good case for this but the risk of morbidity and of a less than perfect result must be clearly spelt out to the patient and his/her parents. Surgery (modified Ravitch) involves mobilising the sternum with the costal cartilages so that the sternum can be flattened to a more anatomical position. Surgery is best left until the late teens, when further growth of the chest wall is unlikely. Alternatively, an external orthotic brace can be worn in young patients with a pliable chest wall to remodel the chest shape over time.

CHAPTER
61 Arterial disorders

Learning objectives

To understand:

- The nature and associated features of occlusive peripheral arterial disease
- The investigation and treatment options for occlusive peripheral arterial disease
- The principles of management of the severely ischaemic limb
- The nature and presentation of aneurysmal disease, including the abdominal aorta and popliteal artery
- The investigation and treatment options for aneurysmal disease
- The arteritides and vasospastic disorders

INTRODUCTION

Arterial disorders represent the most common cause of morbidity and early death in western societies. Much of this is as a result of atheromatous plaque build-up causing stenoses (atherosclerosis) within the arteries that supply the heart muscle (coronary thrombosis and myocardial infarction) and brain (stroke) and the peripheral arterial system. This chapter addresses diseases that are typically the domain of the vascular surgeon, namely those affecting the peripheral arterial system: vascular disease that alters the normal structure and function of the aorta, its visceral branches and the arteries of the lower extremity.

ARTERIAL STENOSIS AND OCCLUSION

Cause and effect

Peripheral arterial stenosis or occlusion is predominantly caused by atherosclerosis and/or thromboembolic disease, but may also occur as a result of trauma. Stenosis or occlusion produces symptoms and signs that relate to the organ supplied by the artery: e.g. lower limb – claudication, rest pain and gangrene; brain – transient ischaemic attacks (TIAs) and stroke; myocardium – angina and myocardial infarction; intestine – abdominal pain and infarction (***Figure 61.1***). The severity of the symptoms relates to the size of the vessel occluded and whether the stenosis or occlusion occurs suddenly (acute) in a previously normal artery or gradually (chronic) with progressive narrowing of the artery over time. In chronic stenosis symptoms may be abated despite being affected by significant steno-occlusive disease as a result of the development of a collateral circulation that provides an alternative, albeit less effective, route for blood to reach the target tissue/organ (***Figure 61.2***).

Figure 61.1 Antegrade aortogram via retrograde brachial artery access demonstrating superior mesenteric artery stenosis (arrow). CA, coeliac artery; SMA, superior mesenteric artery.

Claudication from the Latin 'claudicare' – to limp. The Roman emperor Claudius (10 BCE to 54 CE) walked with a limp, which was possibly due to poliomyelitis.

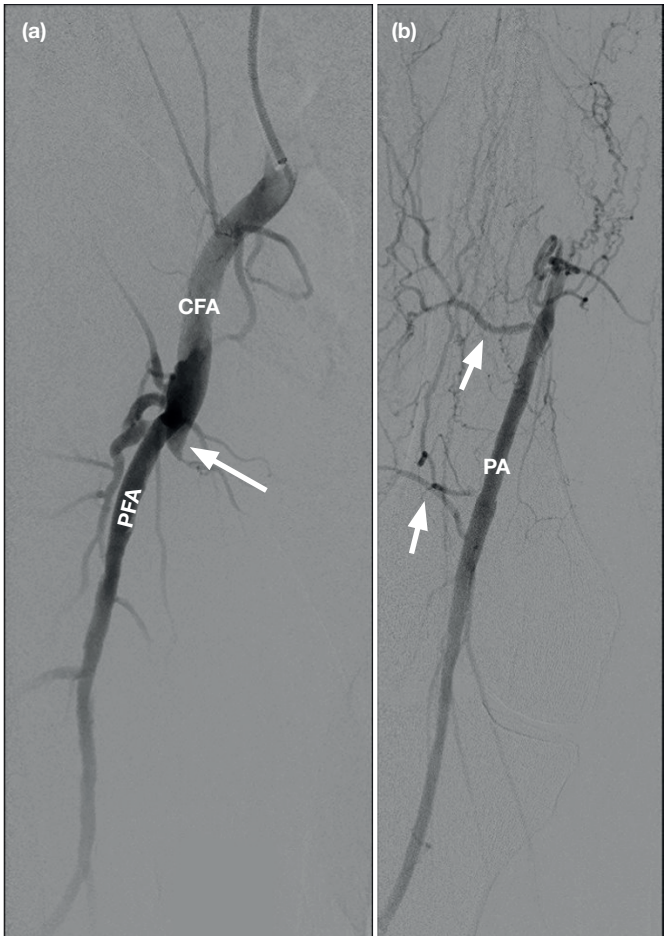

Figure 61.2 (a) Digital subtraction angiogram from the common femoral artery (CFA) demonstrating a flush right superficial femoral artery occlusion (arrow). **(b)** Reconstitution of the popliteal artery (PA) at the adductor hiatus via collateral flow from the profunda femoris artery (PFA) via the geniculate arteries (arrows).

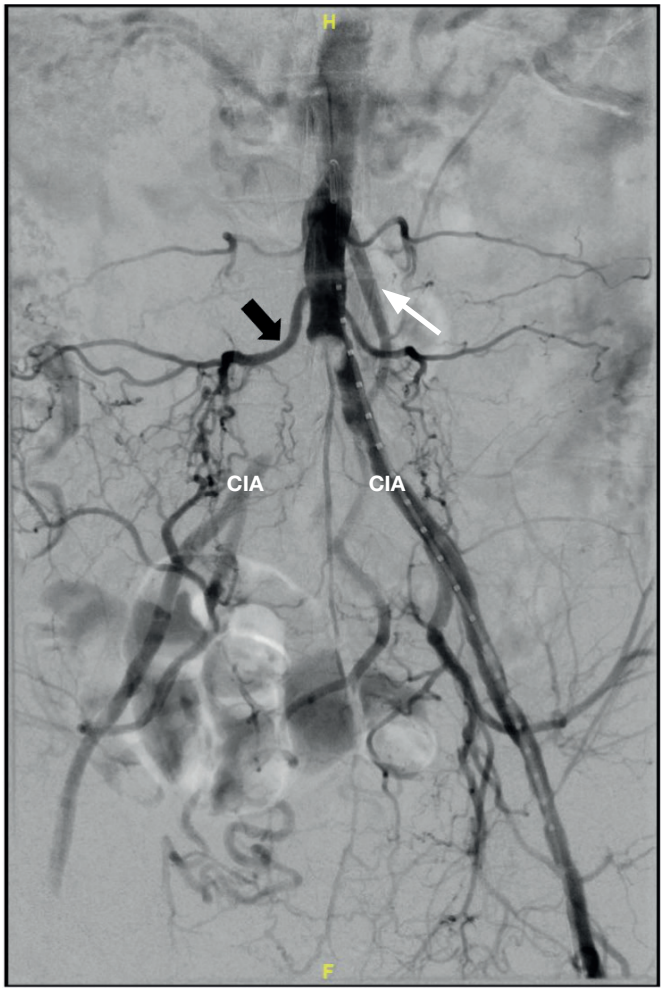

Figure 61.3 Aortoiliac bifurcation disease with an occluded right common iliac artery (CIA) and critically stenosed left CIA. Collateralisation has occurred via the lumbar arteries (black arrow) and the inferior mesenteric artery (white arrow).

Features of chronic arterial stenosis or occlusion in the leg

Intermittent claudication

Intermittent claudication occurs as a result of anaerobic muscle metabolism and is classically described as debilitating cramp-like pain felt in the muscles that is:

- brought on by walking;
- not present on taking the first step (unlike osteoarthritis);
- relieved by rest in both the standing and sitting positions, usually within 5 minutes (unlike nerve compression from a lumbar intervertebral disc prolapse or osteoarthritis of the spine or spinal stenosis, which are typically relieved only when resting in the sitting position for longer than 5 minutes).

The distance that a patient is able to walk without stopping varies (claudication distance) only slightly from day to day. It is decreased, first, by increasing the work demands and hence oxygen requirements of the muscles affected, e.g. walking up hill, increasing the speed of walking and/or carrying heavy weights, and, second, by general health conditions that reduce the oxygen delivery capacity of the arterial system, e.g. anaemia or cardiorespiratory disease.

The muscle group affected by claudication is classically one anatomical level below the level of arterial disease and is usually felt in the posterior calf as the superficial femoral artery is the most commonly affected artery (70% of cases). Aortoiliac disease (30% of cases) may cause thigh or buttock claudication; Leriche's syndrome is buttock claudication combined with sexual impotence, which is secondary to arterial insufficiency (***Figure 61.3***).

Rest pain

As disease progression occurs the claudication distance decreases and perfusion to the leg may be so severely

René Leriche, 1879–1955, Professor of Surgery, Strasbourg, France, described this syndrome.

Figure 61.4 Chronic limb-threatening ischaemia with dry gangrene.

compromised that anaerobic respiration occurs even at rest, typically affecting the foot and/or calf. The pain is exacerbated by lying down or elevation of the foot because of the loss of gravitational effects on the perfusion pressure in the foot. The patient characteristically describes pain that is worse at night and may be lessened by hanging the foot out of bed or by sleeping in a chair (effects of gravity restored). Even the pressure of bedclothes on the foot may exacerbate the pain.

Ulceration and gangrene

Ulceration occurs with severe arterial insufficiency and may present as painful erosions between the toes or as shallow, non-healing ulcers on the dorsum of the feet, on the shins and especially around the malleoli. The blackened mummified tissues of frank gangrene are unmistakable (***Figure 61.4***), and superadded infection often makes the gangrene wet. Patients with ischaemic rest pain with or without ulceration/gangrene (tissue loss) are termed to have chronic limb-threatening ischaemia (CLTI). These patients should be considered to have an imminently threatened leg and require urgent vascular assessment/revascularisation to prevent major amputation.

Colour, temperature, sensation and movement

Unlike an acutely ischaemic foot that is often cold, white, paralysed and insensate, a chronically ischaemic limb tends to equilibrate with the temperature of its surroundings and may feel quite warm under the bedclothes. Chronic ischaemia does not produce paralysis and sensation is usually intact. Patients with CLTI who have been waiting for a consultation with their leg in dependence may have a red swollen foot that may be mistaken for cellulitis by the unwary clinician. However, elevation of the limb reveals the severity of the ischaemia with venous guttering and foot pallor that changes to a red/purple colour when the limb is allowed to hang down again (dependent rubor or the sunset foot sign) (***Figure 61.5***). The capillary refill time may be elicited by pressing the skin of the heel or toe pulp, causing blanching (press for 5 seconds), and then releasing to allow colour to return; normally this takes 2–3 seconds but may be prolonged to 10 seconds in severe ischaemia.

Arterial pulses

It is standard practice to examine the femoral, popliteal, posterior tibial and dorsalis pedis arteries together with the abdomen for an aortic aneurysm, which may coexist with lower limb occlusive disease. Diminution of a femoral and/

Figure 61.5 Colour changes with elevation (a) and dependency (b).

or popliteal pulse can often be appreciated by comparing it with its opposite number; however, pedal pulses are either clinically palpable or absent. Popliteal pulses may be difficult to appreciate; a popliteal artery aneurysm should be suspected if the popliteal pulse is prominent with concomitant loss of the natural concavity of the popliteal fossa. Pulsation distal to an arterial occlusion is usually absent, although the presence of a highly developed collateral circulation may allow distal pulses to be palpable – this is most likely to occur with an iliac stenosis. In this case, exercise (walking until claudication develops) usually causes the pulse to disappear as vasodilation occurs below the obstruction, thereby reducing the pulse pressure. An arterial bruit, heard on auscultation over the pulse, indicates turbulent flow and suggests a stenosis. However, it is an unreliable clinical sign as tight stenoses often do not have bruits. A continuous 'machinery' murmur over an artery usually indicates an arteriovenous fistula.

Summary box 61.1

Features of chronic lower limb arterial stenosis or occlusion

- Intermittent claudication
- Rest pain
- Ulceration
- Gangrene
- Dependent rubor or sunset foot
- Arterial pulsation diminished or absent
- Slow capillary refilling
- Arterial bruit

Relationship of clinical findings to the site of disease

In most cases the anatomical level of arterial stenosis can be determined from accurate assessment of the symptoms and signs (***Table 61.1***). Limb-threatening ischaemia is predominantly caused by multilevel disease, e.g. iliac and femoropopliteal disease.

TABLE 61.1 Relationship of clinical findings to the site of disease.

Aortoiliac obstruction	Claudication in the buttocks, thighs and calves
	Femoral and distal pulses absent in both limbs
	Bruit over the aortoiliac region
	Impotence (Leriche)
Iliac obstruction	Unilateral claudication in the thigh and calf and sometimes the buttock
	Bruit over the iliac region
	Unilateral absence of femoral and distal pulses
Femoropopliteal obstruction	Unilateral claudication in the calf
	Femoral pulse palpable with absent unilateral distal pulses
Distal obstruction	Femoral and popliteal pulses palpable
	Ankle pulses absent
	Claudication in the calf and foot

Investigation of arterial occlusive disease

Most patients with symptomatic lower limb ischaemia present with mild symptomatology and do not require invasive treatment, such as angioplasty or surgical reconstruction, and the decision of whether or not to intervene can often be made without recourse to special investigations. When further investigation is indicated the purpose is to confirm the presence and severity of peripheral arterial disease (PAD), identify the anatomical location of disease and assess the suitability of the patient for intervention.

General investigation

Patients with arterial disease tend to be elderly and atherosclerosis is often a multisystem disease process; the presence of arterial disease in the leg is suggestive of disease in other arterial trees, including the coronary (50%) and cerebral (25–50%) trees. Many patients have other age-related diseases, such as chronic obstructive pulmonary disease and malignancy, that may impact on both their symptoms and suitability for intervention. Blood tests to exclude anaemia, diabetes, renal disease and lipid abnormalities should include a full blood count, blood glucose, lipid profile and serum urea and electrolytes. High blood viscosity (polycythaemia and thrombocythaemia) may be caused by smoking, but may also be associated with cancer; renal impairment (raised serum creatinine and low estimated glomerular filtration rate) may be caused by drugs and may be exacerbated by intravenous contrast agents used during angiography.

An electrocardiogram (ECG) may show coronary ischaemia, left ventricular hypertrophy or a cardiac dysrhythmia, although a normal ECG does not exclude these conditions. More information may be gained by an echocardiogram or exercise testing. Arterial blood gases and a pulmonary function test may be appropriate in patients with severe lung disease.

Doppler ultrasound blood flow detection

A hand-held Doppler ultrasound probe is very useful in the assessment of steno-occlusive arterial disease (***Figures 61.6 and 61.7***). A continuous-wave ultrasound signal is transmitted from the probe at an artery and a receiver within the probe itself picks up the reflected beam. The change in frequency in the reflected beam compared with that of the transmitted beam is due to the Doppler shift, which results from the reflection of the beam by moving blood cells. The frequency change may be converted into an audio signal that is typically pulsatile. Doppler ultrasound equipment can be used in conjunction with a sphygmomanometer to assess systolic pressure in small vessels. This is possible even when the arterial pulse cannot be palpated. Both the pressure and signal quality are important;

Christian Johann Doppler, 1803–1856, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

Figure 61.6 A simple hand-held Doppler ultrasound probe.

Figure 61.7 A hand-held Doppler probe and sphygmomanometer used to determine systolic pressure in the dorsalis pedis artery, as part of assessing the ankle–brachial pressure index.

a normal artery has a triphasic signal whereas a diseased artery may have a biphasic or monophasic signal depending on the extent of disease. However, although the presence of a Doppler signal indicates moving blood, it does not necessarily indicate that the blood flow is sufficient to maintain limb viability and prevent limb loss.

Quantitative assessment can be carried out at the bedside by performing an ankle–brachial pressure index (ABI), which is the ratio of the systolic pressure at the ankle to that in the ipsilateral arm. The highest pressure in the dorsalis pedis, posterior tibial or peroneal artery serves as the numerator, with the highest brachial systolic pressure being the denominator. The normal resting ABI is 0.9–1.4; values below 0.9 indicate

Figure 61.8 Toe pressures being performed from the hallux. An absolute pressure from the hallux of <50 mmHg indicates severe ischaemia that is likely to prevent healing of ulceration.

a haemodynamically significant arterial lesion; a value less than 0.4 suggests CLTI. Values are merely a guide and normal values may be present with intermittent claudication. Retesting after exercise to the onset of pain can be useful; a drop in the resting ABI of >20% after exercise is indicative of flow-limiting arterial disease. Artificially high ABI readings (>1.4) can be caused by media sclerosis and calcification of the arterial wall, causing vessel incompressibility and a falsely elevated ABI; this pattern of disease typically occurs in patients with diabetes mellitus (DM).

Toe (digital) arteries are rarely affected by sclerosis and a toe–brachial pressure index (TBI) in combination with ABI is advocated as a more reliable diagnostic tool for the detection of significant large-vessel steno-occlusive disease in patients with DM. A TBI less than 0.6 suggests a significant arterial lesion that may have been overlooked if ABI was used in isolation (***Figure 61.8***). However, there are limitations to the usage of TBI in the DM population: one in six patients with DM presenting with CLTI will have gangrene or will have undergone an amputation of the hallux.

Duplex Doppler ultrasound

This major non-invasive technique uses B-mode ultrasound to provide an image of vessels (***Figures 61.9 and 61.10***). The image is created because of the varying ability of different tissues to reflect the ultrasound beam. A second ultrasound beam is then used to insonate the imaged vessel and the Doppler shift obtained is analysed by a computer. Most scanners now have colour coding, which allows detailed visualisation of blood flow, turbulence, etc. Different colours indicate changes in direction and velocity of flow with areas of high flow usually indicating a stenosis. In experienced hands, duplex Doppler ultrasound (DUS) is as accurate as angiography and has the advantages of cost-effectiveness and safety. However, there are limitations: the aortoiliac segment can be difficult to visualise because of

Figure 61.9 Duplex Doppler ultrasound scan being performed of the right carotid bifurcation.

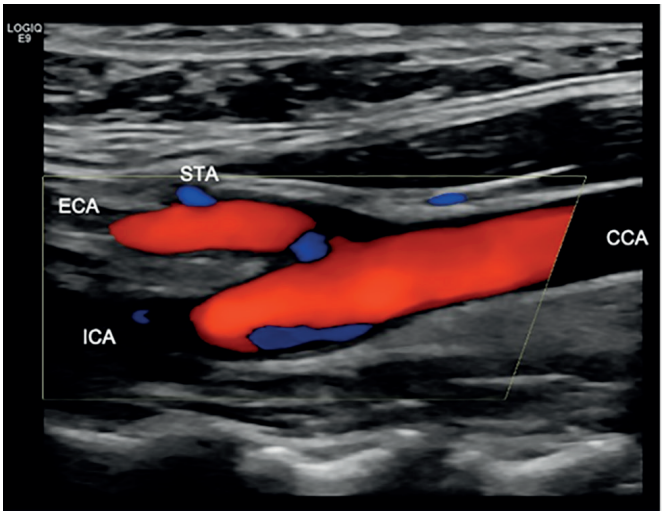

Figure 61.10 Normal duplex Doppler ultrasound of the carotid vessels in the neck. CCA, common carotid artery; ECA, external carotid artery; ICA, internal carotid artery; STA, superior thyroid artery.

bowel gas or obesity; vessels that are heavily calcified may limit the ability of DUS to accurately assess the severity of stenoocclusive disease; the overall accuracy of DUS is determined by operator experience. When DUS inadequately visualises or quantifies the level of disease within an arterial segment an alternative imaging modality, e.g. digital subtraction percutaneous angiography (DSA) or computed tomography angiography (CTA), may be undertaken to delineate the anatomy and extent of disease.

Digital subtraction percutaneous angiography

DSA involves injection of a radio-opaque dye into the arterial tree. Access to the vessel, typically the common femoral artery (CFA), is achieved using the Seldinger technique and is usually done percutaneously (***Figures 61.11 and 61.12***). The images obtained are digitalised by computer and the extraneous background (bone, soft tissues, etc.) is removed to provide clearer images. The benefits of DSA are that it provides dynamic arterial flow information and can be combined with a definitive endovascular intervention when indicated. However, it is associated with potential complications, including bleeding, haematoma, false aneurysm formation, thrombosis, arterial dissection, distal embolisation, renal dysfunction and allergic reaction, which may occur in up to 5% of procedures. Furthermore, it is relatively expensive compared with other investigation modalities and its usage should be limited to patients in whom a concomitant intervention is predicted.

Computed tomography angiography and magnetic resonance angiography

The use of CTA as a minimally invasive alternative to DSA has increased as availability has improved. When used as an adjunct to DSA, CTA is beneficial where DUS is not possible (intrathoracic arteries) or produces poor images (aortoiliac segment). With increased ease of access, better image quality and modern three-dimensional image reconstruction software, CTA has become an invaluable tool when planning revascularisation procedures, enabling the surgeon to visualise and measure diseased arterial segments prior to intervention.

The major concern with CTA, in addition to the exposure to ionising radiation, is the use of iodinated contrast. A substantial proportion of patients presenting with PAD have concomitant renal dysfunction, which may be acutely exacerbated by iodinated contrast, causing contrast-induced nephropathy.

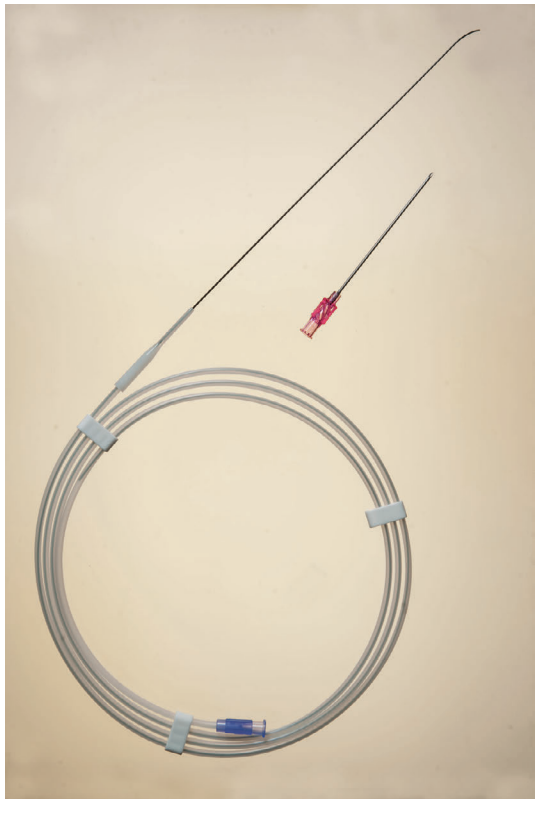

Figure 61.11 A Seldinger needle and guidewire for introducing an arterial catheter.

Sven Ivar Seldinger, 1921–1998, radiologist, Karolinska Institutet, Stockholm, Sweden, introduced percutaneous arterial catheterisation in 1956.

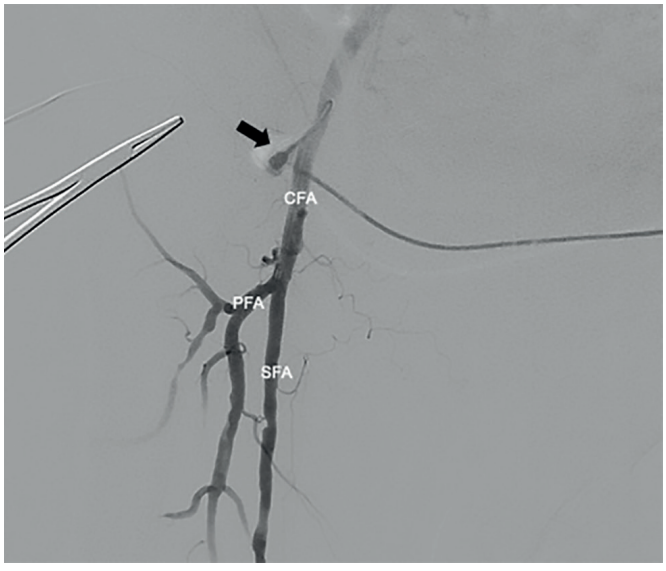

Figure 61.12 Digital subtraction angiogram of the femoral artery complex performed through a sheath (arrow) positioned percutaneously in the common femoral artery (CFA) using the Seldinger technique. PFA, profunda femoris artery; SFA, superficial femoral artery.

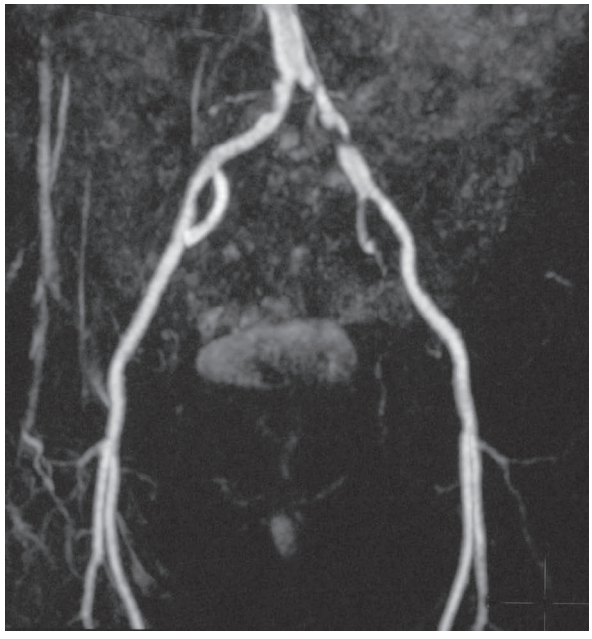

Figure 61.13 Magnetic resonance angiogram showing a tight stenosis at the midpoint of the left common iliac artery.

This is particularly pertinent to the patient with diabetes, in whom one also needs to be mindful of the interactions between contrast and certain pharmacotherapies, e.g. metformin, as their periprocedural usage may cause dangerous metabolic injury.

Magnetic resonance angiography (MRA) is a non-invasive test that avoids the need for ionising radiation and iodinated contrast, thereby having advantages over DSA and CTA. It is becoming more widely utilised, particularly as the proportion of patients with diabetes increases; this patient population typically has calcified crural vessel disease, which is difficult to assess using DUS or CTA.

MRA has the ability to separate out contrast from vessel wall calcification and has become the preferred imaging modality in many institutions.

MRA has a number of limitations and may be contraindicated in patients with claustrophobia or certain metallic implants, e.g. pacemakers. The majority of peripheral arterial stents are now compatible with MRA, although the image quality will often be downgraded, making interpretation of flow difficult. MRA uses gadolinium as a contrast agent and patients with renal dysfunction are at risk of gadolinium-induced nephrogenic systemic fibrosis (***Figure 61.13***).

Management of arterial stenosis or occlusion

General

Only one-quarter of patients presenting with intermittent claudication will experience symptomatic deterioration during their lifetime and the overall risk of progression to CLTI and amputation is small, with <5% of patients requiring amputation over a 5-year period. Patients with an ABI of <0.50 are twice as likely to deteriorate as patients with an ABI of >0.50, and a deteriorating ABI is predictive of future limb loss. For patients with rest pain or tissue necrosis, intervention is usually required to prevent major amputation.

Claudication is often a marker of silent coronary arterial disease whose extent correlates with the ABI: a decrease of 0.1 in ABI below 0.9 is associated with a 10% increase in the relative risk of a major cardiovascular event. Similarly, one-quarter of patients with claudication have significant atherosclerotic disease affecting their carotid and renal arterial systems. It is thus not surprising that the risk of having a major cardiovascular event per year in patients with claudication is >5%, and that 50% of claudicants will die within 10 years from myocardial infarction or stroke. The common modifiable risk factors for PAD mirror those for coronary artery disease: smoking, DM, hypertension and hyperlipidaemia. Therefore, the two main aims when treating claudication are (i) prevention of major cardiovascular morbidity through risk factor modification and (ii) symptom relief/improvement.

Non-surgical management

For many patients with claudication a structured exercise programme of at least 2 hours of exercise per week for 3 months in combination with smoking cessation will lead to sustained improvement in claudication distance and a reduction in cardiovascular risk. DM increases the risk and severity of claudication proportional to the duration of affliction. Strict control in combination with weight loss in obese patients is vital to reduce cardiovascular risk and prevent symptom deterioration.

Drugs

Medication may be required for diseases associated with arterial disorders, such as hypertension and diabetes; some

antihypertensives (particularly β-blockers) may exacerbate claudication. Raised blood lipids require active drug treatment, but even when the lipid profile is normal a statin (3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitor) should be prescribed as it may stabilise atherosclerotic plaques and protect against cardiac death independently of baseline serum lipid levels. An antiplatelet agent is also necessary: global guidelines recommend 75 mg per day of clopidogrel or 75 mg per day of aspirin as an alternative. Other agents, such as vasodilators, are unlikely to provide either significant or sustained benefit. Drugs are now available to help with smoking cessation.

Transluminal angioplasty and stenting

Arterial occlusive disease may be treated by inserting a balloon catheter into an artery and inflating it within a stenosed or occluded segment (***Figures 61.14 and 61.15***). This technique is suitable for patients with claudication, rest pain or tissue necrosis (***Figures 61.16 and 61.17***). Following percutaneous femoral artery puncture under local anaesthetic a guidewire is inserted and negotiated through the stenosis or occlusion under fluoroscopic control. A balloon catheter is positioned within the lesion over the guidewire and inflated at high pressure for approximately 30 seconds. Satisfactory dilatation of the lesion is confirmed by performing an angiogram. Percutaneous transluminal angioplasty (PTA) has proved very successful in dilating the iliac and femoropopliteal segments; the results below the knee are less successful but improving. Long occlusions may be treated by the technique of subintimal angioplasty, in which the guidewire crosses the lesion in the subintimal space (in the arterial wall) and a new lumen is created by inflation of the balloon. Complications occur in about 5% of cases and include failure, haematoma, bleeding, thrombosis and distal embolisation; these may impact on the surgeon's ability to perform a subsequent open surgical revascularisation procedure.

If the vessel fails to stay adequately dilated (often caused by elastic recoil of the artery), it may be possible to hold the lumen open using a metallic stent (***Figures 61.18 and 61.19***). This may be introduced on a balloon catheter and expanded

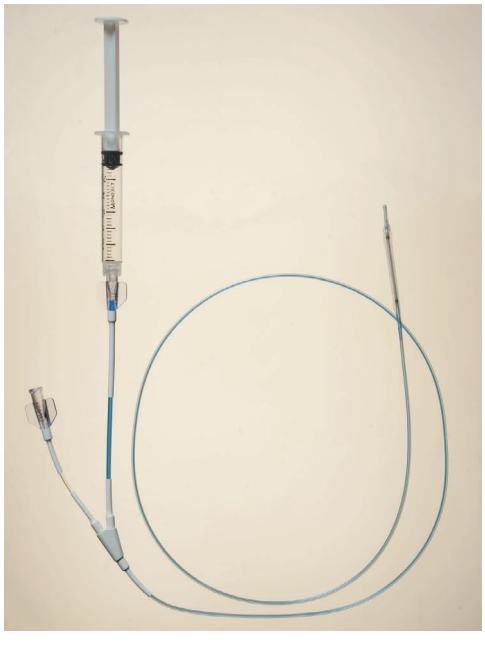

Figure 61.14 Balloon catheter for percutaneous transluminal angioplasty.

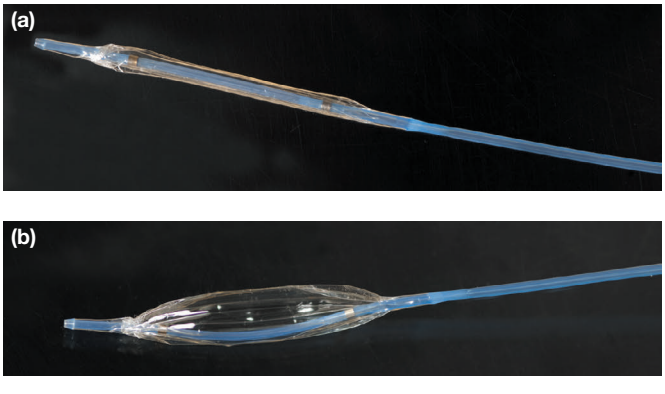

Figure 61.15 (a) Catheter balloon deflated; **(b)** balloon inflated.

Figure 61.16 (a) Digital subtraction angiogram (DSA) demonstrating multiple stenoses within the superficial femoral artery (SFA). **(b)** Balloon angioplasty of the SFA. **(c)** Postangioplasty DSA of the SFA demonstrating improvement in the previously stenotic regions. This technique can be carried out under local anaesthesia using the Seldinger technique of percutaneous arterial puncture. It is therefore especially useful in the treatment of patients who are medically unfit for major bypass surgery.

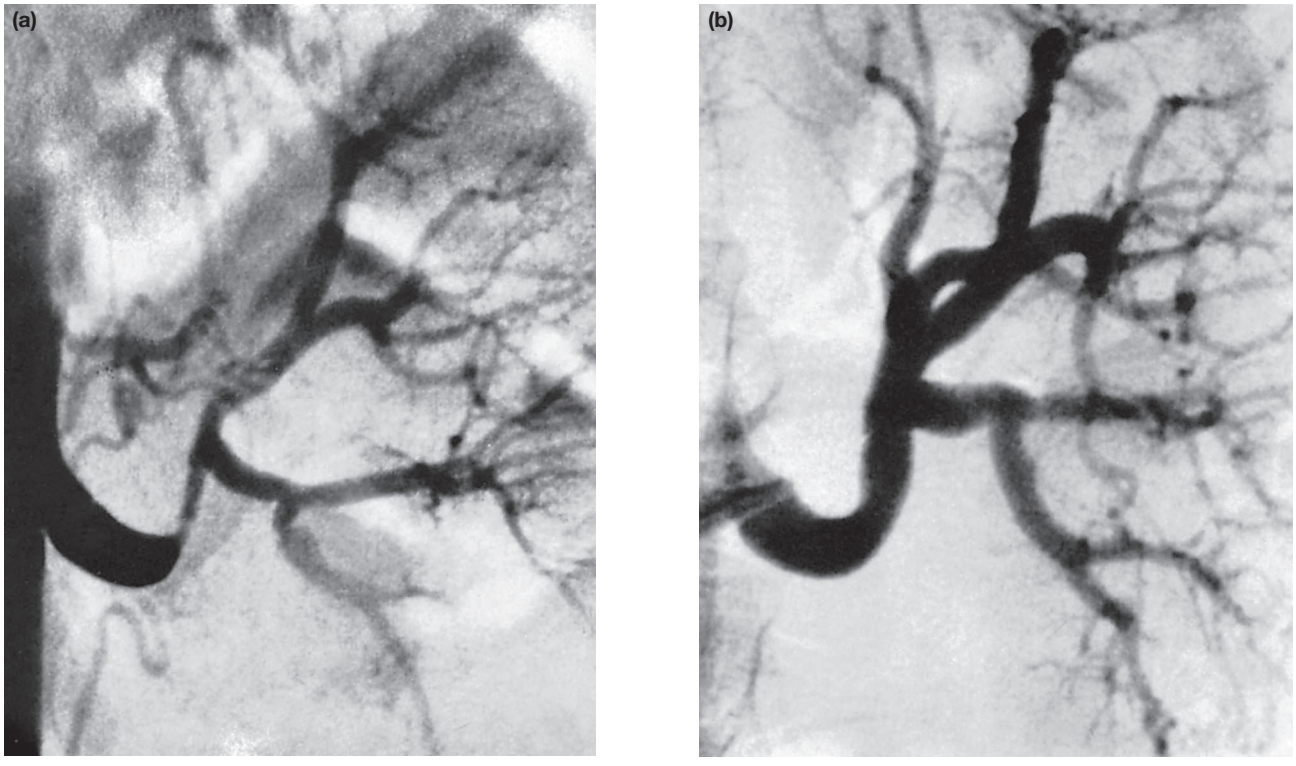

Figure 61.17 Before **(a)** and after **(b)** balloon dilatation of a severely stenosed left renal artery in a 20-year-old woman with uncontrollable hypertension. The patient's blood pressure fell to normal after the procedure. The stenosis was probably due to fibromuscular hyperplasia, but no tissue was available for histological diagnosis.

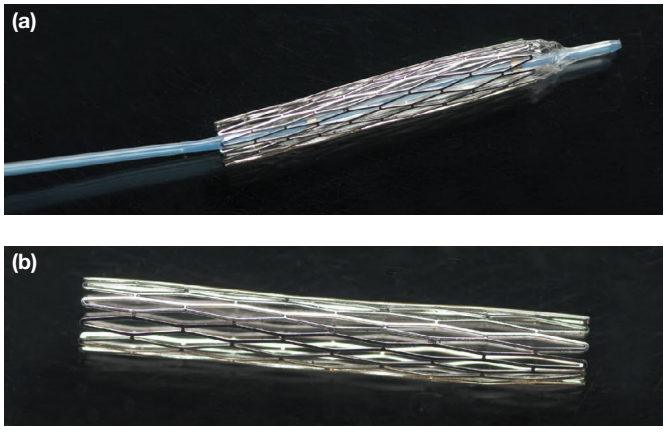

Figure 61.18 (a) A balloon catheter carrying a stent; **(b)** the expanded stent.

by balloon inflation. Alternatively, a self-expanding (typically nitinol) stent may be used; this is contained inside a plastic sheath and deployed by withdrawal of the sheath.

Operations for arterial stenosis or occlusion

Site of disease and type of operation

Surgical operations are usually reserved for patients with severe symptoms (CLTI or lifestyle-limiting claudication) where angioplasty has failed or is not possible. Aortoiliac occlusion responds well to aortobifemoral bypass (***Figure 61.20a***) using a Dacron graft (***Figure 61.21a***), although the operation carries a perioperative mortality and systemic morbidity (stroke, cardiorespiratory failure, renal injury) rate of about 5% and 15%, respectively. In unfit patients, an axillobifemoral bypass is an alternative, although patency rates are less. If only one iliac system is occluded, an iliofemoral or femorofemoral crossover graft may be performed.

Superficial femoral artery disease can be treated by femoropopliteal bypass (***Figure 61.20b***); long-term graft patency is determined by the quality of inflow and outflow, graft length (whether the distal anastomosis is above or below the knee) and the conduit used for the bypass. Autologous great saphenous vein (GSV) gives the best results and can be used reversed or *in situ* after valve disruption. If the GSV is not available from either leg, the lesser saphenous or arm veins may be used. If no vein is available, a prosthetic polytetrafluoroethylene (PTFE) graft may be employed (***Figure 61.21b***), although patency rates are less; many surgeons construct the lower anastomosis using a small collar of vein (Miller cuff or St Mary's boot) between the PTFE and the recipient artery, which may improve patency. Isolated CFA or profunda disease can be treated with endarterectomy and patch (vein or prosthetic) or a short bypass in the groin.

Frequently, in patients with CLTI, particularly those with diabetes, the occlusion extends beyond the popliteal artery into the tibial (crural) vessels. Limb salvage can be attempted with a

Justin H Miller, 1924–1994, vascular surgeon, Royal Adelaide Hospital, Adelaide, Australia.

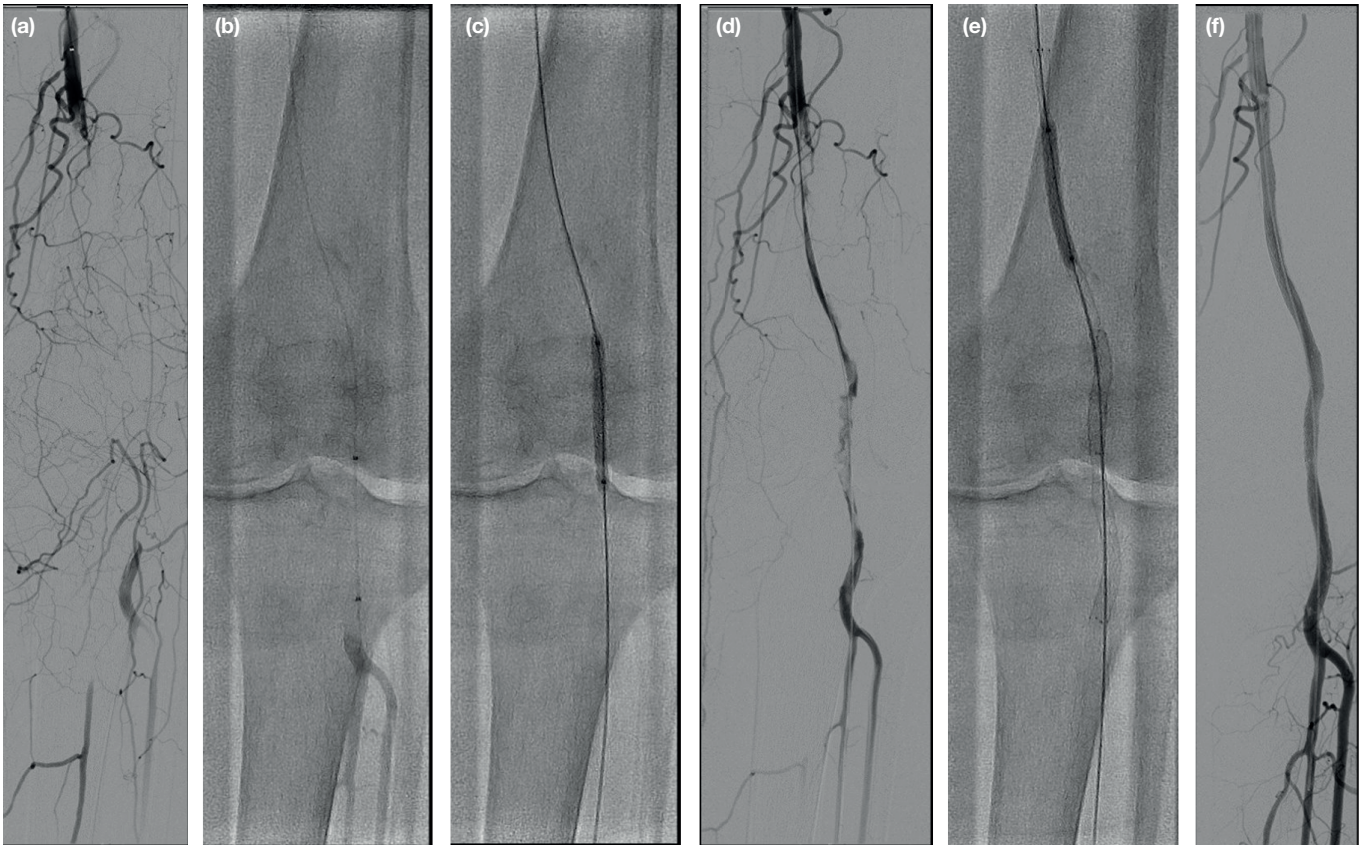

Figure 61.19 (a) Occlusion of the popliteal artery extending into the tibioperoneal trunk. **(b)** A lesion crossed with a catheter angiogram confirming intraluminal positioning beyond the occlusion. **(c)** Balloon angioplasty. **(d)** Angiogram demonstrating vessel recoil. **(e)** Stents inserted to maintain the lumen and balloon moulded. **(f)** Completion angiogram.

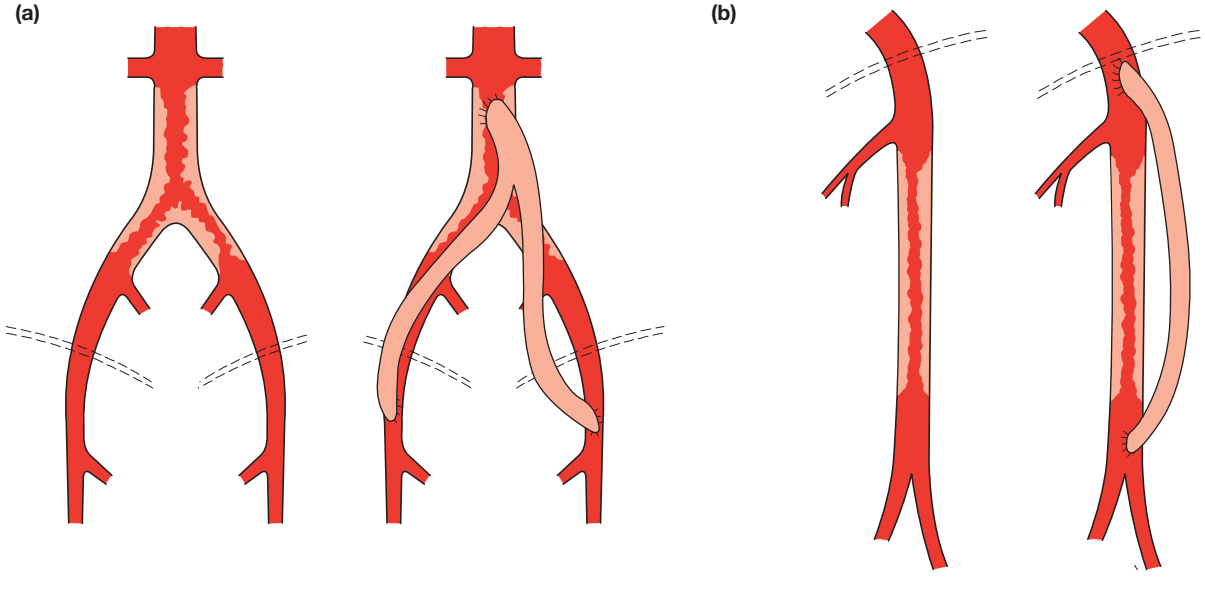

Figure 61.20 (a) Atherosclerotic narrowing of the aortic bifurcation. Aortobifemoral graft to bypass the stenosis. **(b)** Long superficial femoral artery stenosis providing poor collateral circulation. A femoropopliteal graft is used to bypass the occluded area into good 'run-off' below.

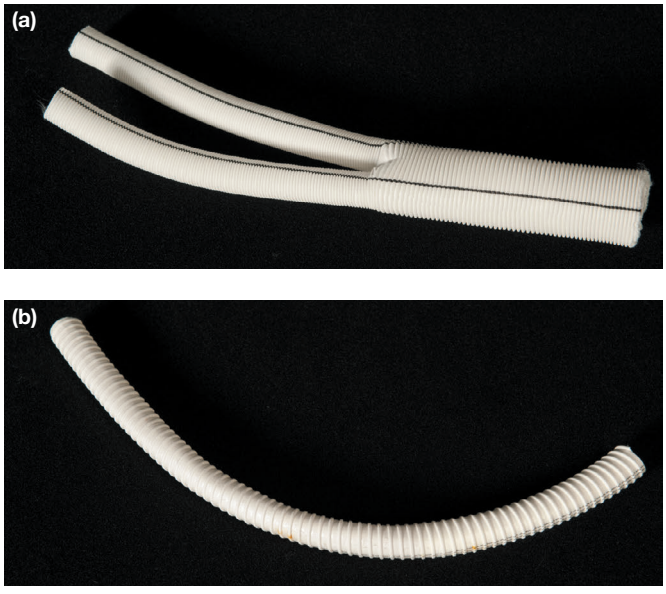

Figure 61.21 (a) A Dacron® bifurcation graft; **(b)** a polytetrafluoroethylene graft.

femorodistal bypass, with success even more dependent on the state of the run-off vessel and the quality of the vein conduit (minimum diameter 3 mm). The risk of early graft failure with limb loss is high (approximately 30% at 30 days) and these long bypasses are only appropriate for limb salvage.

Technical details

For aortobifemoral bypass, the aorta should be approached through a midline abdominal incision; a transverse abdominal incision divides the inferior epigastric vessels (important collateral vessels in patients with an occluded aorta) and should be avoided. The common femoral arteries and their branches are exposed through vertical groin incisions; an oblique or transverse groin incision may be preferred for patients with obesity. The small bowel is retracted to the right and the posterior peritoneum opened. Retroperitoneal tunnels are made from the aorta to the groins. Heparin (5000 U) is given intravenously and the vessels clamped. A vertical incision is made in the anterior aspect of the aorta, to which an obliquely cut, bifurcated Dacron graft is sutured end-to-side with a non-absorbable suture (polypropylene). The graft limbs are then fed down to the groins, where they are anastomosed end-to-side to the common femoral arteries or, if there is evidence of profunda stenosis, to an arteriotomy running from the common femoral vessel down into the profunda. The posterior peritoneum is closed over the Dacron graft to prevent adhesion of the graft to the bowel, and the abdomen and groin wounds are closed.

For femoropopliteal bypass the popliteal artery above or below the knee is exposed through a medial incision. The CFA is exposed at groin level. The GSV may be used in two different ways. First, it may be excised, its tributaries tied and the vein used in a reversed fashion so the valves do not obstruct the flow of blood. Alternatively, it may be left in place (*in situ*) and the valves disrupted with a valvulotome. The graft is sutured to the femoral artery proximally and to the popliteal artery distally. Femorodistal bypass involves fashioning the distal anastomosis to a tibial vessel. If no suitable vein is available, prosthetic material (usually PTFE) may be used, with or without a small vein collar (Miller cuff or St Mary's boot) at its distal end (***Figure 61.22***).

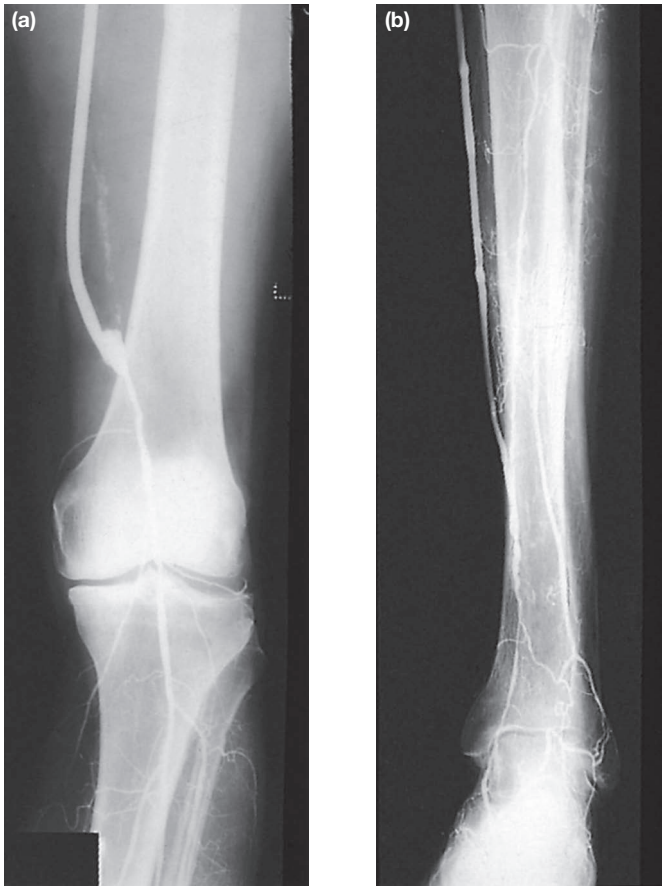

Figure 61.22 (a) Completion angiogram of a femoropopliteal bypass graft (with a Miller cuff). **(b)** Completion angiogram of a femorodistal bypass graft *in situ*.

A femorofemoral crossover graft involves tunnelling a prosthetic graft subcutaneously above the pubis between the groins. An axillofemoral graft is tunnelled subcutaneously between the axillary artery proximally to reach one or both of the femoral arteries; the patency rates of an axillobifemoral bypass are better than those for an axillo(uni)femoral bypass.

Results of operation

The long-term results of aortoiliac reconstructive surgery are good and are usually marred only by progressive infrainguinal disease; 90% remain patent at 5 years post surgery. Femoropopliteal surgery is less successful. Immediate postoperative success for vein bypass exceeds 90% but the 5-year patency is around 60%. PTFE bypass yields poorer results than vein bypass, with 5-year success rates of less than 50%. Although the results of femorodistal bypass are even less satisfactory, such surgery can ensure limb salvage in patients who are generally debilitated and whose expected lifespan is limited; long-term patency is less important.

Other sites of atheromatous occlusive disease

The principles of arterial surgery outlined above can be applied at other arterial sites. Carotid stenosis (at the carotid bifurcation in the neck) may cause TIAs. These short-lived mini-strokes are often recurrent and cause unilateral motor or sensory loss in the arm, leg or face, transient blindness (amaurosis fugax) or speech impairment (dysphasia). They are caused by distal embolisation of platelet thrombi that form on the atheromatous plaque into the cerebral circulation. They are a warning of impending major stroke. Patients should be assessed with a duplex scan. If a tight stenosis (>50%) is detected, carotid endarterectomy should be offered (***Figure 61.23***). This involves clamping the vessels, an arteriotomy in the common carotid artery continued up into the internal carotid artery through the diseased segment, removal of the occlusive disease (endarterectomy) and closure of the arteriotomy, often with a patch. Many surgeons also use a temporary shunt to maintain cerebral blood flow while the carotid system is clamped.

Subclavian artery stenosis may cause claudication in the arm or digital ischaemia from distal embolisation. It may be treated by angioplasty or surgical bypass. Sometimes subclavian artery lesions are associated with neck pathology, such as a cervical rib, which should be removed during arterial repair (***Figure 61.24***). Subclavian steal syndrome may occur if the first part of the subclavian artery is occluded. Arm exercise causes syncope because of reversed flow in the vertebral artery, leading to cerebral ischaemia. It can be treated by angioplasty or surgery and is rare.

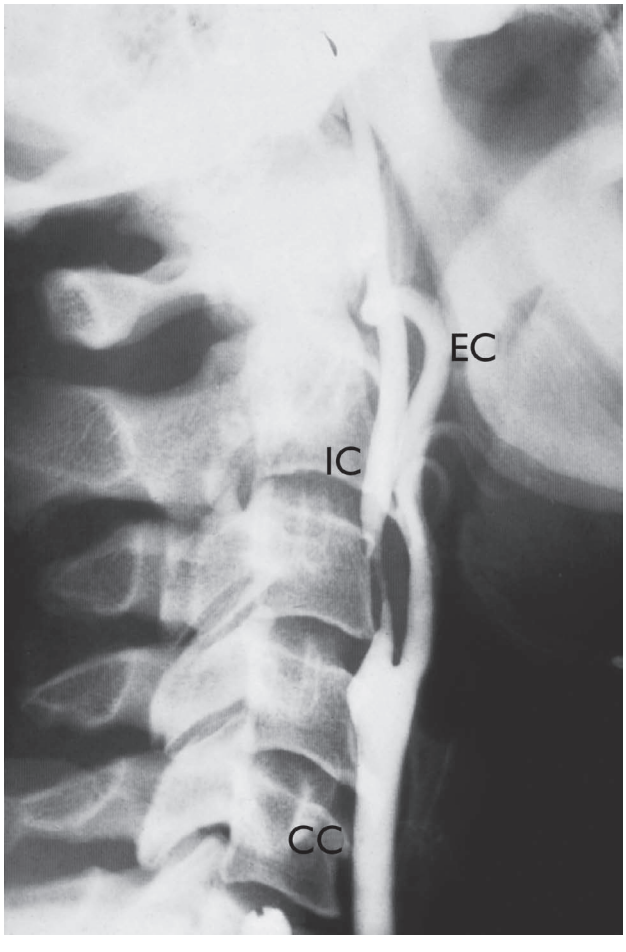

Figure 61.23 Carotid stenosis. A unilateral localised stenosis suitable for operation. CC, common carotid; EC, external carotid; IC, internal carotid.

Summary box 61.2

Indications for carotid endarterectomy in symptomatic patients

50% or greater carotid stenosis and:

- Ipsilateral amaurosis fugax or monocular blindness
- Contralateral facial paralysis or paraesthesia
- Arm/leg paralysis or paraesthesia
- Hemianopia
- Dysphasia (if dominant hemisphere)
- Sensory or visual inattention/neglect

Mesenteric artery occlusive disease may cause pain after eating (intestinal angina) and weight loss. In general, two of the three enteric vessels (coeliac axis, superior mesenteric artery, inferior mesenteric artery) must be occluded to produce symptoms and other intestinal disorders must be excluded before treatment with PTA, endarterectomy or bypass (***Figure 61.25***).

Renal artery stenosis may cause hypertension and eventual renal failure. Although it is possible to improve renal blood flow with PTA or surgery, the mainstays of treatment are drugs to control hypertension, diabetes, etc.

GANGRENE

Gangrene refers to the death of macroscopic portions of tissue, which turns black because of the breakdown of haemoglobin and the formation of iron sulphide. It usually affects the most distal part of a limb because of arterial obstruction (from thrombosis, embolus or arteritis). Dry gangrene occurs when the tissues are desiccated by gradual slowing of the bloodstream; it is typically the result of atheromatous occlusion of arteries. Wet gangrene occurs when superadded infection and putrefaction are present. Crepitus may be palpated as a result of infection by gas-forming organisms, commonly in diabetic foot problems, and should be considered a surgical emergency with urgent tissue debridement or amputation required.

Separation of gangrene

A zone of demarcation between the truly viable and the dead or dying tissue will eventually appear. Separation is achieved by the development of a layer of granulation tissue, which forms between the dead and the living parts. In dry gangrene, if the blood supply of the proximal tissues is adequate, the final line of demarcation appears in a matter of days and separation occurs neatly and with the minimum of infection. If bone is involved, complete separation takes longer than when soft tissues alone are affected, and the stump tends to be conical as the bone has a better blood supply than its coverings. In moist gangrene

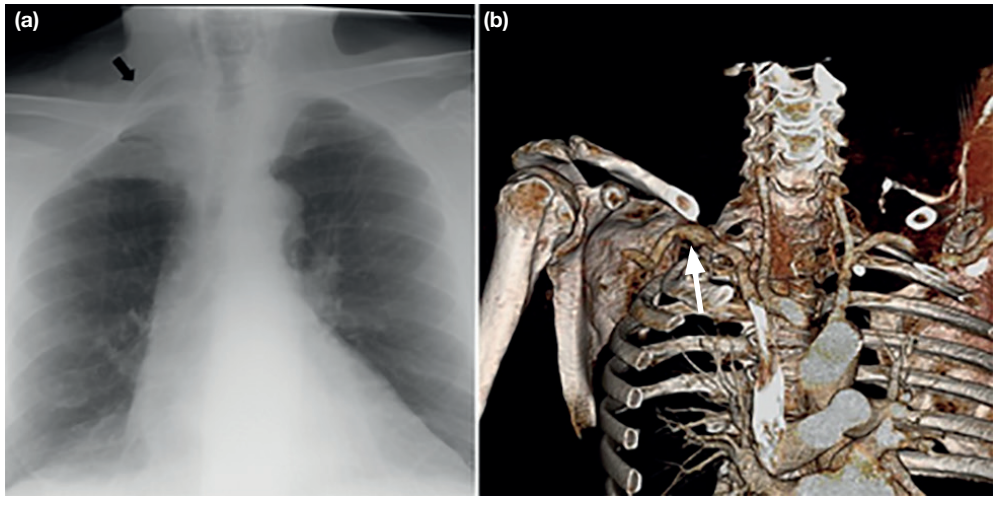

Figure 61.24 This patient presented with an ischaemic right hand. **(a)** A chest radiograph demonstrated a right cervical rib (black arrow). **(b)** A computed tomography angiogram showed stenosis of the subclavian artery (SCA) with poststenotic dilatation (lined with thrombus) (white arrow) caused by the cervical rib. The patient had been embolising from the SCA into the hand. The patient was successfully treated with cervical rib resection, repair of the SCA and distal thromboembolectomy.

the infection and suppuration extend into the neighbouring living tissue, causing the final line of demarcation to be more proximal than in dry gangrene.

If the arterial supply to the proximal living tissue is poor, the line of final demarcation is very slow to form or does not develop at all. Unless the arterial supply can be improved, the gangrene will spread to adjacent tissues or will suddenly appear as 'skip' areas further up the limb. These skip lesions may occur on the other side of the foot, on the heel, on the dorsum of the foot or even in the calf. Infection may also cause gangrene to spread proximally into areas of extensive inflammation. Local amputation in the presence of poor circulation will fail and gangrene will reappear in the wound or skin edges.

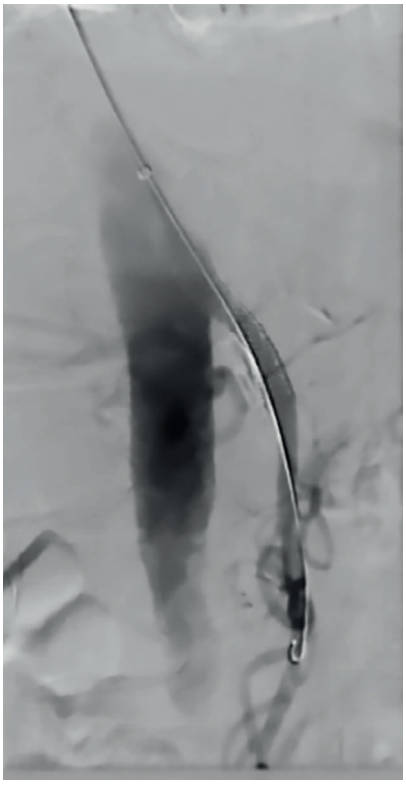

Figure 61.25 The superior mesenteric artery lesion shown in ***Figure 61.1***. It was successfully treated with angioplasty and primary stent insertion.

Treatment of gangrene

How much of a limb or digit can be salvaged depends on the blood supply proximal to the gangrene. Poor circulation should be improved by surgical revascularisation, enabling a more conservative debridement or distal amputation. However, major limb amputation may be required in the presence of life-threatening sepsis, when the blood supply cannot be improved or in patients whose limb is non-functional because of contractures, stroke, etc.

Specific varieties of gangrene

Diabetic gangrene

Diabetic gangrene is usually caused by a combination of three factors: ischaemia secondary to macrovascular disease and microvascular dysfunction; peripheral sensorimotor neuropathy (PSN), which leads to trophic skin changes; and immunosuppression caused by an excess of sugar in the tissues, which predisposes to infection (***Figure 61.26***). Macrovascular

Figure 61.26 Diabetic gangrene.

Figure 61.27 Bedsores typically appear over areas exposed to pressure, such as the sacrum and (as in this case) the heel. They can quickly deteriorate from an area of discoloration **(a)** to gross ulceration extending to the calcaneum **(b)**.

disease is atherosclerotic and typically affects the crural vessels with relative sparing of the pedal vessels, whereas increased microcirculatory shunting causes microvascular dysfunction. The PSN is usually sensory in the early phase – classically in a stocking distribution – and renders the patients at high risk of soft-tissue injury and its subsequent neglect. The PSN may extend to the joints of the foot and ankle, resulting in loss of nociceptive and proprioceptive protective reflexes and a repeated cycle of joint injury and bony destruction. Motor involvement causes an imbalance between flexors and extensor muscle groups of the foot, promoting altered foot biomechanics and abnormal pressure loading, which result in thick callosities developing on the sole of the foot.

Ischaemia and PSN act synergistically to increase the risk of diabetic foot ulceration and reduce its subsequent healing potential. Superadded infection due to poor wound care can spread rapidly and proximally in subfascial planes, leading to fulminant foot sepsis, gangrene and death.

Treatment depends on the degree of arterial involvement, which should be investigated and treated rapidly with angioplasty or surgery. The gangrene is treated by drainage of pus, liberal debridement of dead tissue and antibiotics. Unfortunately, a number of patients present with life-threatening systemic upset and should be considered for primary amputation.

Miscellaneous

Other types of gangrene commonly encountered include bedsores and frostbite. Bedsores are gangrene caused by local pressure (***Figure 61.27***), whereas frostbite is caused by exposure to cold (***Figure 61.28***). Both are preventable with adequate protective measures.

Figure 61.28 (a) Frostbite of the foot. Note the clear demarcation. **(b)** Frostbite of the middle finger in the same patient. The index finger was lost 2 years before, also from frostbite.

ACUTE ARTERIAL OCCLUSION

Sudden occlusion of an artery is usually caused by an embolus. It may also happen when thrombosis occurs on an atherosclerotic plaque, although the outcome is usually less dramatic because collaterals are likely to have developed in chronic arterial stenosis.

Embolic occlusion

An embolus is an object that has become lodged in a vessel and causes obstruction, having been carried in the bloodstream from another site. It is often a thrombus that has become detached from the heart or a more proximal vessel. Sources include the left atrium in atrial fibrillation; a left ventricular mural thrombus following myocardial infarction; vegetations on heart valves in infective endocarditis; and thrombi in aneurysms and on atherosclerotic plaques. Emboli may lodge in any organ and cause ischaemic symptoms.

- **Arm and leg** – pain, pallor, paraesthesia, paralysis and pulselessness (the five Ps of acute limb ischaemia [ALI]) (see ***Acute limb ischaemia***) (***Figure 61.29***). Acute arterial occlusion due to an embolus differs from occlusion due to thrombosis on pre-existing atheroma; in the latter case a collateral circulation has often built up over time (***Figures 61.30 and 61.31***). It is essential to differentiate between the two as they require different management.
- **Brain** – the middle cerebral artery (or its branches) is most commonly affected, resulting in TIA or stroke.
- **Retina** – amaurosis fugax is fleeting blindness caused by a minute thrombus emanating from an atheromatous plaque in the carotid artery passing into the central retinal artery. Lasting obstruction causes permanent blindness.
- **Mesenteric vessels** – possible gangrene and perforation of the corresponding loop of intestine.

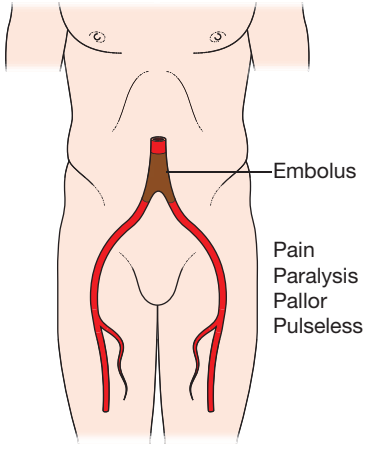

Figure 61.29 The symptoms and signs of embolism (four Ps). The fifth feature, anaesthesia, is often stated to be paraesthesia (the fifth P), but, in truth, complete loss of sensation in the toes and feet is characteristic.

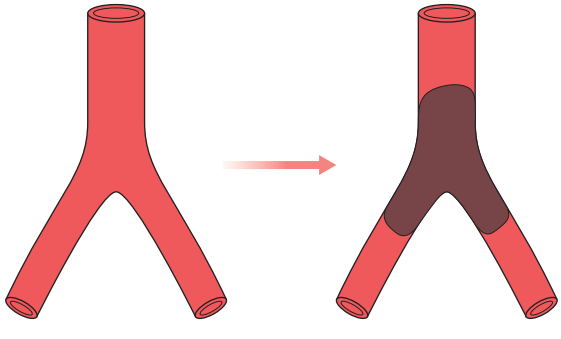

Figure 61.30 Aortic bifurcation embolus. The source of the embolus is a recent myocardial infarct or atrial fibrillation. This causes severe, dramatic symptoms.

Acute limb ischaemia

ALI is an emergency that requires rapid, accurate clinical assessment and emergency surgical treatment. ALI typically occurs as a result of embolic arterial occlusion or trauma, but less common causes, including thrombosed popliteal artery aneurysm and popliteal artery entrapment, should be kept in mind during patient assessment. Clinicians reviewing a patient with sudden onset leg pain should have a high index of suspicion for ALI as an incorrect diagnosis can be catastrophic for the patient; ischaemia beyond 6 hours is usually irreversible and results in limb loss.

Clinical features

Patients presenting with ALI secondary to embolism typically give no history of prior claudication and complain of the sudden development of severe pain or numbness of the limb. Bedside clinical assessment should be aimed at (i) confirming the diagnosis of ALI, (ii) assessing the severity of the limb ischaemia, and (iii) identifying the underlying cause, including an embolic source.

The skin is initially cold and pale, but as time progresses it slowly becomes mottled; first, non-fixed (blanching to pressure) and then fixed (non-blanching), indicating skin death. Neurological function deteriorates with time, progressing from paraesthesia to eventual complete loss of sensory and motor function, causing an insensate and paralysed limb (a poor prognostic sign). Muscle groups are weakened and painful; manual compression of affected muscle groups may cause pain owing to ischaemia-induced injury – rhabdomyolysis.

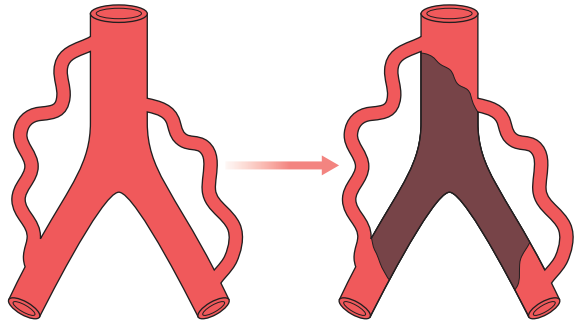

Figure 61.31 Aortic bifurcation thrombosis: claudication is worse but there is no dramatic event owing to the network of collaterals formed as a result of the insidious nature of the stenosis; acute on chronic disease.

TABLE 61.2 Rutherford's classification of acute limb ischaemia.

Grade	Category	Sensory loss	Motor deficit	Doppler signals		Prognosis
				Arterial	Venous	
I	Viable	None	None	Audible	Audible	No immediate threat
IIA	Marginally threatened	None or minimal (toes)	None	Inaudible	Audible	Salvageable if promptly treated
IIB	Immediately threatened	More than toes	Mild/moderate	Inaudible	Audible	Salvageable with immediate revascularisation
III	Irreversible	Profound or insensate	Paralysed	Inaudible	Inaudible	Limb irreversibly damaged, major tissue loss, amputation

Pulses are absent distally but the femoral pulse may be palpable, even thrusting, as distal occlusion results in forceful expansion of the artery with each pressure wave despite the lack of flow. Insonation of the pedal vessels with a hand-held Doppler may elicit faint monophasic signals or no signals at all. Assessment of flow in the limb veins, including the GSV and popliteal vein, can be useful as concurrent venous thrombosis is a very poor prognostic indicator.

Following thorough clinical examination, the limb should be classified according to the Rutherford categories of ALI: class I, viable; class IIa, marginally threatened; class IIb, immediately threatened; and class III, irreversible. The management options and urgency of treatment depend on the appropriate categorisation of the limb (***Table 61.2***).

Investigations should be undertaken as clinically indicated and may include:

- ECG to assess for myocardial infarction and/or atrial fibrillation;
- creatinine kinase to assess for rhabdomyolysis;
- renal function as rhabdomyolysis may lead to myoglobinuria and acute kidney injury;
- imaging assessment of the affected limb's arterial tree, e.g. DUS or CTA, if readily available and not likely to unnecessarily delay emergency treatment when indicated, e.g. Rutherford class IIb

A similar picture will occur in the arm with a brachial embolus.

Treatment

Because of the ensuing stasis, a thrombus can extend distally and proximally to the embolus. The immediate administration of 5000 U of heparin intravenously can reduce this extension and maintain patency of the surrounding (particularly the distal) vessels until the embolus can be treated. The relief of pain is essential because it is severe and constant. Embolectomy and thrombolysis are the treatments available for patients with limb emboli.

Embolectomy

Local or general anaesthesia may be used. The artery (usually the femoral), bulging with clot, is exposed and held in silastic vessel loops. Through a transverse incision the clot begins to extrude and is removed, together with the embolus (***Figure 61.32***), with the help of a Fogarty balloon catheter. The catheter, with its balloon tip, is introduced both proximally and distally until it is deemed to have passed the limit of the clot. The balloon is inflated and the catheter withdrawn slowly, together with any obstructing material (***Figure 61.33***). The procedure is repeated until bleeding occurs. An angiogram

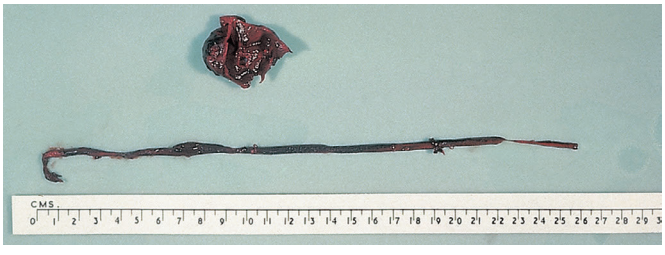

Figure 61.32 Embolic material removed from the common femoral artery, along with a long distal extension thrombus.

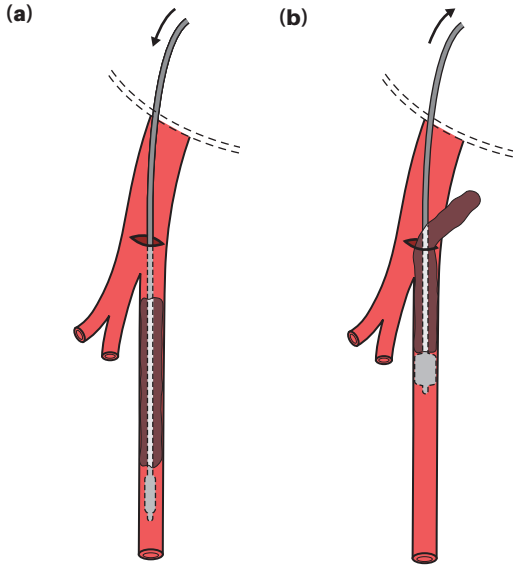

Figure 61.33 (a) A Fogarty catheter is inserted through an arteriotomy in the common femoral artery and fed distally down the superficial femoral artery and through the embolus. **(b)** The balloon is inflated and the catheter withdrawn, removing the embolus; the deep femoral and iliac arteries are similarly treated.

Robert Rutherford, 1931–2013, Professor of Surgery, Colorado, USA.
Thomas J Fogarty, b. 1934, surgeon, University of Oregon Medical School, Portland, OR, USA.

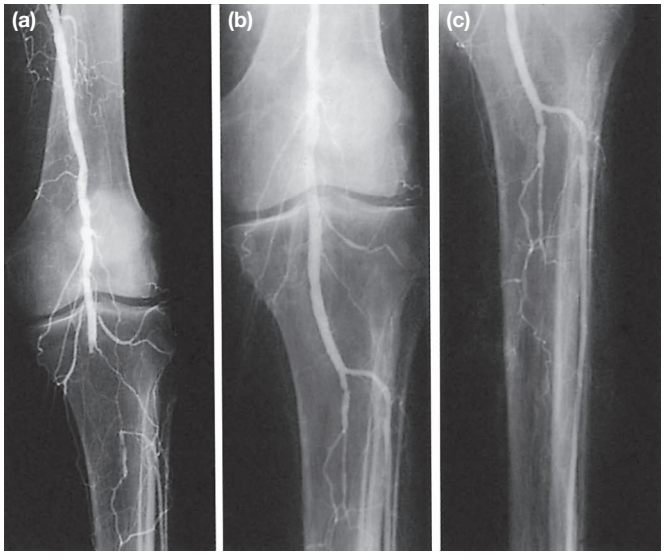

Figure 61.34 Angiogram of an occluded popliteal artery before thrombolysis **(a)**, during successful lysis **(b)** and after completion of lysis **(c)**.

may be performed in the operating theatre at the end of the procedure to ensure that flow to the distal leg has been restored. Postoperatively, heparin therapy is continued until long-term anticoagulation with warfarin is established to reduce the chance of further embolism.

Thrombolysis

If ischaemia is not so severe that immediate operation is essential, it may be possible to treat either embolus or thrombosis by intra-arterial thrombolysis (***Figure 61.34***). At arteriography of the ischaemic limb (usually via the CFA) a narrow catheter is passed into the occluded vessel and left embedded within the clot. Tissue plasminogen activator is infused through the catheter and regular arteriograms are carried out to check on the extent of lysis, which, in successful cases, is achieved within 24 hours. The method should be abandoned if there is no progression of dissolution of clot with time. There are several contraindications to thrombolysis, the most important of which are recent stroke, bleeding diathesis and pregnancy, and results in those over 80 years old are poor.

Compartment syndrome

In limbs that have been subject to sudden ischaemia followed by revascularisation, oedema is likely. Muscles swell within confined fascial compartments and this can itself be a cause of tissue ischaemia, with both local muscle necrosis and nerve damage due to pressure and systemic effects such as renal failure secondary to the liberation of muscle breakdown products.

The classical clinical picture is that of severe pain out of proportion with clinical findings that worsens with time despite appropriate analgesia. The patient often complains of numbness/paraesthesia in the distribution of nerves running within the compartment (non-myelinated type C sensory fibres are most sensitive to hypoxia). Examination of the limb reveals a tense compartment with passive flexion and extension of

Figure 61.35 (a) Foot and calf fasciotomies; (b) thigh fasciotomy: the medial compartment rarely requires decompression

muscles causing pain. The presence of palpable pulses does not rule out compartment syndrome.

The treatment is urgent compartment fasciotomy to release the compression. The usual site for fasciotomy is the calf (especially the anterior tibial compartment), but compartment syndrome may occasionally affect the thigh, arm and foot. Liberal concomitant usage of calf with/without thigh fasciotomies following revascularisation of a prolonged ischaemic limb is advisable (***Figure 61.35***).

Acute mesenteric ischaemia

Acute mesenteric occlusion may be either thrombotic (following atheromatous narrowing) or embolic. Embolic occlusion results in sudden, severe abdominal pain, with bowel emptying (vomiting and diarrhoea) and a source of emboli present (usually cardiac). Unfortunately, the diagnosis is often only made at laparotomy with widespread infarction of the small and large bowel present; in this situation it is often fatal. Occasionally, the degree of bowel infarction is more limited; resection of the dead bowel and embolectomy of the superior mesenteric

artery, or bypass surgery, can reduce the otherwise high mortality rate in these patients. A 'second look' laparotomy 24 hours later to check the viability of the bowel may be indicated.

Other forms of embolism

Infective emboli of bacteria or an infected clot may cause mycotic aneurysms, septicaemia or infected infarcts. Parasitic emboli, caused by the ova of *Taenia echinococcus* and *Filaria sanguinis hominis*, may occur in some countries. Tumour cells (e.g. hypernephroma and cardiac myxoma) are rare causes of emboli. Fat embolism may follow major bony fractures. However, it usually causes venous emboli that travel to the lungs and cause acute respiratory distress syndrome.

Air embolism

Air may be accidentally injected into the venous circulation or sucked into an open vein during head and neck surgery or a cut throat. It may also occur following Fallopian tube insufflation or illegal abortion. If a large volume of air reaches the right side of the heart it may form an airlock within the pulmonary artery and cause acute right heart failure.

The treatment of air embolism is to put the patient in a head-down (Trendelenburg) position to encourage the air to enter the veins in the lower part of the body. The patient should also be placed on the left side to help the air to float to the ventricular apex, away from the ostium of the pulmonary artery. In extreme cases air may be aspirated from the heart through a needle introduced below the left costal margin.

Therapeutic embolisation

This is used to arrest haemorrhage from the gastrointestinal, urinary, gynaecological and respiratory tracts, to treat arteriovenous malformations by blocking their arterial supply and to control the growth of unresectable tumours. Arterial embolisation requires accurate selective catheterisation using the Seldinger technique. A variety of materials may be used, including Gelfoam sponge, plastic microspheres, balloons, ethyl alcohol, quick-setting plastics and metal coils.

AMPUTATION

General

Amputation should be considered when part of a limb is dead, deadly or a dead loss. A limb is dead when arterial occlusive disease is severe enough to cause infarction of macroscopic portions of tissue, i.e. gangrene. The occlusion may be in major vessels (atherosclerotic or embolic occlusions) or in small peripheral vessels (diabetes, Buerger's disease, Raynaud's disease, inadvertent intra-arterial injection). If the obstruction cannot be reversed and the symptoms are severe, amputation is required.

A limb is deadly when the putrefaction and infection of moist gangrene spreads to surrounding viable tissues. Cellulitis and severe toxaemia are the result. Amputation is required as a lifesaving operation. Antibiotic cover should be broad and massive. Other life-threatening situations for which amputation may be required include gas gangrene (as opposed to simple infection), neoplasm (such as osteogenic sarcoma) and arteriovenous fistula.

A limb may be deemed a dead loss in the following circumstances: first, when there is relentless severe rest pain without gangrene and reconstruction is not possible – amputation will improve quality of life; second, when a contracture or paralysis makes the limb impossible to use and renders it a hindrance; and third, when there is major unrecoverable traumatic damage.

Distal and transmetatarsal amputation

In patients with small-vessel disease, typically caused by DM, gangrene of the toes may occur with relatively good blood supply to the surrounding tissues. In such circumstances local amputation of the digits can result in healing. However, if the metatarsophalangeal joint region is involved, a ray excision is required, taking part of the corresponding metatarsal bone and cutting tendons back. Most surgeons leave the wound open. Early mobility aids drainage, provided that cellulitis is not present. For less extensive gangrene, if amputation is taken through a joint, healing is improved by removing the cartilage from the joint surface. A transmetatarsal amputation may be required when several toes are affected but the proximal circulation is adequate. The wound may be closed with a viable long plantar flap or left open (***Figure 61.36***).

Gabrielle Falloppio (Fallopius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy.
Friedrich Trendelenburg, 1844–1924, Professor of Surgery, successively at Rostock, Bonn and Leipzig, Germany.
Leo Buerger, 1879–1943, Professor of Urologic Surgery, New York Polyclinic Medical School, New York, NY, USA, described thromboangiitis obliterans in 1908.
Maurice Raynaud, 1834–1881, physician, Hôpital Lariboisière, Paris, France, described this condition in 1862.

Major amputation

Choice of operation

The major choice is between an above- and below-knee operation. A below-knee amputation preserves the knee joint and gives the best chance of walking again with a prosthesis (***Figure 61.37***). However, an above-knee amputation is more likely to heal and may be appropriate if the patient has no prospect of walking again. If the femoral pulse is absent, the amputation should be above the knee. Unfortunately, the presence of a femoral pulse does not guarantee healing of a below-knee amputation and sometimes a failed below-knee amputation may require revision to an above-knee procedure.

For above- or below-knee amputations with a good stump shape, it is possible to hold a prosthesis in place simply by suction, without any cumbersome and unsightly straps. The stump should be of sufficient length to give the required leverage, i.e. not less than 8 cm below the knee (preferably 10–12 cm) and not less than 20 cm above the knee.

Through-knee or knee disarticulation has regained popularity as an alternative to above-knee amputation if soft-tissue viability permits. This amputation preserves the full length of the femur and patella and provides a long mechanical lever that is controlled by stronger muscles as the line of muscle transection is distal and occurs through fascial tissue as opposed to thick muscular bellies, as is the case with an above-knee amputation. The bulbous nature of the amputation end, initially thought a hindrance for subsequent prosthetic fitting, is now seen as beneficial as it allows for a self-suspending prosthetic that is less likely to rotate than an above-knee amputation prosthetic. For patients unlikely to mobilise with a prosthetic, e.g. elderly patients or patients with bilateral amputations, the increased length of the stump provides better counterweight to the torso, enabling better core stability.

Postoperative care of an amputee

Opiate pain relief should be given regularly. Care of the good limb must not be forgotten – a pressure ulcer on the remaining foot will delay mobilisation despite satisfactory healing of the stump. Exercise and mobilisation are of the greatest importance. After surgery, flexion deformity must be prevented and exercises started to build up muscle power and coordination. Mobility is progressively increased with walking between bars and the use of an inflatable artificial limb, which allows weight bearing to be started before a pylon or temporary artificial limb is ready (***Figure 61.38***). Early assessment of the home is part of the programme; this allows time for minor alterations, such as the addition of stair rails, movement of furniture to give support near doors and provision of clearance in confined passages.

Complications

Early complications include haemorrhage, which requires return to the operating room for haemostasis; haematoma, which requires evacuation; and infection, usually in association with a haematoma. Any abscess must be drained and appropriate antibiotics given. Gas gangrene can occur in a mid-thigh stump from faecal contamination. Wound dehiscence and gangrene of the flaps are caused by ischaemia; a higher amputation may be necessary. Amputees are at risk of deep vein thrombosis and pulmonary embolism in the early postoperative period and prophylaxis with subcutaneous heparin is essential.

Later complications include pain resulting from unresolved infection (sinus, osteitis, sequestrum), a bone spur, a scar adherent to bone and an amputation neuroma. Patients frequently remark that they can feel the amputated limb (phantom limb) and sometimes remark that it is painful (phantom pain). The surgeon's attitude should be one of firm reassurance that this sensation will almost certainly disappear with time; gabapentin or amitriptyline may help. Other late complications include ulceration of the stump because of pressure effects of the prosthesis or increased ischaemia.

ANEURYSM

General

Dilatations of localised segments of the arterial system are called aneurysms when there is a ≥50% increase in the diameter of the vessel; below 50% they are termed ectatic. They can either be true aneurysms, containing the three layers of the arterial wall (intima, media, adventitia) in the aneurysm sac, or false aneurysms, having a single layer of fibrous tissue as the wall of the sac, e.g. aneurysm following trauma. Aneurysms can also be grouped according to their shape (fusiform,

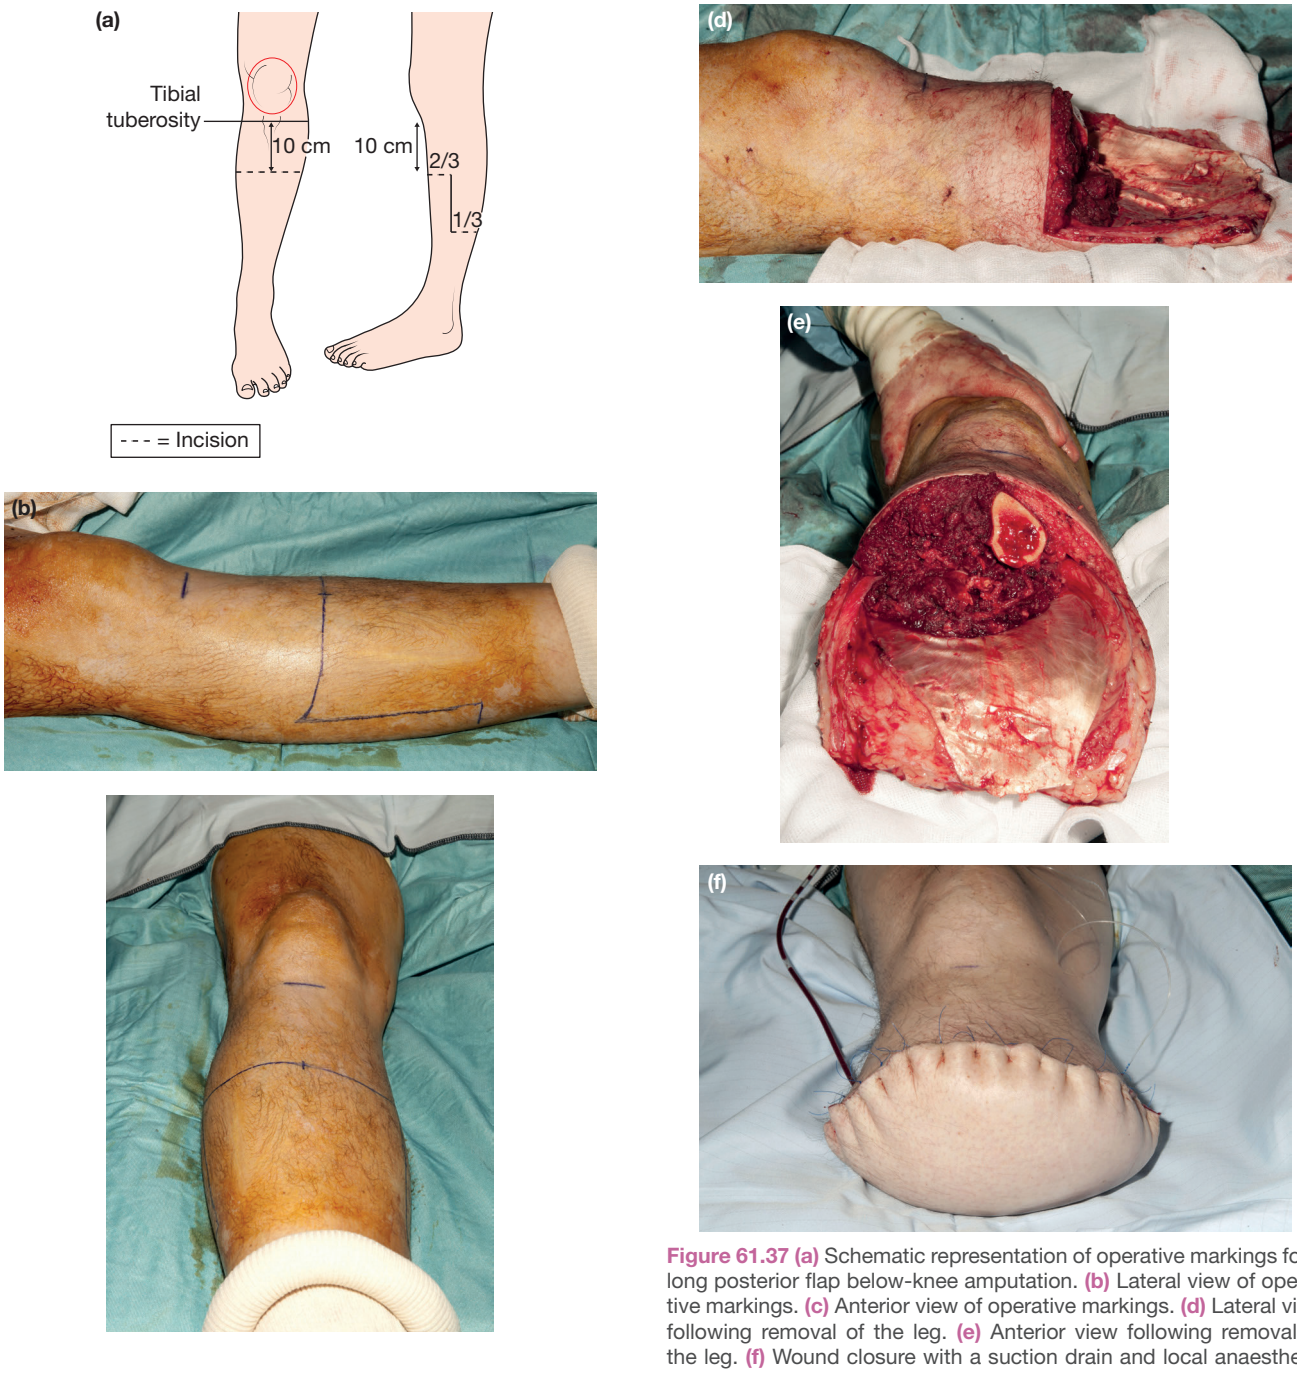

Figure 61.37 (a) Schematic representation of operative markings for a long posterior flap below-knee amputation. **(b)** Lateral view of operative markings. **(c)** Anterior view of operative markings. **(d)** Lateral view following removal of the leg. **(e)** Anterior view following removal of the leg. **(f)** Wound closure with a suction drain and local anaesthetic infusion 'stump' catheter.

saccular) or their aetiology (atheromatous, traumatic, mycotic, etc.). The term mycotic is a misnomer because, although it indicates infection as the cause of the aneurysm, it is due to bacteria, not fungi. Aneurysms may occur in the aorta or in the iliac, femoral, popliteal, subclavian, axillary, carotid, cerebral, mesenteric, splenic and renal arteries and their branches. The majority are true fusiform atherosclerotic aneurysms.

Clinical features

The majority of arterial aneurysms are asymptomatic at the time of identification and are often identified during routine health checks or investigations for other pathologies. Aneurysms measuring twice the size of the corresponding normal vessel are at increased risk of becoming symptomatic. The symptoms relate to the vessel affected and the tissues it supplies and occur as a result of compression of surrounding structures, thrombosis, rupture or the release of emboli. Many aneurysms of clinical significance can be palpated and, typically, an expansile pulsation is felt. Transmitted pulsation through a mass lesion, cyst or abscess lying adjacent to a large artery may be mistaken for aneurysmal pulsation. Before incising a swelling believed to be an abscess it is essential to make sure that it does not pulsate. Finally, a tortuous (and often

ectatic) artery, usually the innominate or carotid, may seem like an aneurysm to the inexperienced clinician.

Abdominal aortic aneurysm

Abdominal aortic aneurysm is by far the most common type of large-vessel aneurysm and is found in 2% of the population at autopsy; 95% have associated atheromatous degeneration and 95% occur below the renal arteries. Most remain asymptomatic until rupture occurs; the risk of rupture increases with increasing size (diameter) of the aneurysm. Asymptomatic aneurysms are found incidentally on physical examination, radiography or ultrasonography investigation. A UK national screening programme for abdominal aortic aneurysm commenced in 2009 offering an ultrasonography scan to men in their 65th year. Symptomatic aneurysms may cause minor symptoms, such as back and abdominal discomfort, before sudden, severe back and/or abdominal pain develops from expansion and rupture. Rarely, symptoms may occur as a result of erosion or compression of surrounding structures, e.g. aortoenteric fistula or ureteric obstruction.

Asymptomatic abdominal aortic aneurysm

An asymptomatic abdominal aortic aneurysm (***Figure 61.39***) in an otherwise fit patient should be considered for repair if >55 mm in diameter, measured by ultrasonography in the anteroposterior plane. The annual incidence of rupture rises exponentially as the aneurysm size passes 55 mm: ≤1% are in aneurysms that are <55 mm in diameter, 5–10% are in those that are 55–60 mm in diameter and ~25% are in those that are ≥70 mm in diameter. Assuming that open elective surgery (transabdominal) carries a 5% mortality rate, the balance is in favour of elective operation once the maximum diameter is >55 mm, provided there is no major comorbidity. Regular ultrasonography surveillance is indicated for asymptomatic aneurysms <55 mm in diameter.

Investigations

Full blood count, electrolytes, liver function tests, coagulation tests and blood lipid estimation should be performed. Blood should be cross-matched a few days prior to surgery. Many

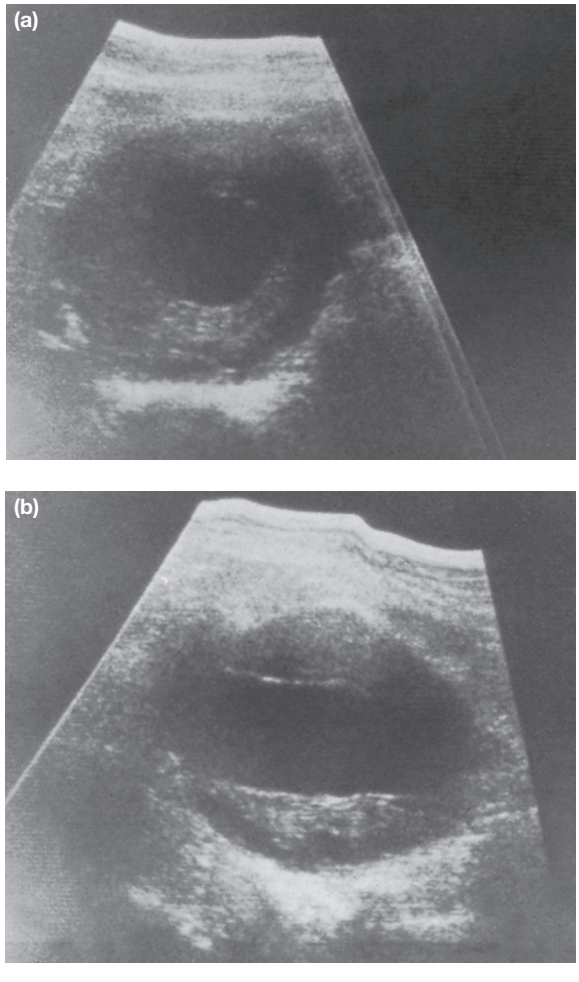

Figure 61.39 Ultrasonogram of an aortic aneurysm showing the large clot-filled sac with a small central lumen (transverse and longitudinal scans).

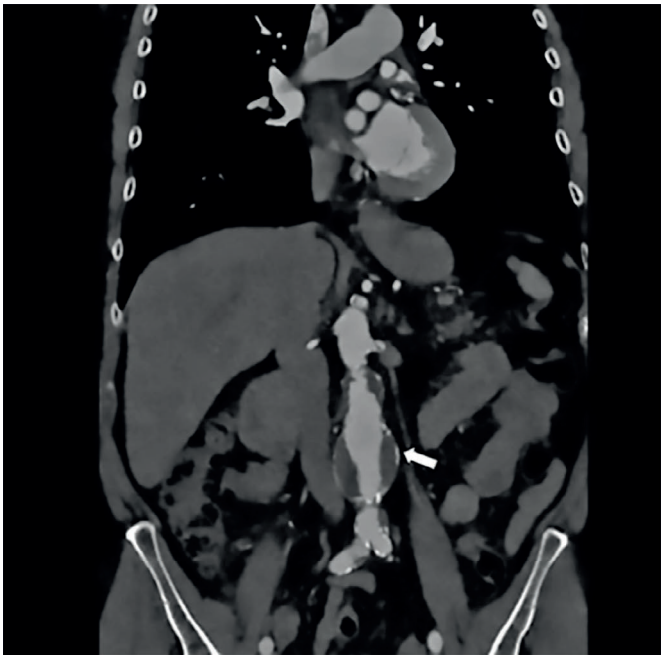

Figure 61.40 Computed tomography of the abdomen showing an infrarenal aortic aneurysm in the coronal plane (arrow). Blood flowing through the thrombus-containing sac is enhanced with contrast agent and appears white.

patients now have an anaesthetic assessment and the need for cardiac and respiratory function tests is decided at this time. ECG and chest radiographs are essential; further assessment may include echocardiograph, cardiopulmonary exercise testing and spirometry.

The morphology of the aneurysm is best assessed by computed tomography (CT) scan; this can be reconstructed on imaging software to create a three-dimensional model of the aneurysm (***Figures 61.40 and 61.41***). Seventy-five per cent of aneurysms are suitable for endovascular (minimally invasive) repair, usually via the femoral arteries in the groin. If lower limb pulses are absent, there may be associated arterial occlusive disease that should be assessed by DUS initially. Further assessment with CT, MRA or digital subtraction angiography may be required and angioplasty may be appropriate. The aneurysm is often filled with circumferential clot (***Figure 61.42a***) that produces a falsely narrowed appearance on DSA (***Figure 61.42b***); this method should not therefore be used to assess aneurysm size.

Choice of operation: open or endovascular repair

In recent years there has been much discussion regarding the optimal way to treat an abdominal aortic aneurysm with both open surgical repair and endovascular aneurysm repair (EVAR) having vocal advocates in the scientific literature. The National Institute for Health and Care Excellence (NICE) in the UK published guidelines in 2020 recommending open surgical repair unless contraindicated, reserving EVAR for high-risk patients or those with a hostile abdomen. This compares to the European Society for Vascular Surgery 2019 guidelines, which recommend EVAR as the first-line treatment option with open surgical repair to be considered for patients with long life expectancy. Pragmatically, the clinician should be prepared to undertake what they and the patient (after a detailed conversation) agree to be the best option, taking into account the skillset and resource availability and often, unfortunately, the financial constraints of the patient or healthcare system.

Open aneurysm repair

Under general anaesthesia, with the patient lying supine, a full-length midline or supraumbilical transverse incision is made. The small bowel is lifted to the patient's right and the aorta identified. The posterior peritoneum overlying the aorta is opened and the upper limit of the aneurysm identified. The aorta immediately above the dilatation is exposed; this is generally just inferior to the left renal vein and renal arteries (***Figure 61.43***). The common iliac arteries are then exposed and clamps applied above and below the lesion.

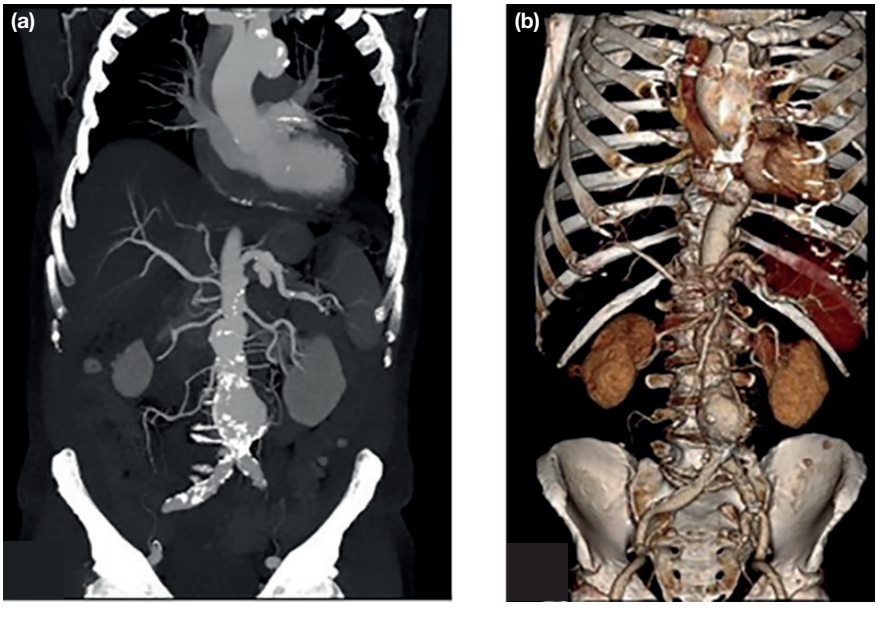

Figure 61.41 **(a)** Maximum intensity projection reconstruction of an aortic aneurysm from a spiral computed tomogram. **(b)** Three-dimensional reconstruction of an abdominal aortic aneurysm.

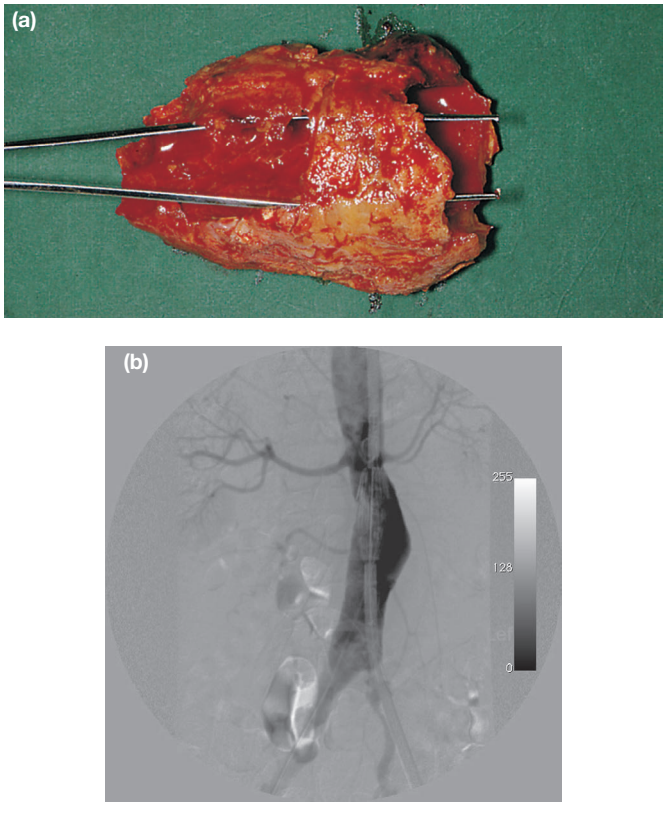

Figure 61.42 (a) Thrombus removed from an abdominal aortic aneurysm; this thrombus is the reason an angiogram may give a false impression of aneurysm diameter on digital subtraction angiography **(b)**.

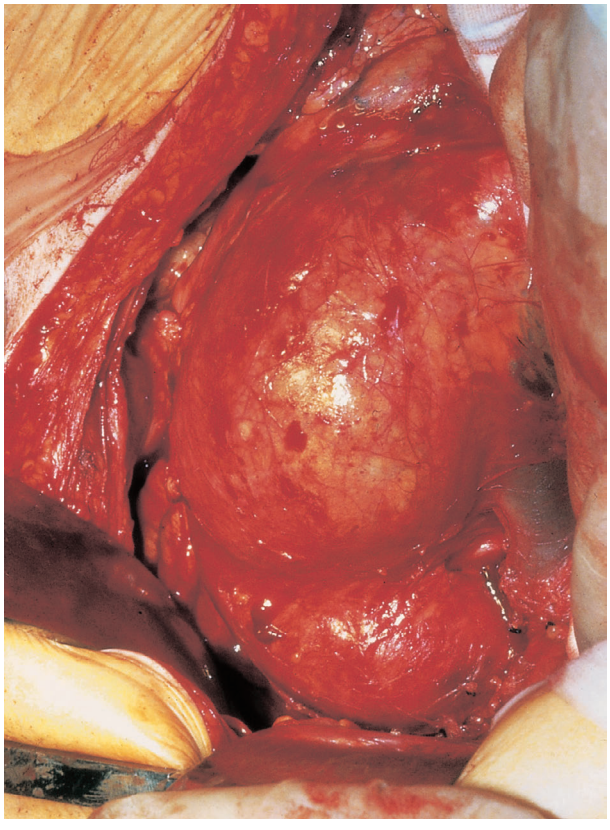

Figure 61.43 Operative appearance of a large, non-ruptured infrarenal abdominal aortic aneurysm.

Many surgeons give systemic heparin (3000–5000 U) before clamping. The aneurysm is opened longitudinally and back-bleeding from the lumbar and mesenteric vessels is controlled by sutures placed from within the sac. Upper and lower aortic necks are prepared to which an aortic prosthesis is then sutured end-to-end inside the sac with a monofilament non-absorbable suture (***Figure 61.44***). Clamps are released slowly to prevent sudden hypotension. If haemostasis is satisfactory at this point, the aneurysm sac is closed around the prosthesis to exclude both it and the suture lines from the bowel to reduce the risk of adherence and potential fistula formation. The abdomen is then closed. Occasionally, when the iliac vessels are also involved with dilatation or severe atheroma, it is necessary to construct an aortobi-iliac or aortobifemoral bypass, rather than use a simple aortoaortic tube.

Endovascular aneurysm repair

EVAR is now established in clinical practice and has been shown to reduce mortality compared with open repair over the first 6 years but there are concerns about long-term durability. Currently about 75% of infrarenal aneurysms are suitable for EVAR, depending on the morphology of the aneurysm as assessed by CT scan. Common causes of unsuitability include a short, flared or angulated neck and difficult iliac artery access because of narrowing or tortuosity. The usual technique is to expose both femoral arteries (under general or local anaesthetic), which allows access to the aorta. Then, under radiological control, guidewires and catheters are used to cross the aneurysm and an angiogram performed to mark the level of the renal arteries.

The endovascular prosthesis (often termed a 'stent graft') is usually made up of three separate parts: a main body (***Figure 61.45a***) and two limbs that are enclosed in separate delivery catheters (***Figure 61.45b***). Some types have only two pieces: a main body with an ipsilateral limb attached and a separate contralateral limb. The prosthesis is made from Dacron or PTFE with integral metallic stents for support. The delivery catheter is inserted into the aneurysm sac and the stent–graft deployed by withdrawal of the delivery system. Most systems now have hooks or barbs to anchor the prosthesis in the aortic wall, and some surgeons inflate a moulding balloon catheter in the stent–graft to ensure that the hooks and barbs are engaged and a good seal is obtained (***Figure 61.46***). Although the top edge of the fabric of the stent–graft has to be deployed below the renal arteries (infrarenal fixation), some systems have additional bare metal stents at the proximal end of the main body that lie across the renal arteries to give better support and fixation (suprarenal fixation). Blood flows between the metal struts of the stent into the renal arteries. Success is dependent on a good seal between the stent–graft and the proximal and distal 'landing zones' in the aorta and iliac arteries. Failure to achieve a good seal results in an endoleak, which means that the aneurysm is not excluded from the circulation and may still expand and rupture. Patients who undergo EVAR require lifelong follow-up and surveillance with duplex (***Figure 61.47***) or CT scans to detect endoleak, disconnection

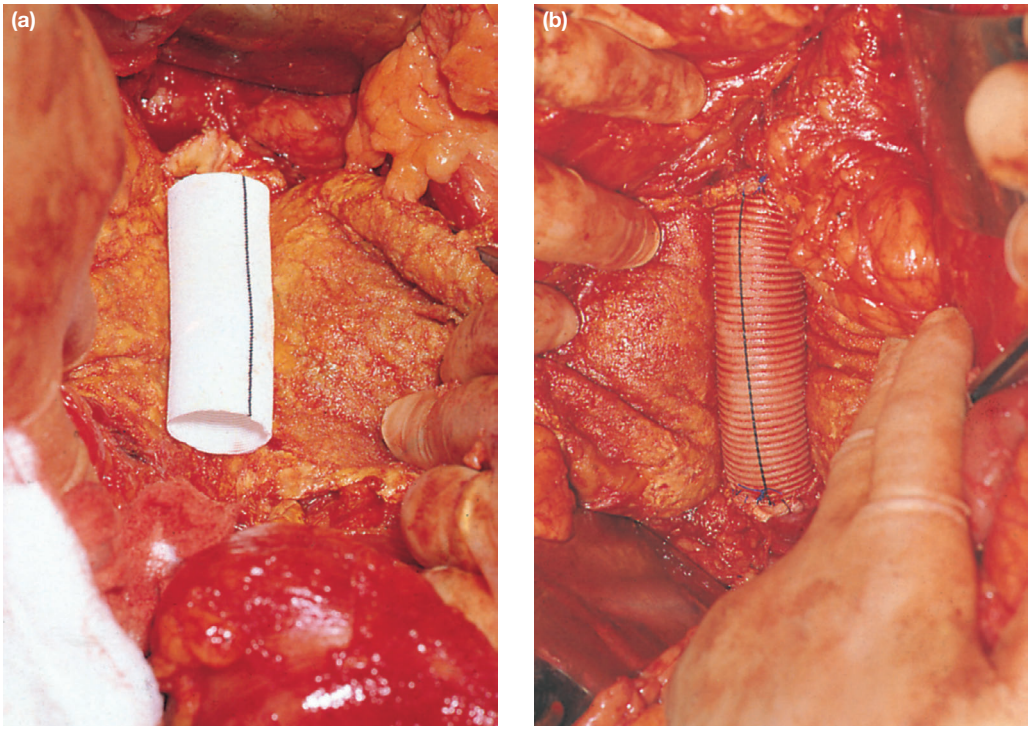

Figure 61.44 (a) Aneurysm sac opened. Note that the posterior wall of the aorta immediately above and below the sac is not divided. A Dacron tube graft is laid in place within the sac ready for suture. **(b)** The graft is sutured in place and the vascular clamps removed.

of the components and migration of the stent–graft, all of which predispose to late rupture (***Figure 61.48***).

Ruptured abdominal aortic aneurysm

Abdominal aortic aneurysms can rupture anteriorly into the peritoneal cavity (20%) or posterolaterally into the retroperitoneal space (80%). Less than 50% of patients with rupture survive to reach hospital. Anterior rupture results in free bleeding into the peritoneal cavity; very few patients reach hospital alive. Posterior rupture on the other hand produces

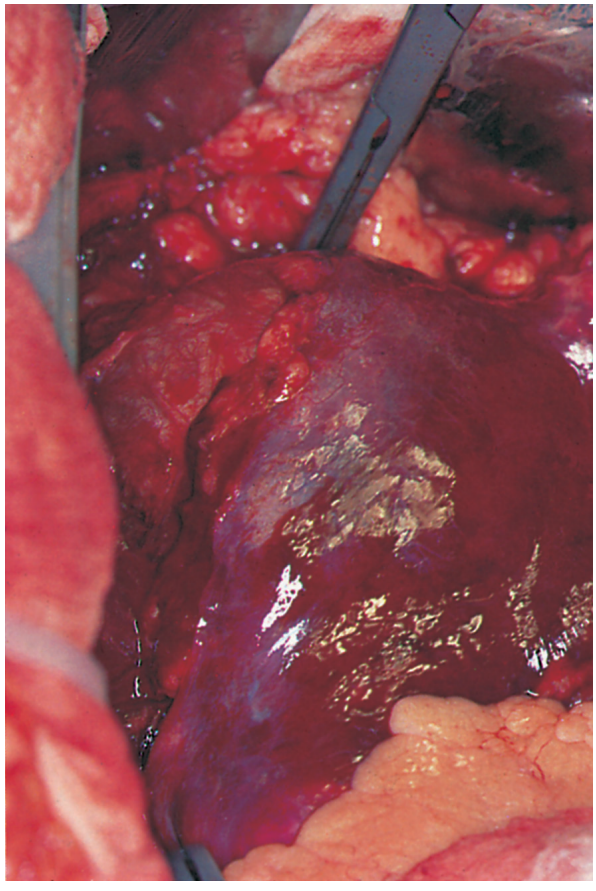

Figure 61.49 The retroperitoneal haematoma of a ruptured aortic aneurysm. The aortic pulsation is palpated through the haematoma at its upper limit and fingers are insinuated on each side of the aorta. With finger control, the upper clamp is positioned and closed on the aorta. The procedure is then as for a planned case. Here, the clamp is at the proximal end of the aneurysm; the haematoma has spread from the left paracolic gutter to encircle the aneurysm and the aortic bifurcation.

a retroperitoneal haematoma (***Figure 61.49***). Often a brief period ensues when a combination of moderate hypotension and the resistance of the retroperitoneal tissues arrests further haemorrhage and may allow transport to hospital. The patient may remain conscious but in severe pain. If no operation is performed, death is virtually inevitable. Operative mortality is around 50% and the overall combined mortality (community and hospital) is around 80–90%.

Ruptured abdominal aortic aneurysm is a surgical emergency; it should be suspected in a patient with the triad of severe abdominal and/or back pain, hypotension and a pulsatile abdominal mass. If there is doubt about the presence of an aneurysm an ultrasonography scan may help but this cannot diagnose rupture. CT scanning should be used to establish the diagnosis and to confirm a rupture and whether an EVAR is possible: EVAR should be considered as the first-line option for all anatomically suitable ruptured aortic aneurysms.

Good venous access is needed for infusion of saline or volume-expanding fluids, but the systolic blood pressure should not be raised any more than is necessary to maintain

consciousness and permit cardiac perfusion (<100 mmHg). After CT scanning, the patient should be transferred immediately to an operating theatre where a urinary catheter and arterial line are usually inserted. If the patient appears stable, surgery may be delayed until cross-matched blood is available but surgery should commence immediately if haemodynamic instability develops. For open surgical repair the abdomen is usually prepared and draped with the patient awake, minimising potential delays in cross-clamping the aorta as general anaesthesia is often accompanied by haemodynamic deterioration. Endovascular repair can often be performed under local anaesthetic and, if indicated, an aortic occlusion balloon catheter can be inserted to gain control in a patient with significant haemodynamic compromise. Always remember that the treatment of ruptured aneurysm is an operation, not monitoring and resuscitation.

Summary box 61.5

Management of ruptured abdominal aortic aneurysm

- Early diagnosis (abdominal/back pain, pulsatile mass, shock)
- Immediate resuscitation (oxygen, intravenous replacement therapy, central line)
- Maintain systolic pressure, but not >100 mmHg
- Urinary catheter
- Cross-match blood
- Rapid transfer to the operating room

Symptomatic abdominal aortic aneurysm

These patients most commonly present with abdominal and/or back pain but the aneurysm is not ruptured on CT scan. Pain may also occur in the thigh and groin because of nerve compression. Gastrointestinal, urinary and venous symptoms can also be caused by pressure from an abdominal aneurysm. About 3% of all aneurysms cause pain as a result of inflammation of the aneurysm itself (***Figure 61.50***). Finally, a few cause symptoms from distal embolisation of intraluminal thrombus. An operation is usually indicated in patients who are otherwise reasonably fit. Pain may be a warning sign of stretching of the aneurysm sac and imminent rupture; surgery should be performed as soon as possible (usually on the next available operating list). The operative mortality of symptomatic aneurysms is usually higher than that for elective cases.

Postoperative complications

The most common complications after open repair are cardiac (ischaemia and infarction) and respiratory (atelectasis and lower lobe consolidation). A degree of colonic ischaemia because of a lack of a collateral blood supply occurs in about 10% of patients, but this usually resolves spontaneously. Acute kidney injury is an uncommon event after elective procedures but may complicate procedures undertaken for rupture. Acute kidney injury is more likely if there is preoperative renal impairment or considerable intraoperative blood loss. Neurological complications include sexual dysfunction and spinal cord ischaemia. An aortoduodenal fistula is an uncommon but treatable complication of abdominal aortic replacement surgery. It should be suspected whenever haematemesis or melaena occurs in the months or years after operation. Prosthetic graft infection is also uncommon; it may require explantation of the original graft and replacement with an autologous deep vein (superficial femoral vein) graft or removal of the original graft with oversewing of the aortic stump and limb revascularisation by insertion of an axillobifemoral bypass. Both techniques are associated with significant risk of perioperative morbidity and mortality.

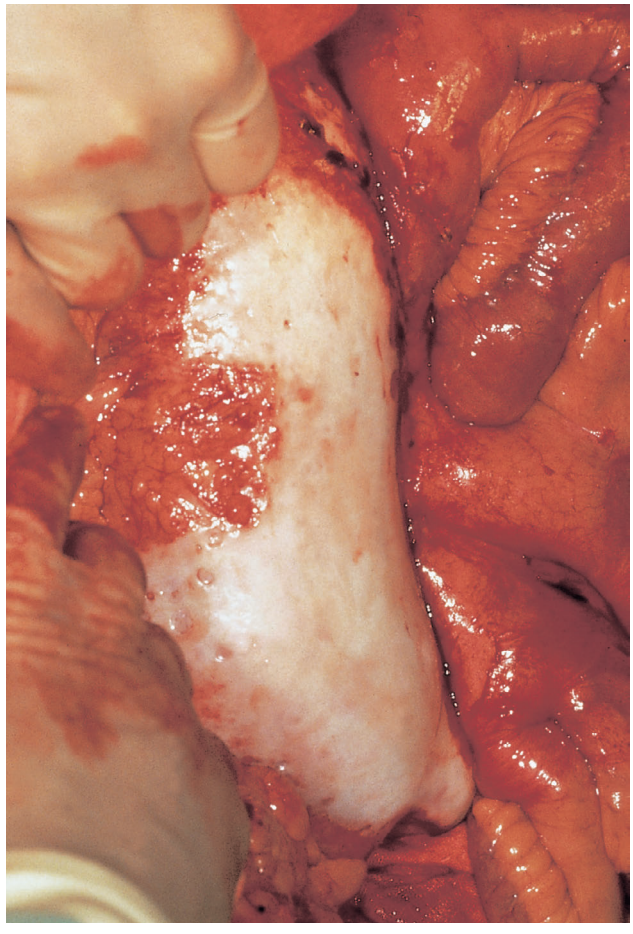

Figure 61.50 An inflammatory abdominal aortic aneurysm. Note the white 'icing' effect. Such lesions can be technically difficult to manage.

Cardiac, respiratory, renal and neurological complications are less common after endovascular repair. However, there are complications that are unique to EVAR, such as endoleak (***Table 61.3***), graft migration, metal strut fracture and graft limb occlusion. Lifelong surveillance with duplex or CT scans (together with plain abdominal radiographs for strut fracture) is required to detect endoleak and migration. High-pressure endoleaks may require repeat ballooning or a proximal cuff or distal limb extension to reseal the endograft. Migration may also require extension of the graft. Overall, 10–20% of patients with EVAR will require secondary interventions to treat complications at some future date, although many of the interventions can be performed with a percutaneous approach via the femoral artery in the angiography suite.

TABLE 61.3 Classification of endoleaks following endovascular aneurysm repair.

Type of endoleak	Definition
Type I	Persistent filling of the aneurysm sac owing to an ineffective seal at the proximal (Ia) or distal (Ib) end of the stent–graft
Type II	Persistent filling of the aneurysm sac owing to retrograde flow of blood from aortic collaterals, e.g. IMA, lumbar arteries
Type III	Persistent filling of the aneurysm sac owing to structural failure of the stent–graft as a result of component disconnection (IIIa) or stent fabric tear (IIIb)
Type IV	Persistent filling of the aneurysm sac owing to stent–graft fabric porosity
Type V (endotension)	Persistent filling of the aneurysm sac without evidence of types I–IV endoleak

IMA, inferior mesenteric artery.

PERIPHERAL ANEURYSM

Popliteal aneurysm

Popliteal artery aneurysm accounts for 70% of all peripheral aneurysms classically diagnosed in men in their seventh decade of life; 50% are bilateral. Examination of the abdominal aorta is indicated if a popliteal aneurysm is found because one-third are accompanied by aortic dilatation. Popliteal aneurysms present as a swelling behind the knee or with symptoms caused by complications, such as severe ischaemia following thrombosis or distal ischaemia as a result of emboli. The diagnosis is usually confirmed with DUS but assessment of the distal vessels (with CT, MRA or DSA) is important prior to repair if the foot pulses are diminished or absent. An asymptomatic aneurysm greater than 20 mm in diameter should be considered for elective repair to prevent future complications. Some surgeons would also offer elective repair for smaller diameters if the sac contains thrombus because of a perceived increased risk of distal embolisation. All symptomatic popliteal aneurysms, including those in which single crural vessel embolisation has occurred, should be considered for repair.

Two techniques for surgical repair may be used: exclusion bypass and inlay repair. An exclusion bypass involves a medial approach to the above- and below-knee popliteal arteries, ligation of the aneurysm and restoration of flow to the foot with a bypass graft using saphenous vein. Many surgeons favour this approach because the anatomy is similar to that for a femoropopliteal bypass and therefore familiar. An inlay graft repair is performed through a posterior approach and has the benefits of allowing free ligation of feeding geniculate branches as well as aneurysmectomy in patients with neurovascular compression. However, the posterior approach limits exposure of the superficial femoral and crural arteries and should only be used when the popliteal aneurysm is confined to the popliteal fossa.

In the acute situation, the presentation is usually with a thrombosed aneurysm and an ischaemic foot; popliteal aneurysms very rarely rupture. Aneurysm thrombosis tends to occur following a period of chronic embolisation to the run-off vessels. As successive run-off vessels occlude over time the outflow to the popliteal artery diminishes, resulting in reduced flow rates in the aneurysm sac and eventual thrombosis. In such cases surgery is often unsuccessful because the outflow for the graft reconstruction is chronically diseased. Attempts to re-establish a patent run-off vessel with embolectomy and intra-arterial thrombolysis may be successful, but the limb loss rate is high (50%).

Femoral aneurysm

True aneurysm of the femoral artery is uncommon. Complications occur in less than 3% so conservative treatment is generally indicated, but it is important to look for aneurysms elsewhere as over half are associated with abdominal or popliteal aneurysms. Large aneurysms should be repaired. False aneurysm of the femoral artery occurs in 2% of patients after arterial surgery at this site. Local repair may involve reanastomosis of the bypass in the groin under suitable antibiotic cover. However, if infection is the cause, the treatment may involve excision of the infected graft and insertion of a further bypass routed around the infected area. In the latter case, the failure rate is high, and limb loss may be unavoidable. For false aneurysms caused by femoral artery puncture measuring ≤3 cm, thrombin injection under ultrasonography guidance may be successful and avoids surgery. False aneurysms measuring >3 cm usually require open surgical repair with suturing of the puncture site.

Iliac aneurysm

This usually occurs in conjunction with aortic aneurysm and only rarely on its own. When occurring in isolation it is difficult to diagnose clinically so about half present already ruptured. Open surgery usually involves an inlay graft but some iliac aneurysms may be suitable for endovascular repair.

ARTERIOVENOUS FISTULA

Communication between an artery and a vein may be either a congenital malformation or the result of trauma. Arteriovenous fistulae for haemodialysis access are also created surgically. All arteriovenous communications have a structural and a physiological effect. The structural effect of arterial blood flow on the veins is characteristic; they become dilated, tortuous and thick walled (arterialised). The physiological effect, if the fistula is large, is an increase in cardiac output that may lead to cardiac failure.

A pulsatile swelling may be present if the lesion is superficial. A thrill is detected on palpation and auscultation reveals a buzzing continuous bruit ('machinery murmur'). Dilated veins may be seen and pressure on the artery proximal to the fistula reduces the swelling and the thrill and bruit cease.

Duplex scan and/or angiography confirms the lesion that shows rapid venous filling.

Management

Treatment is often complex and usually involves embolisation. Excision surgery is sometimes used for severe deformity or recurrent haemorrhage; the assistance of a plastic surgeon is wise. Ligation of a 'feeding' artery usually fails and may preclude treatment by embolisation.

ARTERITIS AND VASOSPASTIC CONDITIONS

Thromboangiitis obliterans (Buerger's disease)

This is characterised by occlusive disease of small and medium-sized limb arteries, thrombophlebitis of superficial or deep veins and Raynaud's syndrome; it usually occurs in young male smokers. Histologically, there are inflammatory changes in the walls of arteries and veins, leading to thrombosis. Treatment is total abstinence from smoking, which arrests, but does not reverse, the disease. Established arterial occlusions are treated as for atheromatous disease, but amputations may eventually be required.

Other forms of arteritis

Arteritis occurs in association with many connective tissue disorders, e.g. rheumatoid arthritis, systemic lupus erythematosus and polyarteritis nodosa.

Temporal arteritis is a disease in which localised infiltration with inflammatory and giant cells leads to arterial occlusion, ischaemic headache and tender, palpable, pulseless (thrombosed) arteries in the scalp. Irreversible blindness occurs if the ophthalmic artery becomes occluded. The surgeon may be required to perform a temporal artery biopsy, but this should not delay immediate steroid therapy to arrest and reverse the process before the ophthalmic artery is involved. Takayasu's disease is an arteritis that obstructs major arteries, particularly the large vessels coming off the aortic arch. It usually pursues a relentless course.

Cystic myxomatous degeneration

This is typified by an accumulation of clear jelly (like a synovial ganglion) in the outer layers of a main artery, especially the popliteal artery. The lesion may narrow the vessel, causing claudication. Duplex scan is the investigation of choice. Decompression, by removal of the myxomatous material, may be successful but in some cases excision of the diseased artery with interposition vein graft repair is required.

Raynaud's disease

This idiopathic condition usually occurs in young women and affects the hands more than the feet. There is abnormal sensitivity in the arteriolar response to cold. These vessels constrict and the digits (usually the fingers) turn white and become incapable of fine movements. The capillaries then dilate and fill with slowly flowing deoxygenated blood, resulting in the digits becoming swollen and dusky. As the attack passes off, the arterioles relax, oxygenated blood returns into the dilated capillaries and the digits become red. Thus, the condition is recognised by the characteristic sequence of blanching, dusky cyanosis and red engorgement, often accompanied by pain. Superficial necrosis is very uncommon. This condition must be distinguished from Raynaud's syndrome, which has similar features (see ***Raynaud's syndrome***). Treatment of Raynaud's disease consists of protection from cold and avoidance of pulp and nail bed infection. Calcium antagonists, such as nifedipine, may also have a role to play and electrically heated gloves can be useful in winter. Sympathectomy has been used in the past but it is either ineffective or its effects are short-lived.

Raynaud's syndrome

Raynaud's syndrome is the peripheral arterial manifestation of a collagen disease such as systemic lupus erythematosus or rheumatoid arthritis. The clinical features are as for Raynaud's disease but they may be much more aggressive. Raynaud's syndrome may also follow the use of vibrating tools. In this context it is a recognised industrial disease and is known as 'vibration white finger'.

Treatment is directed primarily at the underlying condition, although the conservative measures outlined above are often helpful. The syndrome when secondary to collagen disease leads frequently to necrosis of digits and multiple amputations. Sympathectomy yields disappointing results and is not recommended. Nifedipine, steroids and vasospastic antagonists may all have a role in treatment. Patients with vibration white finger should avoid vibrating tools.

Acrocyanosis

Acrocyanosis may be confused with Raynaud's disease but it is painless and not episodic. It tends to affect young women and the mottled cyanosis of the fingers and/or toes may be accompanied by paraesthesia and chilblains.

Sympathectomy

Endoscopic transthoracic sympathectomy is now reserved as a minimally invasive treatment of palmar and axillary hyperhidrosis. Open cervical sympathectomy was used in the past as a treatment of vasospastic disorders but was usually unsuccessful. Lumbar sympathectomy was used to treat lower limb ischaemia in the past but has also become obsolete.

PART 10 | Vascular

CHAPTER 62

Venous disorders

Learning objectives

To understand:

- Venous anatomy and physiology
- The pathophysiology of venous hypertension
- The clinical significance and management of superficial venous reflux
- The management of venous ulceration
- Venous thromboembolism

INTRODUCTION

Up to 40% of the adult population in resource-rich countries have diseases of the veins of the leg. This extraordinary prevalence along with the associated impairment in health-related quality of life make it a very important area of surgical practice. Surgical intervention has been revolutionised by the development of endovenous techniques, and level 1 evidence has demonstrated that treatment can be associated with very high clinical- and cost-effectiveness. Despite the considerable importance placed on lower limb function during the management of orthopaedic and arterial diseases, venous diseases are often forgotten or dismissed as cosmetic practice. An understanding of the nature and management of venous disease is critical to address this imbalance and improve the quality of patients' lives.

THE ANATOMY OF THE VENOUS SYSTEM OF THE LOWER LIMB

The venous system of the lower limb can be divided anatomically into the **superficial venous system**, which is located within the superficial tissues, and the **deep venous system**, beneath the deep fascia of the leg, accompanying the arterial tree. The superficial veins drain into the deep system, either at junctions or via fascial perforating veins, and the deep veins then return blood to the right atrium of the heart. Venous anatomy is characteristically variable. The terminology used below is consistent with international consensus.

The deep veins of the lower limb (***Figure 62.1a***) include three pairs of venae comitantes, which accompany the three crural arteries (anterior and posterior tibial and peroneal arteries). These six veins intercommunicate and come together in the popliteal fossa to form the popliteal vein, which also receives the soleal and gastrocnemius veins. The popliteal vein passes up through the adductor hiatus to enter the subsartorial canal as the femoral vein, which receives the deep (profunda) femoral vein (or veins) in the femoral triangle before passing behind the inguinal ligament to become the external iliac vein. The internal iliac vein combines with the external iliac vein in the pelvis to form the common iliac vein. The left common iliac vein passes behind the right common iliac artery to join the right common iliac vein on the right side of the abdominal aorta to form the inferior vena cava, which goes on to the right atrium.

Far more anatomical variations exist within the superficial veins of the lower limb, but there are almost always two trunks or axes – the great and small saphenous veins (***Figure 62.1b,c***). These lie superficial to the fascia lata (deep fascia) but deep to the saphenous fascia, in the saphenous 'envelope'.

As the sole of the foot is often placed under significant pressure, the majority of the venous drainage of the foot is into the dorsal venous arch, running in the subcutaneous tissues over the metatarsal heads. The medial end of this arch drains into the first axis: the great saphenous vein (GSV). This is the longest vein in the body and is the most frequently affected by superficial incompetence. The GSV passes anterior to the medial malleolus and ascends the leg accompanied by the saphenous nerve in the superficial tissues medial to the tibia, looping posteriorly at the level of the medial condyle of the femur and continuing in the medial thigh. In the groin, it unites with tributaries corresponding to the arterial branches of the common femoral artery, before piercing the cribriform fascia covering the saphenous opening (approximately 2.5 cm below and lateral to the pubic tubercle, but often somewhat higher) and terminates by draining into the common femoral vein (CFV) at the saphenofemoral junction (SFJ). Throughout its course the GSV unites variably with other superficial tributaries. The anterior accessory of the great saphenous vein (AAGSV) is one of the most common. This is often seen originating around the lateral border of the knee, although it sometimes originates as low as the lateral end of the dorsal venous arch. Occasionally, this vein may also course up the medial aspect of the thigh, anterolateral to the GSV and

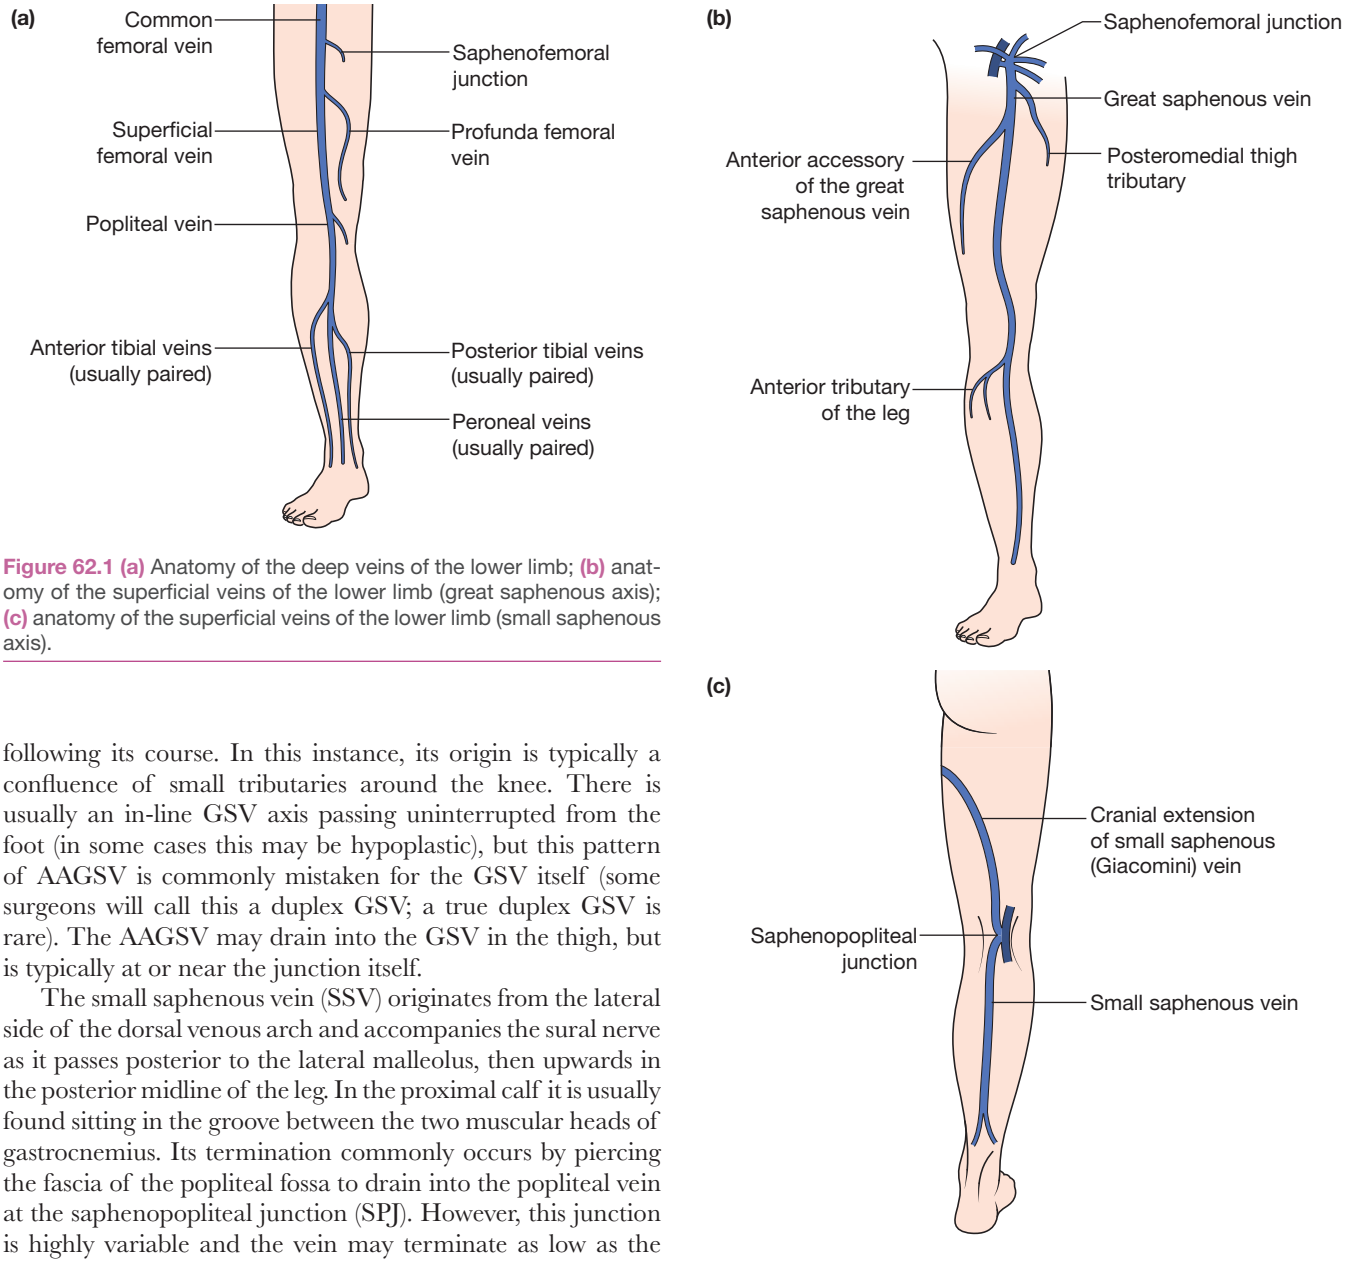

Figure 62.1 (a) Anatomy of the deep veins of the lower limb; **(b)** anatomy of the superficial veins of the lower limb (great saphenous axis); **(c)** anatomy of the superficial veins of the lower limb (small saphenous axis).

following its course. In this instance, its origin is typically a confluence of small tributaries around the knee. There is usually an in-line GSV axis passing uninterrupted from the foot (in some cases this may be hypoplastic), but this pattern of AAGSV is commonly mistaken for the GSV itself (some surgeons will call this a duplex GSV; a true duplex GSV is rare). The AAGSV may drain into the GSV in the thigh, but is typically at or near the junction itself.

The small saphenous vein (SSV) originates from the lateral side of the dorsal venous arch and accompanies the sural nerve as it passes posterior to the lateral malleolus, then upwards in the posterior midline of the leg. In the proximal calf it is usually found sitting in the groove between the two muscular heads of gastrocnemius. Its termination commonly occurs by piercing the fascia of the popliteal fossa to drain into the popliteal vein at the saphenopopliteal junction (SPJ). However, this junction is highly variable and the vein may terminate as low as the mid-calf. The SSV may extend cranially beyond the SPJ, in which case it is known as either a cranial extension of the SSV, which terminates by piercing the fascia in the posterior thigh to drain into the deep system, or the Giacomini vein, which communicates with the GSV system occasionally joining the GSV at or about the SFJ. In some cases, the SSV does not terminate at or below the popliteal fossa at all, but continues on as described above.

In the calf and thigh there are a number of valved perforating (communicating) veins that join the superficial to the deep veins at inconstant sites and which allow blood to flow from the superficial to the deep venous system. The most important of these are the direct perforating veins of the medial and lateral calf and the communicating veins around the knee and in the mid-thigh.

VENOUS PATHOPHYSIOLOGY

The purpose of the venous system is primarily to return blood back to the heart so that it can be delivered into the pulmonary circulation. The venous system contains approximately 60% of the total blood volume, with an average pressure of around 5–10 mmHg. Mechanical factors, alongside the autonomic nervous and endocrine systems, control the rate at which blood is delivered to the right atrium. Through its effects upon myocardial contractility via the Starling mechanism, venous return is one of the factors responsible for determining cardiac output.

Blood enters the lower limb through the femoral arteries before passing through arterioles into the capillaries, which

Carlo Giacomini, 1840–1898, anatomist, Turin, Italy. On his death he left his skeleton to the Anatomical Museum in Turin.
Ernest Henry Starling, 1866–1927, physiologist, University College, London, UK.

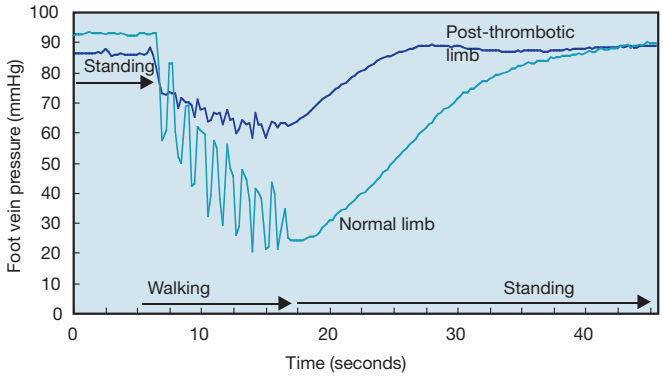

Figure 62.2 Effect of exercise on the superficial venous pressure in health and disease. The light blue line demonstrates the reduction in pressure primarily related to the action of the calf muscle pump. The dark blue line demonstrates how venous dysfunction is associated with reduced net antegrade flow during exercise, resulting in a relative increase in venous pressure when compared with normal (venous hypertension).

have a pressure of about 32 mmHg at their arterial ends. This pressure is reduced along the course of the capillaries and is approximately 12 mmHg at the venular end of the capillary. The pressure continues to fall in the main veins, and is as low as 5 mmHg at the upper end of the vena cava where it enters the right atrium.

The venous pressure in a foot vein on standing is equivalent to the height of a column of blood extending from the heart to the foot, e.g. approximately 100 mmHg. To enable blood to be returned against gravity in the standing position a pressure gradient must exist between the veins in the leg and those in the chest. This gradient is created in two ways. First, the increase in thoracic volume during inspiration decreases intrathoracic pressure. Second, the pressure in the veins of the leg is increased by compression by the surrounding muscles (the 'calf muscle pump') and to a lesser extent the tone of the venous wall. The deep veins of the calf are capacious and are joined by blind-ending sacks called the soleal sinusoids, which force blood into the popliteal and crural veins during calf muscle pump contraction, e.g. walking. The foot pump also ejects blood from the plantar veins during walking. As the calf muscles contract, the veins are compressed and the valves only allow blood to pass in the direction of the heart. The pressure within the calf compartment rises to 200–300 mmHg during muscle contraction. Rapid blood flow in the deep veins at junctions and perforators draws blood from the superficial veins, driving this up the deep veins also. During muscle relaxation, the pressure falls and further blood from the superficial veins enters the deep vein. Each time this occurs the pressure falls in the superficial venous compartment until a threshold is reached, when the venous inflow keeps pace with ejection from the deep veins. This is normally around 30 mmHg, a fall of approximately two-thirds of the resting venous pressure. The net reduction in the pressure of the superficial system is dependent on the presence of a pressure gradient between the leg and the thorax and a patent and compliant venous system containing competent valves (***Figure 62.2***). An absence of one or more of these results in venous hypertension, which leads to further vein wall damage, including loss of compliance, thickening, dilatation and valvular dysfunction. This venous damage goes on to reduce the function of the affected veins, worsening the venous hypertension in a vicious cycle. When exposed to high venous and capillary pressures chronically, the soft tissues of the leg will be damaged, causing a spectrum of damage that becomes irreversible. The causes of venous hypertension are listed in ***Table 62.1***.

TABLE 62.1 Factors causing venous hypertension.

Pressure gradient dysfunction
• Increased abdominal or thoracic pressure
◦ COPD
◦ Pregnancy
◦ Obesity
◦ Large tumour
◦ Constipation
• Decreased calf muscle pump function
◦ Immobility
◦ Ankle joint fusion
◦ Paralysis
Dysfunction of the venous system
• Venous structural deficit
◦ Valvular agenesis
◦ Valvular incompetence
◦ Venous dilatation
◦ Venous tortuosity
◦ Loss of vein wall compliance
◦ Loss of venous tone
◦ Arteriovenous fistula
• Venous occlusion
◦ Agenesis
◦ Thrombosis
◦ Iatrogenic/trauma
• Venous compression
◦ May–Thurner syndrome
◦ Pelvic/abdominal tumour
◦ Pelvic/abdominal radiotherapy

COPD, chronic obstructive pulmonary disease.

The majority of patients with venous disease have a problem primarily with the vein wall structure and in most this is confined to the superficial veins. Little is known about the mechanism of initiation of the changes in the vein wall. These changes are complex, but are typified by valvular failure allowing retrograde flow within the vein with gravity (venous incompetence). It is no longer thought that venous incompetence is caused by a primary mechanical valvular failure.

The vein wall changes include inflammatory cell infiltration and activation, dysfunctional smooth muscle cell proliferation, collagen deposition, decreased elastin content and increased matrix metalloproteinases. These effects typically lead to loss

Rudolf Virchow, 1821–1902, pathologist, Charité Hospital, Berlin, Germany, was the first to be credited with describing iliac vein compression. It was not until 1957 that **May** and **Thurner** (Innsbruck, Austria) clearly described compression of the left common iliac vein by the right common iliac artery.

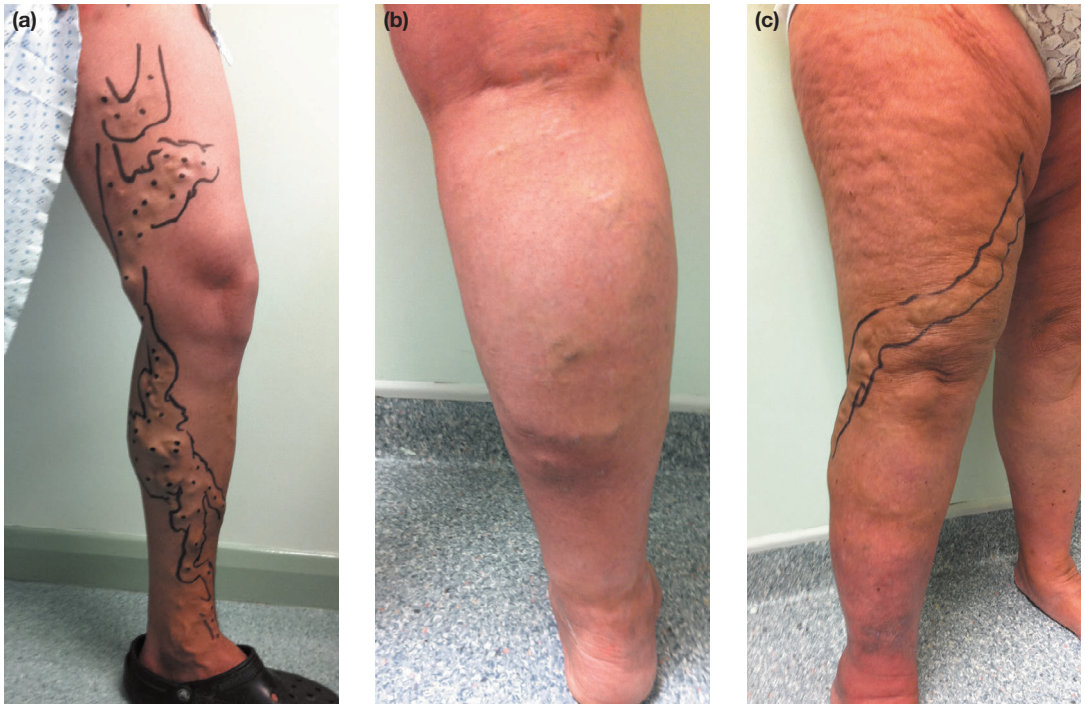

Figure 62.3 Varicose veins: **(a)** left leg varicose veins in the distribution of an incompetent great saphenous vein (marked for intervention); **(b)** right leg varicose veins in the distribution of the small saphenous system with a recent episode of phlebitis; **(c)** varicose veins in the distribution of an isolated incompetent anterior accessory of the great saphenous vein with associated gaiter area skin changes.

of compliance, dilatation, elongation (causing tortuosity) and secondary valvular dysfunction. This process can be initiated anywhere in the venous tree. Secondary varicose veins may develop in patients with post-thrombotic limbs and in patients with congenital abnormalities such as the Klippel–Trénaunay syndrome or multiple arteriovenous fistulae.

The extent and number of incompetent veins governs the extent of the venous hypertension and correlates with the severity of the soft-tissue complications seen. Importantly, however, neither the reflux burden nor the presence of skin changes, short of ulceration, correlate with the presence or degree of symptoms.

CLINICAL FEATURES OF VENOUS HYPERTENSION OF THE LEG

The following clinical features are commonly seen:

- Varicose vein: subcutaneous dilated vein 3 mm in diameter or larger. They are frequently elongated and tortuous, with intermittent 'blowouts', but are defined by the presence of reflux and may be straight and uniform tubes morphologically (***Figure 62.3***).
- Telangiectasia (thread veins, spider veins and hyphen webs): represent tiny intradermal venules less than 1 mm in diameter (***Figure 62.4***).
- Reticular vein: small dilated 'bluish' subdermal vein 1–2.9 mm in diameter, usually tortuous, can be difficult to distinguish this from a normal subdermal vein in someone with white thin transparent skin.
- Saphena varix (***Figure 62.5***) is a (usually painless) groin swelling apparent on standing.
- Corona phlebectatica (malleolar flare): a fan-shaped pattern of telangiectasia on the ankle or foot. This is an early sign of advanced venous disease.
- Oedema: increased volume of fluid in the skin and soft tissues of the leg. Commonly starts distally and moves more proximally with increasing venous dysfunction. Classically this is 'pitting oedema', with firm digital pressure leaving an indentation in the soft tissues.
- Eczema: an erythematous dermatitis, often appears minor, although it may be associated with significant itching and discomfort. In extreme cases it may progress to blistering and weeping (***Figures 62.6–62.8***).
- Pigmentation (haemosiderosis): a brownish discoloration of the skin, usually permanent. It is usually seen around the ankle, but is also seen in proximity to varicose veins and incompetent perforators (***Figures 62.7 and 62.9***).
- Lipodermatosclerosis (LDS): chronic inflammation and fibrosis of the skin and subcutaneous tissues, resulting in a tight, contracted, 'woody' leg on examination. It occasionally results in significant contractures of the Achilles

Maurice Klippel, 1858–1942, neurologist, La Salpêtrière, Paris, France.
Paul Trénaunay, 1875–1938, French neurologist. Klippel and Trénaunay described this condition in a joint paper in 1900.
A **gaiter** is a leather or cloth covering for the lower leg and ankle. The name is derived from the French 'guetre' for the same piece of clothing.

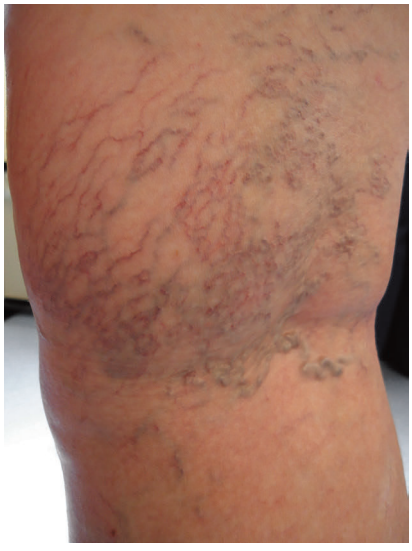

Figure 62.4 Telangiectasia and reticular veins.

Figure 62.5 A saphena varix.

tendon. This is a sign of severe chronic venous disease (***Figures 62.6 and 62.9***).

- Atrophie blanche: localised areas of atrophic, white skin, often surrounded by telangiectasia and pigmentation. Some authors distinguish this from the white scarring left by ulceration; others do not. Either way, this is a sign of severe chronic venous disease (***Figure 62.6***).
- Venous ulcer: full-thickness skin loss, usually around the ankle, which fails to heal spontaneously and is propagated by continuing venous hypertension and the changes associated with chronic venous disease (***Figure 62.10***).

Classification system

The descriptive CEAP (Clinical–aEtiology–Anatomy–Pathophysiology) classification for chronic venous disorders is widely utilised.

Figure 62.6 Advanced skin changes: lipodermatosclerosis, eczema and atrophie blanche.

Figure 62.7 Pigmentation (haemosiderosis) and mild eczema.

Figure 62.8 Severe eczema.

Figure 62.9 Haemosiderosis and mild lipodermatosclerosis of the calf skin.

Figure 62.10 Venous ulcer.

For clinical classification:

- C0: no signs of venous disease;
- C1: telangiectasia or reticular veins;
- C2: varicose veins;
- C3: oedema;
- C4a: pigmentation or eczema;
- C4b: LDS or atrophie blanche;
- C4c Corona phlebectatica
- C5: healed venous ulcer;
- C6: active venous ulcer.

Clinical class can be further characterised as symptomatic (s), asymptomatic (a) or recurrent following previous successful treatment or healing (r), e.g. C2a, C2s, C6r.

For aetiological classification:

- Ec: congenital;
- Ep: primary;
- Es: secondary (post-thrombotic);
- En: no venous cause identified.

For anatomical classification:

- As: superficial veins;
- Ap: perforator veins;
- Ad: deep veins;
- An: no venous location identified.

For pathophysiological classification:

- Pr: reflux;
- Po: obstruction;
- Pr,o: reflux and obstruction;
- Pn: no venous pathophysiology identifiable.

VARICOSE VEINS

In clinical practice, patients are normally categorised as having 'varicose veins' or 'venous ulcers'. Cases of varicose veins may be uncomplicated or complicated. Complications may be chronic (as discussed above) or acute, including superficial vein thrombosis (thrombophlebitis) and bleeding. Uncomplicated varicose veins may be asymptomatic or symptomatic.

Epidemiology

The adult prevalence of visible varicose veins is between 30% and 50%. Factors affecting prevalence include:

- Gender: the vast majority of studies report a higher prevalence in women than in men, though community prevalence may differ.
- Age: the prevalence of varicose veins increases with age. In the Edinburgh Vein Study, the prevalence of trunk varicosities in the age groups 18–24 years, 25–34 years, 35–44 years, 45–57 years and 55–64 years was 11.5%, 14.6%, 28.8%, 41.9% and 55.7%, respectively.
- Ethnicity: does seem to influence the prevalence of varicose veins.
- Body mass and height: increasing body mass index and height may be associated with a higher prevalence of varicose veins.
- Pregnancy: increases the risk of varicose veins.
- Family history: evidence supports familial susceptibility to varicose veins.
- Occupation and lifestyle factors: there is inconclusive evidence regarding increased prevalence of varicose veins in smokers, in patients who suffer constipation and in those with occupations that involve prolonged standing.

Symptoms

Varicose veins frequently cause symptoms. Patients describe aching, heaviness, throbbing, burning or bursting over affected areas and sometimes the whole limb. Such symptoms typically increase throughout the day or with prolonged standing, and are relieved by elevation or compression hosiery. Itching is also commonly described, though this is more frequent in the presence of complications, as is swelling of the ankle. Venous symptoms in the absence of complications can be vague and it may be difficult to ascertain from history alone whether they are truly venous in origin and, therefore, whether treatment will help. A trial of compression hosiery can help as venous symptoms should show some beneficial improvement.

Symptoms can be very severe and interfere with a patient's daily activities such as work, recreation and caring for children and adults. Such symptoms are independent of the degree of venous incompetence or the presence of complications, including skin changes short of ulceration. Studies have also shown that symptoms are associated with a significant deficit in health-related quality of life, and significant improvements are seen with treatment to remove or ablate the refluxing veins. The maximal benefit is seen in those with uncomplicated symptomatic varicose veins, as skin changes and a proportion of the associated morbidity are frequently irreversible.

Telangiectasia (not associated with malleolar flare) and reticular veins occur very commonly in the absence of significant reflux or obstruction and in the vast majority do not cause any physical symptoms, though cosmetic treatment is commonly sought.

Signs

The presence of tortuous dilated subcutaneous veins is usually clinically obvious. These are confined to the GSV and SSV systems in approximately 60% and 20% of cases, respectively. The distribution of varicosities may indicate which superficial axis is defective; medial thigh and calf varicosities suggest GSV incompetence (***Figure 62.3a***), posterolateral calf varicosities are suggestive of SSV incompetence (***Figure 62.3b***), whereas anterolateral thigh and calf varicosities may indicate isolated incompetence of the AAGSV (***Figure 62.3c***). Any of the clinical features above may be present. Large, dilated veins around the SFJ may present as a (usually painless) lump, emergent when standing and disappearing when recumbent. This is a saphena varix (***Figure 62.5***). Gentle palpation over the varix during coughing may elicit an impulse and it may be mistaken for a groin hernia.

Investigation

Tourniquet tests and the use of hand-held Doppler have now been abandoned. There is good evidence to support the policy of duplex ultrasound scanning for all patients with varicose veins prior to any intervention. The best clinical results come from clinicians who are personally very skilled in the use of duplex ultrasound and use it to design a bespoke treatment for each individual patient, based upon their unique anatomy.

A high-frequency linear array transducer of 7.5–13 MHz is appropriate for the majority of lower limbs in order to obtain good quality images. The B-mode settings (depth, focal zone, overall gain and dynamic gain) should be optimised to ensure that the area of interest is in the centre and occupies the majority of the image, and that the lumen of the vein appears as a dark void in the subcutaneous and deep tissues. The pulsed wave spectral or colour Doppler settings should be optimised for the low-flow velocities encountered within veins. It is conventional to use blue to represent antegrade venous flow towards the heart and red for the reverse. Visible venous flow can be augmented by a calf squeeze.

The aim of the duplex scan in a patient with varicose veins is to establish:

- the presence of reflux in the deep and superficial venous system;
- the exact distribution and extent of reflux in the superficial venous system, including affected junctions and perforators;
- the presence of obstruction in the deep venous system;
- the suitability of the incompetent superficial veins for the different treatments available (based upon diameter, extent, tortuosity, saphena varix);
- the presence of thrombus within the superficial veins;
- an indication of a pelvic source of reflux or obstruction.

In order to standardise measurements of venous diameter and reflux, it is recommended that examination of the superficial veins is performed with the patient standing. Superficial or crural vein reflux is defined as retrograde flow in the reverse direction to physiological flow lasting for 0.5 seconds or more. The proximal deep veins require a duration of 1 second or more to be classified as incompetent. Reflux may be elicited by release of a calf or foot squeeze for proximal or calf varicosities, respectively, manual compression over varicosity clusters, pneumatic calf cuff deflation, active foot dorsiflexion and relaxation or the Valsalva manoeuvre.

The patient should stand facing towards the examiner with the leg rotated outwards, heel on the ground and weight on the opposite limb (***Figure 62.11***). The use of a platform, ideally with a handle or support bar for the patient and a stool that can drop to a low height, will improve the ergonomic comfort of both the sonographer and the patient. The scan should commence in the groin, using a transverse view to identify the GSV and CFV lying medial to the common femoral artery (the 'Mickey Mouse' sign; ***Figure 62.12***). SFJ competence is assessed in the transverse view and potential destinations for reflux, including the GSV, the AAGSV and other major thigh tributaries superficial to the saphenous fascia, are noted. Any indication of a pelvic source of reflux suggests the need for more proximal imaging. The full length of the GSV within its fascial compartment should be examined (***Figure 62.13***), and its diameter measured if required. The groin is next examined

Figure 62.11 Patient position for venous duplex examination of the great saphenous system.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.
Antonio Valsalva, 1666–1723, anatomist, Bologna, Italy. Also described the Eustachian tube and aortic sinuses.

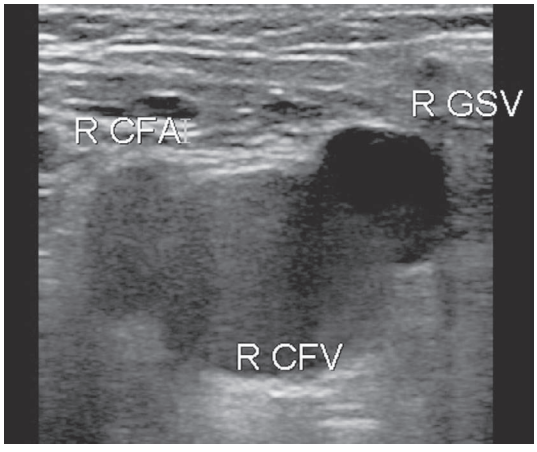

Figure 62.12 'Mickey Mouse' transverse B-mode image of the right (R) common femoral vein (CFV) and artery (CFA), great saphenous vein (GSV) and saphenofemoral junction.

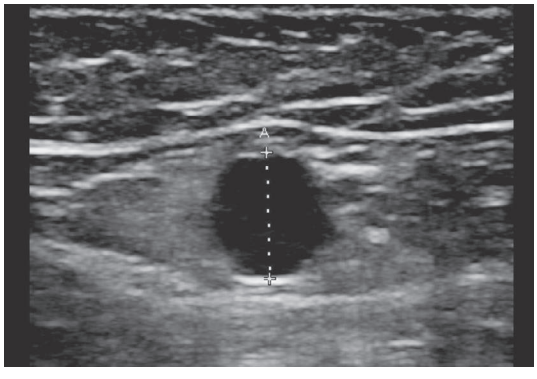

Figure 62.13 'Saphenous eye' transverse B-mode view of the great saphenous vein in fascial compartments of the thigh. The fascial line above the vein is the saphenous fascia. A true great or small saphenous vein will not cross this line, although the fascia may become discontinuous around the knee. The line deep to the vein is the fascia lata, with the muscle beneath.

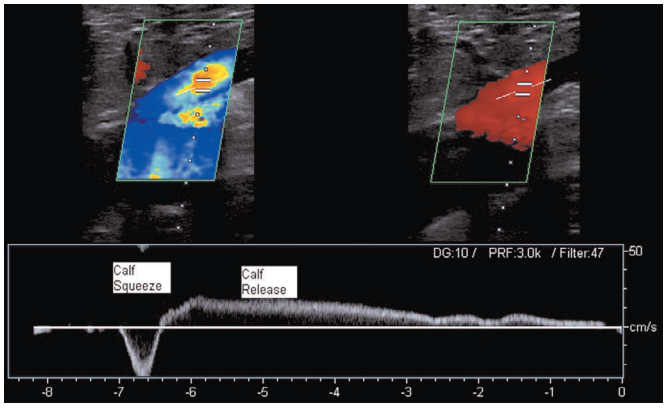

Figure 62.14 Spectral Doppler trace of the saphenofemoral junction showing antegrade and retrograde flow. The downward spike on the trace is the antegrade augmented flow and this is followed by approximately 4 seconds of retrograde flow.

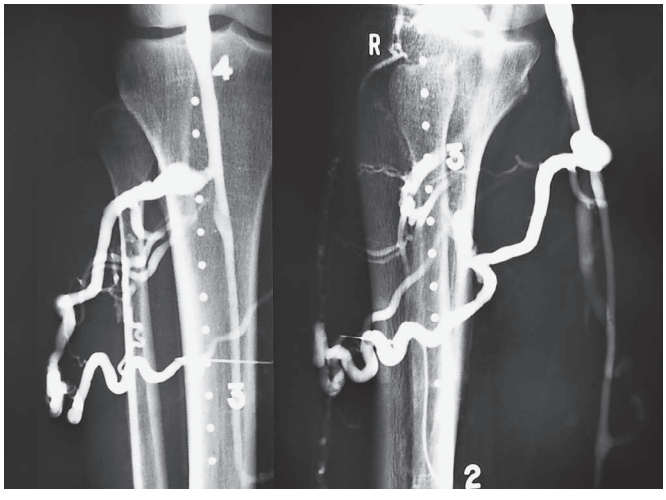

Figure 62.15 Varicogram. (This is now a historical investigation.)

for reflux or obstruction in the CFV, superficial femoral vein and SFJ using spectral and/or colour Doppler (***Figure 62.14***).

A loss of phasic flow with respiration in the CFV suggests upstream obstruction and the need for proximal imaging. The presence and competence of thigh and calf perforators should be noted and the crural veins examined for reflux or obstruction. For examination of the SSV and posterior thigh extension of the SSV (Giacomini vein), the patient is positioned facing away, knee slightly flexed, heel on the ground and the weight taken on the opposite leg. If the SPJ is incompetent, the level of the SPJ in relation to the knee crease and whether the SSV joins the popliteal vein posteriorly, medially or laterally is noted if open surgical ligation is to be entertained. In the transverse view, the SSV vein is followed distally, checking its competence and diameter in the proximal, mid- and distal calf. Finally, the patency and competence of the popliteal vein is assessed.

Pelvic and iliac veins may be investigated using transabdominal or transvaginal duplex. Very occasionally investigations other than duplex are required, and these may be non-invasive, such as magnetic resonance (MR) venography, or invasive, such as contrast venography or intravenous ultrasound (IVUS). The use of varicography has become historical (***Figure 62.15***).

Management

Many patients with asymptomatic varicose veins do not progress to develop complications, although a significant proportion do, and there is no clear confirmatory evidence that treating such patients prevents the development of future complications. There is clear evidence, however, that those with symptoms and/or complications see a significant quality-of-life benefit from treatment to remove or ablate refluxing superficial veins.

When interventional treatment is planned there are considerable variations in practice and treatment strategies. A detailed description of the nuances, merits and criticisms of the various options is beyond the scope of this chapter; however, a description of the basic treatment modalities available is presented below. An experienced surgeon will have his/her own preferred methods, but will frequently employ several or all methods in chosen circumstances, not infrequently in the same patient.

Compression

Compression hosiery relies on graduated external pressure to improve deep venous return and reduce venous pressures. It may be knee length or thigh length; there is no evidence which length of stocking is more effective and hence below-knee stockings are usually prescribed as they are easier to don and have much better patient acceptance. Compression hosiery is classified according to the pressure it exerts: the British classification class 1 stockings exert pressure of 14–17 mmHg, class 2 exert 18–24 mmHg and class 3 exert 25–35 mmHg.

Compression hosiery significantly improves varicose vein symptoms but is not popular with patients, with compliance rates and long-term tolerance being universally poor. There is no evidence to suggest that compression hosiery prevents the occurrence or progression of varicose veins. Furthermore, incorrect application of compression hosiery can have serious consequences (pressure necrosis, tourniquet effects); thus assessment, prescription and application of compression hosiery should be limited to those with the appropriate skills and training. There are level 1 trial data to demonstrate that interventional treatment offers superior improvements in quality of life and is cost-effective. Compression is therefore to be regarded as an adjunct to assessment or treatment, unless by patient choice.

Endothermal ablation

Endothermal ablation technologies replaced surgical ligation and stripping as the gold standard treatment once randomised trials demonstrated that they were marginally safer, have extremely high technical efficacy, offer superior quality of life post procedure (with a rapid recovery) and equivalent improvements in quality of life in the longer term. The techniques are cost-effective as they can be performed as an outpatient under local anaesthetic. The basic concept is that a treatment device is inserted into the incompetent axial vein percutaneously. The vein is surrounded by tumescent local anaesthetic solution. This compresses the vein onto the treatment device, emptying it of blood. It also hydro-dissects tissues such as nerves away from the zone of injury. Finally, it acts as a heat sink, mopping up excess thermal energy to prevent remote damage. The treatment device then produces thermal energy that destroys the structure of the vein, resulting in permanent occlusion. Two broad technologies exist: laser ablation and radiofrequency ablation (RFA).

Laser ablation

Endovenous laser ablation (EVLA) utilises a small flexible glass fibre that is inserted into the vein. Laser energy (typically at a wavelength of 1470 nm) is transmitted down the fibre and is absorbed at the point of treatment at the end of the fibre. Absorption of this radiation results in a vigorous generation of thermal energy. The tip of the fibre may be bare, focusing the energy in a very small area; divergent forward firing, spreading the energy over a larger area; or divergent side or radial firing. It is postulated that the last two designs allow a more even distribution of energy, reducing vein wall perforations that are thought to be associated with postprocedural pain and bruising. There is no clear evidence to support one design over another. This procedure is very good for treatment of any vein that will allow the passage of a guidewire. No technique has reported a higher technical efficacy rate.

The procedure begins with ultrasound-guided marking of the truncal vein to be treated and the site of proposed cannulation. The varicosities are also marked at this stage if concomitant treatment (phlebectomy or foam sclerotherapy) is to be undertaken. The patient is then positioned on the procedure couch in the reverse Trendelenburg position. For the GSV, the patient is supine with the hip of the leg to be treated externally rotated and slightly flexed. A pillow under the contralateral hip/lower back may improve patient comfort. For the SSV the patient is positioned in the prone position. The vein is then cannulated percutaneously under ultrasound guidance, at the lowest point of reflux. Some devices allow passage of the fibre directly through a short sheath, while others use a wire first, allowing passage of a catheter that then carries the laser fibre. The former is slightly faster with fewer steps; the latter allows greater success with more tortuous veins. Accurate positioning of the fibre tip with ultrasound is crucial (***Figure 62.16***), but the exact location is controversial, with some surgeons positioning the tip several centimetres distal to the junction and others aiming for a flush occlusion. Proponents of the former cite that this strategy protects the deep vein from inadvertent damage and/or thrombosis. Proponents of the latter argue that neoreflux in junctional tributaries is a common pattern of recurrence and that in expert hands the rate of deep vein injury is no different and the thrombosis rate may be lower (presumably as there is minimal patent stump in which to form thrombus). Following the administration of perivenous tumescent anaesthesia (***Figure 62.17***), the ablation can be performed. Practice varies as to the power of the laser and the withdrawal speed, but commonly an energy delivery

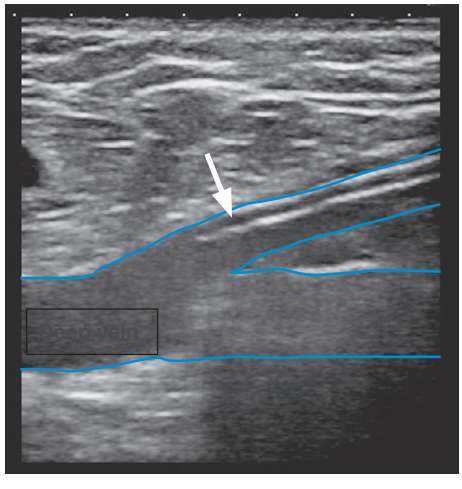

Figure 62.16 Endovenous laser ablation; B-mode longitudinal imaging during catheter tip positioning at the saphenofemoral junction. The saphenofemoral junction is highlighted (in blue) with an arrow pointing to the catheter.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

of around 60–80 J/cm is used to achieve a durable closure. There is no clear evidence to guide the optimal power and pullback speed. Compression is usually applied following treatment, but there is no consensus over the method, degree or duration, and this is true of postprocedural compression with all techniques.

Radiofrequency ablation

RFA uses the same treatment principles, but an electromagnetic current is used to create the thermal energy. A range of different devices have been created but the most popular, which has the most supportive evidence, is the ClosureFast™ device (Medtronic) (***Figure 62.18***). This device has a wire coil on the end of a treatment catheter. The generator passes an electrical current through the coil until the surrounding temperature reaches 120°C. This is then maintained for a treatment cycle of 20 seconds. The coil is then withdrawn for a set length and another treatment cycle is commenced. Coils of 3 cm and 7 cm are produced, with the latter increasing the speed of treatment, while still being suitable for most anatomies.

There have been a range of studies comparing EVLA and RFA. The evidence is generally equivocal, with both treatments having relative advantages and disadvantages; choice often comes down to personal preference. Both are excellent treatment options and can be applied successfully to the majority of patients.

There have been a range of studies comparing EVLA and RFA. The evidence is generally equivocal, with both treatments having relative advantages and disadvantages; choice often comes down to personal preference. Both are excellent treatment options and can be applied successfully to the majority of patients.

Some summary points:

- Both treatments have a very high efficacy (>95% closure rate) and are suitable for treatment of the vast majority of patients presenting with superficial vein reflux in association with superficial axial incompetence.
- Veins that are very tortuous may still be suitable for endothermal ablation but require a guidewire and in the case of EVLA, a catheter-based, rather than direct fibre system. Both techniques offer this.

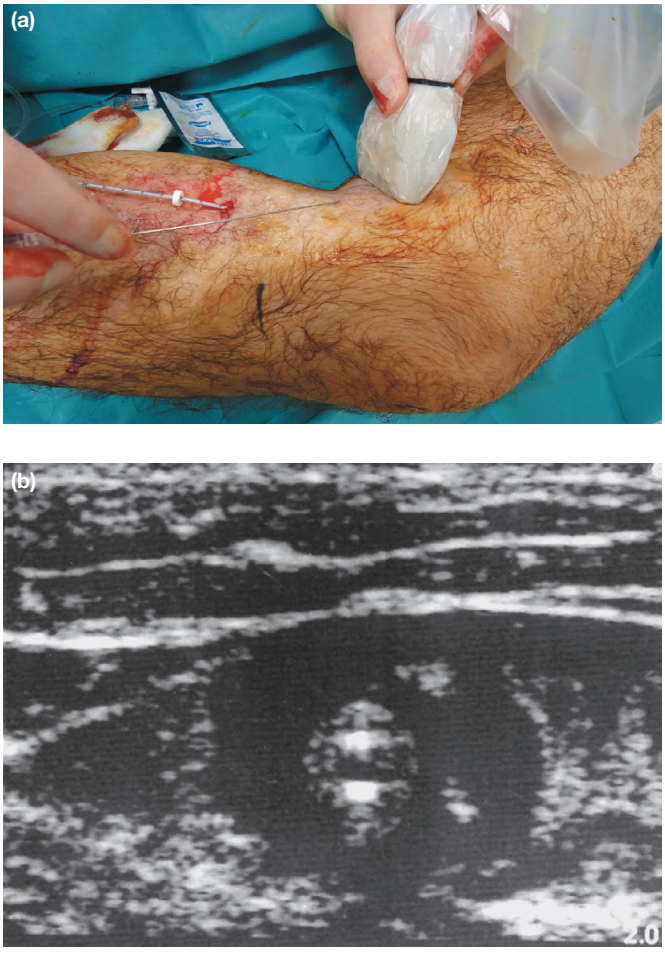

Figure 62.17 (a) Ultrasound-guided infiltration of perivenous tumescent anaesthetic via a long spinal needle. The anaesthetic solution is infiltrated using an electronic foot-operated pump; **(b)** ultrasound image of a perivenous 'halo' of anaesthetic solution around the vein and catheter in transverse section.

Figure 62.18 Radiofrequency ablation with ClosureFast™ introducing the treatment catheter through a sheath. The distal 7 cm of this device comprises a metal coil.

- Catheter-based systems have the additional advantage of allowing direct and targeted delivery of adjuvant foam sclerotherapy, e.g. to ablate areas of neovascularisation. This is more difficult with radiofrequency catheters due to a smaller lumen (0.018 versus 0.035 in), but it is still possible.

Advantages in favour of RFA over EVLA include:

- The core skill set to plan and perform these procedures is the same; however, EVLA requires an understanding of power settings and pullback speeds, whereas a radiofrequency device typically has a set treatment cycle on a single button press. This reduces the device-specific learning curve and the possibility of a novice making a mistake with the energy delivery.
- The automatic treatment cycle also frees the surgeon's focus, allowing better communication with the patient and with care, concurrent treatment, e.g. infiltrating local anaesthetic into the tributaries and performing phlebectomy, reducing procedural times.
- EVLA requires specific laser safety protocols including the design and function of the room as well as specific training for the operator and theatre team. This can have an impact on the set-up and flexibility of the service.
- RFA may be associated with a marginal reduction in pain and bruising, although this has not been shown to impact on periprocedural quality of life or recovery.

Advantages in favour of EVLA over RFA include:

- When it comes to veins that are very large in diameter (>15 mm) EVLA can be a better option, allowing an increase in energy delivery and higher efficacy rates.
- EVLA consumables are typically much less expensive; however, costs vary by device and market and the price difference has reduced over time.
- A standard EVLA fibre may be used to treat perforators, whereas a specific additional device is typically required for RFA, increasing costs. The clinical utility and indications for perforator management remain uncertain.

As endothermal ablation treats only junctional and truncal incompetence, debate exists regarding the management of varicosities. These can be managed concomitantly or sequentially by either phlebectomy or sclerotherapy. Concomitant phlebectomy (***Figure 62.19***) results in a more rapid improvement in disease-specific quality of life, and allows the vast majority of patients to complete treatment in a single visit.

Non-endothermal, non-tumescent ablation

Endothermal ablation was a large step forwards in the management of superficial incompetence; however, all techniques require the injection of tumescent local anaesthetic solution and this can be uncomfortable for the patient. Other techniques that avoid injection are being developed.

Ultrasound-guided foam sclerotherapy

Sclerotherapy is the original non-endothermal, non-tumescent technique and has been performed for over 100 years. It involves the injection of a sclerosing agent directly into the superficial veins. The most commonly used is sodium tetradecyl sulphate. The direct contact with detergent causes cellular death and initiates an inflammatory response, aiming to result in thrombosis, fibrosis and obliteration (sclerosis). Blood deactivates the action of the sclerosing agent and the doses administered need to be limited to avoid adverse effects, causing a trade-off between poor efficacy and safety. This led to the development of ultrasound-guided foam sclerotherapy (UGFS). The use of foam increases the effective volume of the agent, maximising endothelial contact and displacing any blood that deactivates it.

The procedure commences with the patient standing, and the sites of venous cannulation are selected and marked using ultrasound. With the patient supine, the major venous trunks and superficial varicosities to be treated are then all cannulated using ultrasound guidance prior to any injection (***Figure 62.20***). Once all injection sites are cannulated the foam can be prepared. The most widely used method is that of Tessari; this utilises two syringes connected using a three-way

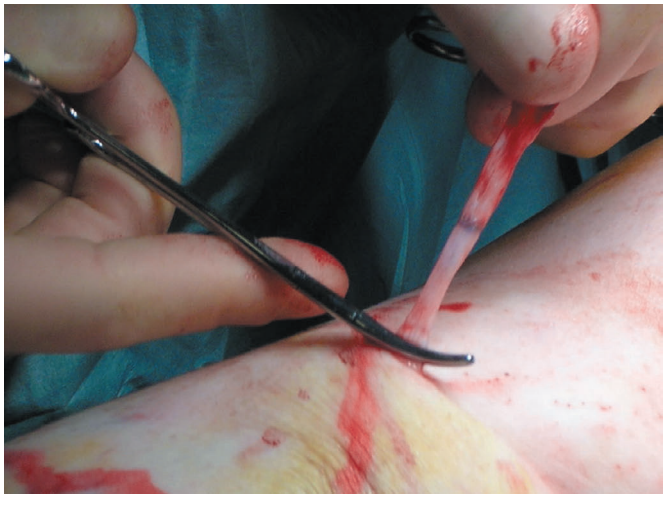

Figure 62.19 Phlebectomy performed under tumescent anaesthesia following endothermal ablation.

Figure 62.20 Foam sclerotherapy; cannulation of veins during ultrasound-guided foam sclerotherapy.

Lorenzo Tessari, b. 1949, physician, Trieste, Italy.

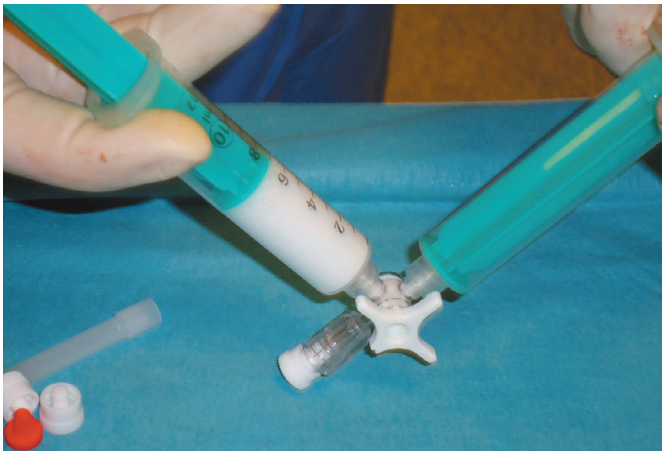

Figure 62.21 Foam sclerotherapy; Tessari method of foam sclerosant preparation.

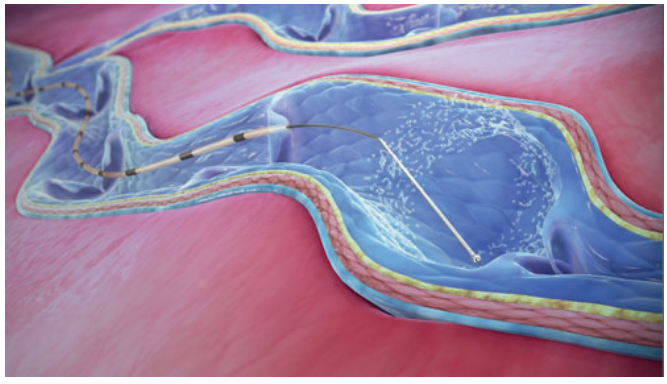

Figure 62.22 Mechanochemical ablation device (reproduced with permission from Vascular Insights).

tap. A 1:3 or 1:4 ratio mixture of sclerosant and air is drawn into one syringe, and is then oscillated vigorously between the two syringes about 10 or 20 times (***Figure 62.21***). The foam produced in this way is stable for about 2 minutes so it should be injected as soon as it has been made. The leg is then elevated to empty the veins of blood, and injection of foam commences first with superficial varicosities and ends with injection of the GSV or SSV. Only 1–2 mL of foam should be injected at a time and the distribution of the foam should be monitored and massaged with the ultrasound probe. When the foam is visualised at the site of junctional incompetence no further foam should be injected. The maximum volume of foam that should be injected at a single session should not exceed 10–12 mL as the incidence of complications is directly related to the volume of foam injected. Compression is then applied as following endothermal ablation. While it is postulated that compression may have a larger effect upon efficacy for this treatment, practice is not informed by evidence and a wide variation exists.

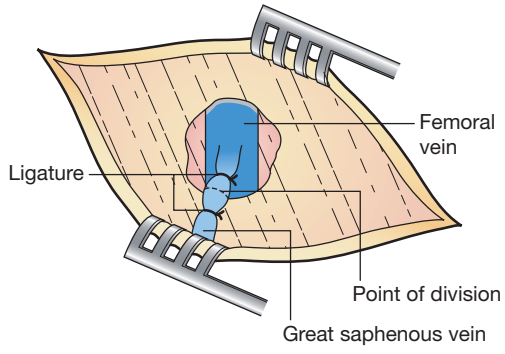
Outside of a small number of centres, the efficacy of UGFS is significantly worse than for endothermal ablation, leading to high reintervention rates, and the rates of complications such as phlebitis and pigmentation can be high. UGFS does however carry some significant advantages:

- It avoids tumescent anaesthetic and is therefore a less painful procedure (although postoperative pain is probably similar).
- No axial or tributary veins are too tortuous.
- It also allows the treatment of calf veins with overlying skin damage or ulceration without the need to pierce through damaged skin.
- Consumable treatment costs are very low.

These factors mean that many surgeons using endothermal techniques also use foam sclerotherapy as an adjunct in specific circumstances.

Catheter-directed sclerotherapy and mechanochemical ablation

The efficacy of sclerotherapy relies on endothelial contact with fresh, undiluted sclerosant. Some have therefore experimented with catheter-delivered sclerotherapy rather than trying to milk the sclerosant down the vein lumen. There is no good evidence to date that this increases efficacy and the technique is not in widespread use.



A related technology that has shown more promise is mechanochemical ablation (***Figure 62.22***). This involves a treatment device that deploys an angled wire from the end. This attaches to a motorised handle. The catheter is placed within the vein lumen as for endothermal ablation. The trigger on the handle is depressed, spinning the wire around and liquid sclerosant is infiltrated via the catheter simultaneously during catheter withdrawal. It is thought that the spinning wire causes physical damage to the endothelium and allows a deeper penetration of the sclerosant into the vein wall. The technique is possible in most cases without tumescent anaesthesia, although a small number of patients find the procedure uncomfortable and the device can 'snag' on the vein, tearing it or rarely stripping it altogether. Comparative studies with endothermal ablation suggest similar early efficacy rates but increased medium-/long-term recanalisation rates. The axial ablation is usually less painful than endothermal ablation, but this advantage is lost when it is combined with phlebectomy of the tributaries; therefore, it is uncertain whether it can replace endothermal ablation, unless axial ablation is to be performed in isolation. Treating longer veins can also be challenging owing to limitations in catheter length and the safe dose of sclerosant. It is a good choice for a patient with needle phobia who is happy to forgo treatment of varicose tributaries.

Endovenous glue

The final non-tumescent technique is the endoluminal application of cyanoacrylate adhesive (***Figure 62.23***). Again, this involves a treatment catheter placed within the vein lumen. A handle is used to infiltrate the adhesive in 0.1-mL applications via the catheter. The vein is then compressed, sealing the lumen closed. Early efficacy results are similarly promising and patients experience minimal intraprocedural pain. Long-term results and the optimal management of tributaries are unknown (similar to mechanochemical ablation). The consumable costs are currently the highest for any venous ablative technique.

Figure 62.23 Endovenous glue device (reproduced with permission from Medtronic Inc.).

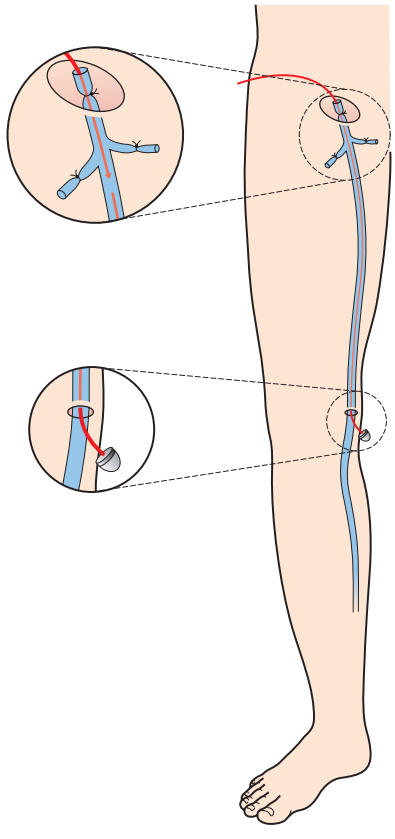


Figure 62.24 Saphenofemoral junction ligation and great saphenous vein stripping.

Open surgery

The principles of traditional ligation and stripping are to fully dissect the point of junctional incompetence and to remove the refluxing axial vein and dilated tributaries. The operation is usually performed under general anaesthesia but locoregional anaesthesia is used by some; the infiltration of tumescent local anaesthesia around the axial vein prior to stripping may have some advantages, but is not widely used.

The role of open surgery as a primary treatment of a refluxing superficial axis has been considerably reduced with the development of the minimally invasive techniques described above, the long-term results of which are at least comparable to open surgery but with significantly less morbidity and faster recovery. Experienced endovenous surgeons do still use open surgery in some circumstances and a venous surgeon needs to be trained and experienced in this area.

Surgical adjuncts including phlebectomy and, occasionally, perforator ligation are much more commonly used, and the former has been shown to have a significant impact upon outcome.

Saphenofemoral ligation and great saphenous stripping

An oblique groin incision is made at the level of, and lateral to, the pubic tubercle, ideally above the groin crease. The GSV is identified and dissected to the SFJ, which should be clearly established before the vein is divided to avoid disastrous inadvertent transection of the superficial femoral vein. The anatomy is often variable but six GSV tributaries may be encountered close to the SFJ:

- Laterally:
  - superficial inferior epigastric vein;
  - superficial circumflex iliac vein.
- Medially:
  - superficial external pudendal vein;
  - deep external pudendal vein.
- Distally:
  - anterior accessory of the great saphenous vein;
  - posteromedial thigh vein.

Classically, these are ligated distal to their divisions. A flush SFJ ligation is then performed and the GSV retrogradely stripped to around the knee (***Figure 62.24***). Phlebectomy is performed as discussed above.

Closure of the cribriform fascia, with sutures or synthetic patches over the ligated SFJ, does not reduce groin recurrence. Stripping to the lowest point of reflux may improve results, but at a cost of increased saphenous nerve complications and is not widely performed. More recently, some surgeons have argued that surgical trauma and subsequent inflammation in the groin are associated with neovascularisation, which in turn may lead to recurrence. Furthermore, others hypothesise that it is the loss of the normal groin tributaries that may be responsible for driving the process of neovascularisation. These concepts have led some to believe that ligation of the refluxing vein should be distal to the tributaries and that the junction itself should be left untouched. There is no clear clinical evidence to support these hypotheses.

Figure 62.25 Preoperative marking of the saphenopopliteal junction and small saphenous vein mapped using duplex scanning.

Saphenopopliteal junction ligation and small saphenous stripping

Preoperative duplex to mark the position of the SPJ is highly recommended (*Figure 62.25*). The patient is positioned in the prone position, a transverse incision is made over the premarked SPJ, the fascia is divided and the SSV is exposed. The SPJ can then be formally dissected with a flush ligation or the SSV can be gently retracted and ligated as proximally as possible. No good evidence exists to favour one technique over the other; proponents of the flush ligation would argue that it avoids leaving a stump of SSV, a common source of recurrence, while proponents of the simple SSV ligation technique argue that it reduces the incidence of the most common serious complications – nerve injury and popliteal vein injury.

The SSV can then either be stripped or the proximal section of the vein can be resected. Those who strip argue that it reduces the incidence of recurrence, while opponents feel it increases the incidence of sural nerve injury. There are no randomised trials comparing these techniques. Once again, phlebectomy is then performed.

Adjunctive surgical techniques

Phlebectomy

This may be performed following treatment of junctional incompetence and axial vein reflux, or as a sole treatment under local anaesthetic in patients with isolated tributary incompetence, or possibly in very early axial reflux, which reverts to normal upon occlusion of the refluxing tributary on duplex ultrasound. Phlebectomy is usually performed through small stab incisions using small mosquito forceps and/or phlebectomy hooks that have been demonstrated to be superior – in terms of bruising, pain and generic quality of life – to transilluminated-powered phlebectomy (*Figure 62.19*).

Perforator ligation

The majority of studies assessing the role of perforator ligation have been in patients with venous ulcers, analysing the effects on ulcer healing; even in this situation randomised data are lacking. The role of perforator ligation in patients with uncomplicated varicose veins is even less clear. In uncomplicated varicose veins perforators may be ligated through a small, duplex-guided incision, while in patients with skin changes subfascial endoscopic perforator ligation may be preferred, although the benefits are unproven. Perforators can also be ablated with endovenous techniques.

Complications of standard varicose vein surgery

Complications (minor and major) are reported in up to 20% of patients who undergo traditional varicose vein surgery. Wound infections, the most common complication, are reduced by prophylactic antibiotics. Nerve injury is the most common serious complication. The incidence of saphenous nerve neuralgia is up to 7% following GSV stripping to the knee (the incidence is higher with stripping to the ankle). The incidence of sural nerve neuropraxia and common peroneal nerve injury may be as high as 20% and 4%, respectively, following SSV surgery. The incidence of venous thromboembolic complications is approximately 0.5% following varicose vein surgery; however, patient risk factors must be individually assessed and appropriate prophylaxis administered according to guidelines.

Recurrent varicose veins

Approximately 10–20% of patients who present to hospital with varicose veins have had previous intervention. Prospective data on long-term results following intervention for recurrent varicose veins are sparse and the criteria for defining recurrence are variable.

Significant clinical recurrence 5–10 years following varicose vein surgery occurs in 10–35% of patients, but minor/duplex-detected recurrence is much more common, being of the order of 70%. Causes of recurrence include: neovascularisation, reflux in the residual axial vein, inadequate initial surgery and new junctional reflux. Neovascularisation is the development of new veins within postsurgical tissue. These veins lack valves and over time can span the tissue between a ligated junction and nearby tributary veins. If significant in size and/or number, these may contribute to recurrent venous hypertension.

Recurrence is more common following SSV surgery than following GSV surgery, and in patients with high body mass index, while stripping of the incompetent axial vein reduces recurrence rates. Limited data suggest that recurrence rates following endovenous thermal ablation may be lower than

following surgery. Recurrent varicose veins often have an atypical distribution and duplex assessment is mandatory (***Figures 62.26 and 62.27***). Open surgery for recurrent varicose veins is associated with a high (40%) complication rate, the most common being lymph leak and wound infection, thus endovenous interventions would seem to offer an attractive alternative, where feasible.

Summary box 62.1

Varicose veins

- Are one of the most common conditions causing a physical impairment in quality of life
- Interventional treatment improves quality of life and is highly cost-effective
- Anatomical and physiological assessment using duplex ultrasound is invaluable in the diagnosis and planning of treatment
- Ultrasound-guided endovenous ablation has revolutionised treatment, minimising procedural morbidity while being highly effective

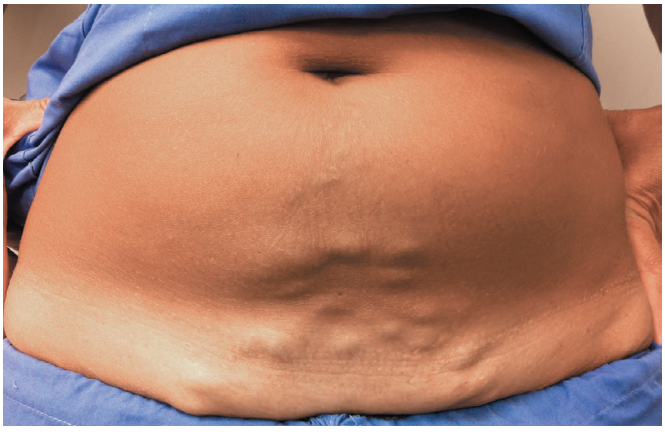

Figure 62.26 Recurrent anterior abdominal wall varicose veins following saphenofemoral junction ligation complicated by iliac deep vein thrombosis.

VENOUS LEG ULCER

Venous disease is responsible for around 85% of all chronic lower limb ulcers in resource-rich countries. Community-based prevalence is 0.1–0.3% in adults (2–4% in the elderly). Venous leg ulcer has a disproportionate cost to society, with profound impairment in health-related quality of life for both patients and their carers; the dressings alone account for 1–3% of western healthcare expenditure. Furthermore, 15–30% of patients with 'venous' leg ulcers have concomitant arterial occlusive disease. This is termed a 'mixed' ulcer. There are many other causes of leg ulcers and these must be excluded in any patient presenting with ulceration. Causes of leg ulceration include:

- venous disease: superficial incompetence, deep incompetence or obstruction;
- arterial ischaemic ulcers;
- vasculitic ulcers;

Figure 62.27 Recurrent varicose veins secondary to an incompetent thigh perforator.

- traumatic ulcers;
- neuropathic ulcers;
- neoplastic ulcers;
- infections, especially in low and middle income countries.

Pathophysiology of ulceration

The exact pathophysiology of ulcer development has not been established. Originally, it was thought that static blood within the superficial veins led to hypoxia, which caused tissue death (stasis ulcers). This was not confirmed by investigation of venous oxygen saturation, which was found to be higher in ulcerated limbs. This led to the concept of arteriovenous fistulae, which were thought to develop in response to the high venous pressure; however, this could not be confirmed. High venous pressure was found to be associated with a pericapillary infiltrate. This includes fibrin and other proteins, which are known to lead to fibrosis. It was hypothesised that these 'cuffs' could act as an impediment to diffusion of oxygen and nutrients.

Leukocytes were found to be reduced in the blood returning from legs with venous hypertension. This decrease in leukocyte passage was shown to increase if short-term venous hypertension was induced by application of a tourniquet. This led to the concept of white cell 'trapping', which, however, has not been confirmed by further investigation. Polymorphonuclear leukocytes were not found within the tissues, but increased numbers of mast cells, monocytes and lymphocytes have been found in periulcer tissues.

Reactive oxygen species are increased in the ulcer environment and these may generate free radicals, leading to tissue

damage. Proteolytic enzymes are also increased in ulcers and the fibroblasts in the ulcer surrounds are also abnormal, being in a 'senescent' state. Growth factors may be inhibited, leading to poor repair, and their absence may also lead to ulceration. It is debated whether these factors are the cause or effect of an ulcer.

At present, ambulatory venous hypertension is the only accepted underlying cause of venous ulceration. This also explains why venous ulcers are never seen in the upper limb. It is important to try to define the exact mechanism of ulcer development. Venous hypertension may be the result of primary valve incompetence of the saphenous veins, incompetence of the perforating veins or incompetence or obstruction of the deep veins.

Clinical features

The ulcer must be carefully examined. A venous ulcer usually has a gently sloping edge and the floor contains granulation tissue covered by a variable amount of slough and exudate. Any significant elevation of the ulcer edge should indicate the need for a biopsy to exclude a carcinoma (usually a squamous cell).

Venous leg ulcers characteristically develop in the skin of the gaiter region, the area between the muscles of the calf and the ankle. This is the region where many of the Cockett perforators join the posterior tibial vein to the surface vein, known as the posterior arch vein. The majority of ulcers develop on the medial side of the calf, but may develop anywhere in the gaiter area. Extension onto the foot or into the upper calf is uncommon and, if there is ulceration at these sites, other diagnoses should be seriously considered. Ulcers often develop in response to minor trauma; many patients notice some itching, perhaps associated with mast cell degranulation, before the ulcers develop. Almost all venous ulcers have surrounding haemosiderosis (seen as pigmentation) and the more chronic ulcers develop LDS with associated fibrosis of the subcutaneous tissue (***Figure 62.10***). This is manifest as thickening, pigmentation, inflammation and induration of the calf skin. The pigmentation comes from haemosiderin and melanin and the haemosiderin itself may be an important factor in ulcer development.

A full examination of the front and back of the limbs with the patient standing should be carried out to assess the presence of varicosities and truncal incompetence of the saphenous systems (note that venous ulcers are not always accompanied by varicose veins). All patients should have their pulses palpated and, if there is any doubt, their arterial Doppler pressures should be measured. Sensation and proprioception should be assessed to exclude neuropathy, especially in patients with diabetes. A careful examination of the hand and other joints may confirm the presence of rheumatoid arthritis or osteoarthritis.

Investigation

Most vascular surgeons will carry out a duplex scan when the patient with an ulcer is first seen to assess the status of the deep and superficial veins. The presence of reflux in these veins does not confirm a venous ulcer, but supports the diagnosis in the absence of another cause and helps direct treatment.

Venous ulcers are characteristically difficult to heal; however, persistence may indicate that there is another or coexisting cause (e.g. malignancy, rheumatoid arthritis or arterial ischaemia). Biopsies are indicated if malignancy is suspected and it is important to remember that a Marjolin's type of ulcer (a squamous cell or basal cell carcinoma) can develop in a chronic longstanding venous ulcer (***Figure 62.28***).

Patients with atypical or with ulcers not responding to treatment should have a full blood count, blood glucose, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) assessment as well as a sickle cell test if they have an appropriate ethnic background. Anaemia can both cause ulcers (e.g. sickle cell disease and pernicious anaemia) and be a result of ulceration (e.g. iron deficiency anaemia and the anaemia of chronic disease). Polycythaemia is a rare cause of ulceration. An antibody screen should be obtained if the ulcer appears 'atypical' or if there is any suggestion of joint disease (e.g. rheumatoid arthritis). All patients presenting with a new ulcer should have their Doppler pressures measured unless the foot pulses are easily palpable and have been confirmed as such by a vascular specialist.

Management

The very best results are seen in specialist multidisciplinary ulcer services. The cause of a venous leg ulcer is venous hypertension and the keystone of management is to decrease this hypertension using venous ablation and compression therapy.

Figure 62.28 A Marjolin's ulcer (a squamous cell cancer arising in a chronic venous ulcer).

Frank Bernard Cockett, 1916–2014, surgeon, St Thomas's Hospital, London, UK.
Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of malignant ulcers in scars in 1828.

Superficial venous ablation or surgery

In patients with venous leg ulcers, treatment of superficial venous incompetence has been demonstrated to accelerate healing and reduce recurrence; therefore, expeditious referral to a vascular service for assessment is recommended.

Compression

The most clinical and cost-effective compression regimes are two-layer compression hosiery or four-layer compression bandaging. The latter includes:

- Orthopaedic wool: distributes the pressure and reduces undue pressure on sensitive areas susceptible to pressure damage. Also helps to absorb excess exudate that escapes the primary dressing.
- Cotton crepe: smooths the wool and holds it in place.
- Elastic bandage: first compressive layer, contributes about one-third of the interface pressure.
- Cohesive bandage: second compressive layer, increases stiffness and adds approximately two-thirds of the interface pressure.

The ideal interface pressure in pure venous ulceration is 35–40 mmHg. Skilled application of these dressings is essential for both safety and efficacy, and the best results come from specialist nursing teams based either in secondary care or in the community.

Compression in mixed ulcers is controversial, but emerging evidence suggests that it is both safe and effective when performed and monitored appropriately. With an ankle–brachial pressure index (ABPI) of 0.5–0.8 modified compression with an interface pressure of 30 mmHg is safe and effective and pressures of up to 40 mmHg have been described in studies using inelastic bandages without ill effect. Contrary to conventional thinking, studies have shown an increase in perfusion in patients treated in this way, presumably by a reduction in capillary back pressure. Patients do see respectable healing rates in this group, but they remain lower than in those patients with an ABPI >0.8. It is not clear whether revascularisation followed by full compression yields better results, but this is common practice. Patients with an ABPI <0.5 or an ankle pressure <60 mmHg must undergo revascularisation prior to any compression treatment.

Other treatments

Pentoxifylline, which increases microvascular perfusion by decreasing plasma cellular viscosity and cytokine inhibition, has been demonstrated to be a useful adjunct to compression by augmenting ulcer healing.

Horse chestnut seed extract has been shown to be a safe and efficacious treatment for chronic venous hypertension, improving symptoms and reducing leg volume.

A number of biological dressings have been developed, including fetal keratinocytes and collagen meshes, which have been shown to improve healing; however, they are not cost-effective for the majority of ulcers. Pinch grafts and ulcer excision with mesh grafting have been shown to provide good early healing with moderate long-term results (50% healed at 5 years).

Antibiotics do not speed ulcer healing in the absence of cellulitis and all other specific ulcer-healing drugs are of dubious validity. A large range of topical therapies and primary dressings have similarly failed to have an impact.

Prevention of recurrence

Once an ulcer has healed the patient must be re-evaluated in an attempt to prevent recurrence. If not already performed, patients should undergo treatment for their superficial venous incompetence. Class 2 below-knee graduated compression stockings should be prescribed for all patients with residual reflux or deep venous occlusion, or those with recurrent ulceration despite not being in this group. These should be worn for life.

Prognosis

Nearly all venous ulcers can be healed, but, even in those who have successful ablation or wear their stockings religiously, there is a 20–30% incidence of reulceration by 5 years. The greatest risk of reulceration is in the post-thrombotic leg.

Summary box 62.2

Venous leg ulcer

- Is associated with a profound impairment in quality of life
- Ulcers are not infrequently difficult to heal and prone to recurrence
- The treatment of these chronic wounds is associated with high costs to healthcare systems and patients
- The mainstay of treatment is the reduction in venous hypertension, with ablation of superficial venous incompetence and compression
- Early endovenous ablation of superficial reflux almost halves the time to healing of venous leg ulcers, reduces ulcer recurrence rates and is cost-effective

PELVIC CONGESTION SYNDROME

Pelvic congestion syndrome (PCS) is among the differential diagnoses to be considered in female patients presenting with chronic pelvic pain and may be significantly underdiagnosed. PCS sufferers are typically premenopausal, multiparous women aged 20–45 years, who present with severe dull aching pelvic pain thought to be the direct result of ovarian and pelvic varicosities. The pain is usually non-cyclical, and may be precipitated by prolonged standing. Other symptoms include dysmenorrhoea, menorrhagia, rectal discomfort or urinary frequency. Signs may include tenderness over the uterus/ovaries, vulval varicosities and haemorrhoids. There may be vulval and atypically distributed thigh varicosities. The road to a diagnosis of PCS is often a long and laborious one, usually only made following extensive investigations to exclude other more common causes of pelvic pain. Abdominal, pelvic and transvaginal duplex examination allows dynamic visualisation of pelvic blood flow and should be the initial investigation of choice, as these are rapid, readily accessible outpatient procedures that are also valuable in excluding

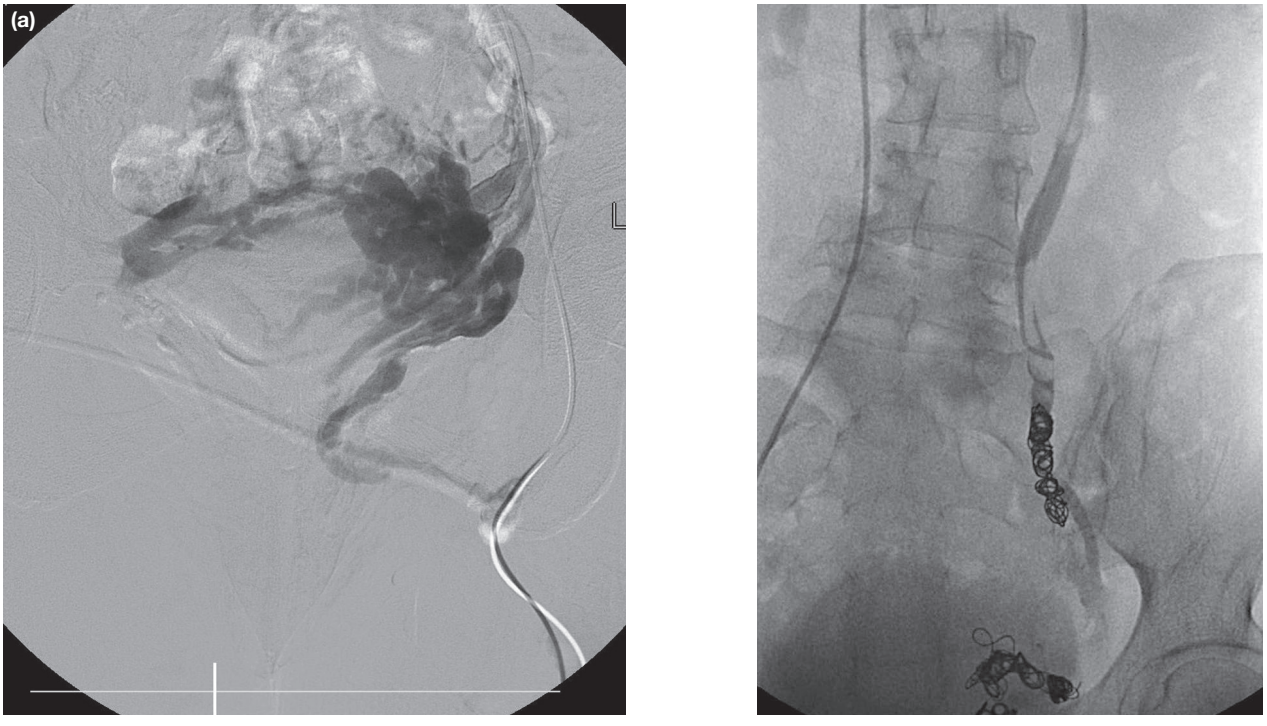

Figure 62.29 (a, b) Left ovarian vein incompetence supplying the pelvic and pudendal varicosities: **(a)** diagnostic venogram; **(b)** therapeutic embolisation.

other pathologies. Alternatives include MR venography and diagnostic venography.

Medical treatments for PCS include psychotherapy, progestins, danazol, gonadotropin receptor agonists (GnRH) with hormone replacement therapy, and non-steroidal anti-inflammatory drugs (NSAIDs). Historical open surgical procedures (extraperitoneal resection of ovarian veins) have now largely been superseded by percutaneous pelvic vein embolisation (***Figure 62.29***), reducing peri- and post-procedural morbidity while maintaining high success rates.

VENOUS THROMBOEMBOLISM

Venous thromboembolism (VTE) is an important condition within surgery, and autopsy studies suggest that it is the most common direct cause of death in surgical patients. Venous thrombosis is the formation of a semisolid coagulum within the venous system and may occur in the superficial system (superficial vein thrombosis [SVT] or 'thrombophlebitis') or the deep system (deep vein thrombosis [DVT]). Venous thrombosis of the deep veins of the leg may be complicated by the immediate risk of pulmonary embolus and sudden death. Subsequently, patients are at risk of developing PTS (***Figure 62.30***) and venous ulceration. While DVT may occur in the upper limb, it is the leg that gives rise to the vast majority of the morbidity and subsequent complications of this condition.

Aetiology

The three factors described by Virchow over a century ago are still relevant in the development of venous thrombosis. These are:

- contact of blood with an abnormal surface (e.g. endothelial damage);
- abnormal flow (e.g. stasis);
- abnormal blood (e.g. thrombophilia).

There are many predisposing causes for VTE. These are listed in ***Table 62.2***. The most important factor is a hospital admission for treatment of a medical or surgical condition. Injury, especially fractures of the lower limb and pelvis, pregnancy and the oral contraceptive pill are other well-recognised predisposing factors. Endothelial damage is now known to be critically important. The interaction of the endothelium with inflammatory cells, or previous deep vein damage, renders the endothelial surface hypercoagulable and less fibrinolytic. Stasis is a predisposing factor seen in many of the conditions described in ***Table 62.2***, especially in the postoperative period, in patients with heart failure and in those with arterial ischaemia.

Figure 62.30 Post-thrombotic leg demonstrating features of eczema, pigmentation and mild lipodermatosclerosis.

TABLE 62.2 Risk factors for venous thromboembolism.

Patient factors
• Age
• Obesity
• Varicose veins
• Immobility
• Pregnancy
• Puerperium
• High-dose oestrogen therapy
• Previous deep vein thrombosis or pulmonary embolism
• Thrombophilia (see *Table 62.3*)
Disease or surgical procedure
• Trauma or surgery, especially of pelvis, hip and lower limb
• Malignancy, especially pelvic, and abdominal metastatic
• Heart failure
• Recent myocardial infarction
• Paralysis of lower limb(s)
• Infection
• Inflammatory bowel disease
• Nephrotic syndrome
• Polycythaemia
• Paraproteinaemia
• Paroxysmal nocturnal haemoglobinuria antibody or lupus anticoagulant
• Behçet's disease
• Homocystinaemia

A number of conditions are associated with increased coagulability of the blood (thrombophilia) (*Table 62.3*). Deficiencies of antithrombin, activated protein C and protein S have all been shown to predispose to venous thrombosis in young patients. Activated protein C deficiency is associated with inheritance of the factor V Leiden gene and may account for the higher incidence of venous thrombosis in white populations (being present in 6–7%). It results in a small increase in the risk of VTE, although it may act in concert with some of the other predisposing factors. A thrombophilia should be excluded in any patient presenting with an episode of VTE who gives a family history of VTE or in whom there is no other predisposing factor.

Although the development of DVT is probably multifactorial, immobility (and hence stasis) remains one of the most important factors. DVT is recognised as a complication of long-haul flights and other forms of travel.

Pathology

The thrombus commences as a platelet aggregate. Subsequently, fibrin and red cells form a mesh until the lumen of the vein wall occludes. The coralline thrombus then progresses as a propagated loose red fibrin clot containing many red cells (*Figure 62.31*). This is likely to extend up to the next large venous branch and it is possible for the clot to break off and embolise to the lung as a pulmonary embolus. In this situation the embolus arising from the lower leg veins becomes detached, passes through the large veins of the limb and vena cava, through the right heart and lodges in the pulmonary arteries. This may totally occlude perfusion to all or part of one or both lungs. This results in a clinical spectrum from tachycardia and pain, through respiratory failure (despite adequate ventilation) to cardiovascular collapse and death. Moderate-sized emboli can cause pyramidal-shaped infarcts on imaging.

TABLE 62.3 Abnormalities of thrombosis and fibrinolysis (thrombophilia) that lead to an increased risk of venous thrombosis.

Congenital
• Deficiency of antithrombin III, protein C or protein S
• Antiphospholipid antibody or lupus anticoagulant
• Factor V Leiden gene defect or activated protein C resistance
• Dysfibrinogenaemias
Acquired
• Antiphospholipid antibody or lupus anticoagulant

Diagnosis

The most common presentation of a DVT is pain and swelling, especially in the calf, usually in one leg; however, bilateral DVTs are common, occurring in up to 30%. When the swelling

Figure 62.31 An organised thrombus.

Hulusi Behçet, 1889–1948, Turkish dermatologist, described a disease of inflamed blood vessels in 1937.

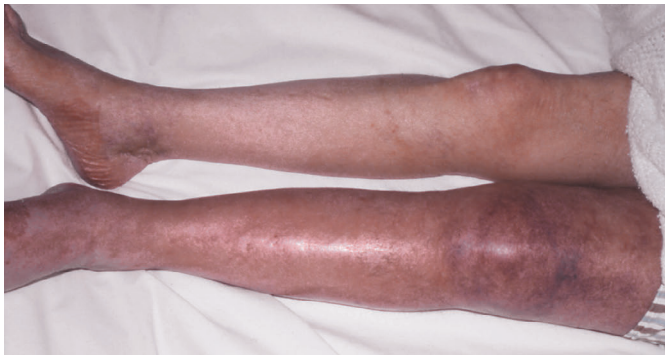

Figure 62.32 Phlegmasia cerulea dolens.

Figure 62.33 A foot with venous gangrene. The gangrene is symmetrical, involving all of the toes. There is no clear-cut edge and there is marked oedema of the foot.

is bilateral, DVT must be differentiated from other causes of systemic oedema, such as hypoproteinaemia, renal failure and heart failure. Some patients have no symptoms of thrombosis and may first present with signs of a pulmonary embolus, e.g. pleuritic chest pain, haemoptysis and shortness of breath. Patients may also develop shortness of breath from chronic pulmonary hypertension. Sometimes the leg appears cellulitic and very occasionally it may be white or cyanosed: phlegmasia alba dolens and phlegmasia cerulea dolens (*Figure 62.32*). This indicates venous pressures that are so high they are impeding tissue perfusion. Patients who present with venous gangrene (*Figure 62.33*) often have an underlying neoplasm.

Clinical examination for DVT is unreliable. Physical signs may also be absent. Mild pitting oedema of the ankle, dilated surface veins, a stiff calf and tenderness over the course of the deep veins should be sought. Leg pain occurs in about 50% of patients with DVT but is non-specific. Homans' sign – resistance (not pain) of the calf muscles to forcible dorsiflexion – is not specific and should not be elicited. Tenderness occurs in 75% of patients but is also found in 50% of patients without objectively confirmed DVT. The pain and tenderness associated with DVT does not usually correlate with the size, location or extent of the thrombus. Clinical signs and symptoms of pulmonary embolus occur in about 10% of patients with confirmed DVT.

A low-grade pyrexia may be present, especially in a patient who is having repeated pulmonary embolus. Patients may have signs of cyanosis, dyspnoea, raised neck veins, a fixed split second heart sound and a pleural rub if they have pulmonary emboli causing right heart strain, although these signs may be subtle or absent.

Investigation

The diagnosis of DVT and pulmonary embolus should be established by special investigations as the symptoms and signs are non-specific and may be absent. In addition, treatment with anticoagulation is not without risk and the diagnosis must be made with reasonable certainty.

Many centres direct investigations based upon the modified Wells score (*Table 62.4*), with further imaging dictated by these results. These scores can be unreliable though, especially in hospital inpatients, and should only be considered a guide.

Venous duplex ultrasound is commonly performed to look for evidence of thrombosis throughout the deep or superficial venous system. Ideally, this should be performed by an experienced vascular sonographer, but the volume of cases is such that compression ultrasound is frequently being performed by non-specialists. Compression ultrasound involves applying pressure with the ultrasound probe over the common femoral

TABLE 62.4 Modified Wells criteria for predicting deep vein thrombosis (DVT).

Variable	Score
Lower limb trauma or surgery or immobilisation in a plaster cast	1
Bedridden for >3 days or surgery in last 4 weeks	1
Tenderness along the line of femoral or popliteal veins	1
Entire limb swollen	1
Calf >3 cm larger circumference than other side 10 cm below tibial tuberosity	1
Pitting oedema	1
Dilated collateral superficial veins (not varicose veins)	1

Philip Wells, contemporary, physician, University of Ottawa, Ottawa, ON, Canada.

and popliteal veins. Under normal circumstances these veins will compress tightly shut. In the presence of DVT they will not fully compress. It is rapid to both learn and perform, but not ideal and most importantly misses calf vein thrombosis. Calf vein thromboses may propagate to form a more extensive thrombus, which may in turn embolise. The optimal management of calf vein thrombosis when detected is not clear; some units use surveillance, with others anticoagulating such patients upon detection.

Ascending venography, which shows a thrombus as a filling defect, is now rarely required unless thrombolysis is being considered (***Figure 62.34***). MR venography may also be used. Pulmonary embolus is diagnosed definitively by computed tomography (CT) pulmonary angiogram, which will demonstrate the presence of filling defects in the pulmonary arteries (***Figure 62.35***). Pulmonary angiography is rarely required unless thrombolysis is being considered.

The differential diagnosis of a DVT includes a ruptured Baker's cyst, a calf muscle haematoma, a ruptured plantaris muscle, a thrombosed popliteal aneurysm and arterial ischaemia. Duplex scanning will detect many of these conditions but often patients present with non-specific pain in the calf that resolves with no firm diagnosis being made. The differential diagnosis of a pulmonary embolism includes myocardial infarction, pleurisy, pneumonia and aortic dissection.

Prophylaxis

Prophylactic methods can be divided into mechanical and pharmacological. A variety of mechanical methods have been tried, but only the use of graduated elastic compression stockings and external pneumatic compression have been shown to be worthwhile by reducing the incidence of thrombosis. Newer devices, such as electronic nerve stimulators, lack evidence of efficacy to date. More recent emerging evidence is casting some doubt on the benefit of mechanical prophylaxis in surgical patients and there are further studies underway. Compression-based prophylactic measures should be avoided in patients with peripheral vascular disease.

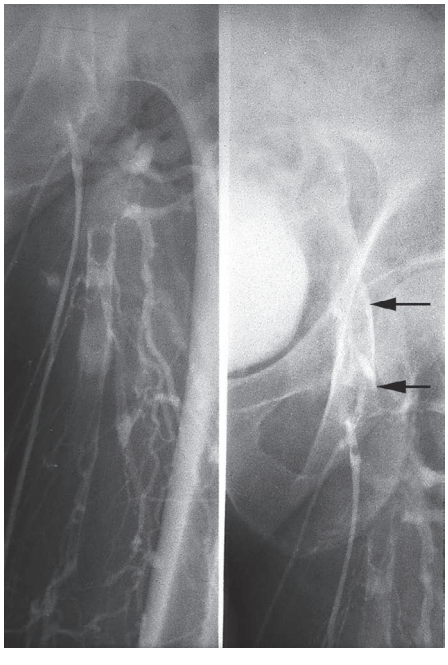

Figure 62.34 An ascending venogram of a deep vein thrombosis seen as filling defects (arrows) with contrast passing around the thrombus.

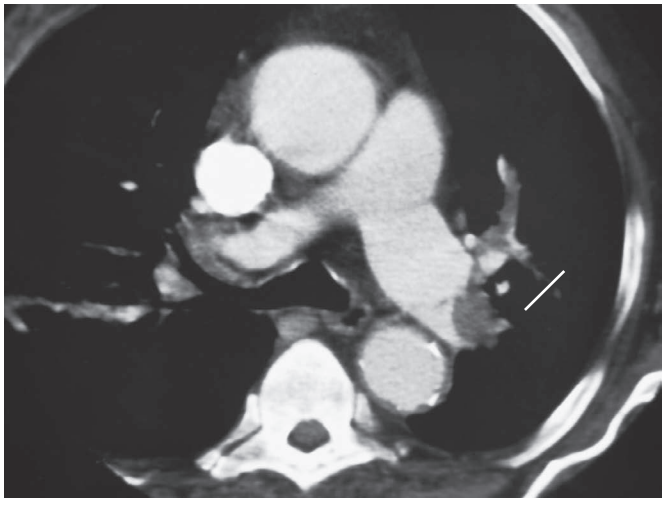

Figure 62.35 A computed tomography pulmonary angiogram showing pulmonary emboli as filling defects (arrow) in the pulmonary artery.

Pharmacological methods are more effective than mechanical methods at risk reduction, although they carry an increased risk of bleeding. In the past, low-dose unfractionated heparin was used both intravenously and subcutaneously. In the absence of renal impairment, most centres currently use low-molecular-weight heparin (LMWH) given subcutaneously. This is given once daily, does not require monitoring and has a lower risk of bleeding complications.

Patients who are being admitted for surgery may be graded as low, moderate or high risk for pulmonary embolism and VTE (***Tables 62.5 and 62.6***). Patients in the medium- or high-risk groups should be considered for pharmacological

TABLE 62.5 Modified Wells criteria for predicting pulmonary embolism (PE).

Variable	Score
Clinical signs and symptoms of DVT (minimum of leg swelling and pain on palpation of deep veins)	3
Alternative diagnosis less likely than PE	3
Heart rate >100 bpm	1.5
Immobilisation >3 days or surgery within past 4 weeks	1.5
Previous DVT or PE	1.5
Haemoptysis	1
Malignancy (treatment or palliation within past 6 months)	1

A score of <4 means PE is unlikely (12.4%); >4 is suggestive of PE (37.1%).

bpm, beats per minute; DVT, deep vein thrombosis.

William Morrant Baker, 1839–1896, surgeon, St Bartholomew's Hospital, London, UK, described these cysts in 1877.

TABLE 62.6 Low-, medium- and high-risk patient groups for venous thromboembolism.

Low
• Minor surgery <30 minutes; any age; no risk factors
• Major surgery >30 minutes; age <40; no other risk factors
• Minor trauma or medical illness
Medium
• Major surgery; age 40+ or other risk factors
• Major medical illness: heart/lung disease, cancer, inflammatory bowel disease
• Major trauma/burns
• Minor surgery, trauma, medical illness in patient with previous DVT, PE or thrombophilia
High
• Major orthopaedic surgery or fracture of pelvis, hip, lower limb. Major abdominal/pelvic surgery for cancer
• Major surgery, trauma, medical illness in patient with DVT, PE or thrombophilia
• Lower limb paralysis (e.g. stroke, paraplegia)
• Major lower limb amputation

DVT, deep vein thrombosis; PE, pulmonary embolus.

prophylaxis with an anticoagulant medication. Recent level 1 evidence suggests that the addition of mechanical prophylaxis in such patients affords no additional benefit.

Treatment

Deep vein thrombosis

The management of DVT has in the past been focused upon reducing the risk of pulmonary embolus. Patients who are confirmed to have a DVT on duplex imaging should be rapidly anticoagulated with a 'treatment dose' of subcutaneous LMWH. Patients with significant renal impairment should be commenced on intravenous unfractionated heparin. Patients who have a sensitivity towards heparinoids, such as those with heparin-induced thrombocytopenia, should commence on another anticoagulant, such as fondaparinux (an indirect factor Xa inhibitor) or bivalirudin (a direct thrombin inhibitor). This will achieve rapid anticoagulation and reduce the risk of embolisation. Typically, patients will then commence on oral anticoagulation for at least 3 months (or longer depending upon the persistence of risk factors or in recurrent cases). Oral anticoagulation using new or 'novel' anticoagulants (NOACs), which directly inhibit either factor Xa (rivaroxaban and apixaban) or thrombin (dabigatran), is recommended as they are equally effective as vitamin K antagonists (warfarin) in preventing recurrent symptomatic VTE but are associated with less major bleeding complications.

Patients who cannot be safely anticoagulated (usually because of bleeding risks) should be considered for a temporary inferior vena cava filter, until either they are safe to be anticoagulated or the risk of embolisation has subsided and the filter may be retrieved.

Endovascular surgery aiming to restore patency, including thrombus removal, lysis and stenting techniques, are increasingly used in patients with acute DVT aiming to reduce the risk of chronic post-thrombotic syndrome. Research suggests this may be beneficial in selected patients, for example those with iliofemoral thrombosis.

Pulmonary embolus

Most pulmonary emboli can be treated by anticoagulation and observation, but severe right heart strain and shortness of breath indicate the need for thrombolysis or radiologically guided catheter embolectomy.

Superficial vein thrombosis

This condition was previously known as thrombophlebitis. An abnormal endothelium is a much more common precipitating factor than in most DVTs. Common causes include external trauma (especially to varicose veins), venepunctures and infusions of hyperosmolar solutions and drugs. The presence of an intravenous cannula for longer than 24–48 hours often leads to local thrombosis. Some systemic diseases such as thromboangiitis obliterans (Buerger's disease) and malignancy, especially of the pancreas, can lead to a flitting thrombophlebitis (thrombophlebitis migrans), affecting different veins at different times. Finally, coagulation disorders such as polycythaemia, thrombocytosis and sickle cell disease are often associated, as is a concomitant DVT.

The surface vein feels solid and is tender on palpation. The overlying skin may be attached to the vein and in the early stages may be erythematous before gradually turning brown. A linear segment of vein of variable length can be easily palpated once the inflammation has died down.

A full blood count, coagulation screen and duplex scan of the deep veins should usually be obtained. Any suggestion of an associated malignancy should be investigated using

Summary box 62.3

Venous thromboembolism

- May be unprovoked, in which case an association with an inherited thrombophilia should be considered
- Is much more commonly seen as a complication of illness or surgery
- Is associated with both quality-of-life impairment and a risk of mortality
- All healthcare professionals should actively assess the risk and consider preventative measures where this risk is increased
- Management should involve measures to reduce the risk of extension and/or embolisation, typically with systemic anticoagulation
- Early thrombus removal is increasingly being used aiming to prevent chronic post-thrombotic syndrome, and rarely for limb salvage

Leo Buerger, 1879–1943, Professor of Urologic Surgery, The New York Polyclinic Medical School, New York, NY, USA, described thromboangiitis obliterans in 1908.

appropriate endoscopy and imaging studies, such as an abdominal CT scan.

Most patients are treated with NSAIDs and topical heparinoid preparations and the condition resolves spontaneously. Proximity to a deep venous junction or long affected length are indications for short-term anticoagulation and interval duplex assessment. Rarely, infected thrombi require incision or excision. Ligation to prevent propagation into the deep veins is almost never required. Associated DVT or thrombophilia is treated with anticoagulation.

CONGENITAL VENOUS ANOMALIES

There are four main types of anomaly:

- aplasia;
- hypoplasia;
- duplication;
- persistence of vestigial vessels.

Aplasia is most commonly seen in the inferior vena cava and has a similar presentation to the post-thrombotic limb. Membranous occlusion of the left common iliac vein (May–Thurner syndrome) often develops where the vein passes behind the right common iliac artery (iliac vein compression syndrome). This leads to an iliac vein thrombosis, which most commonly affects the left common and external iliac veins. Membranes may also narrow the hepatic veins, which can become totally occluded, leading to a Budd–Chiari syndrome.

Hypoplasia results in a narrow vein, which frequently offers little significant venous function and amounts to a functional venous occlusion, being circumvented by enlarged collateral venous tributaries. Duplications are quite common, with double vena cava, femoral and renal veins; they often present as an incidental finding.

Klippel–Trénaunay syndrome

This is a combined anomaly of a cutaneous naevus, persistent vestigial veins with varicose veins and soft-tissue and bone hypertrophy. The condition is a mesodermal abnormality that is not familial (***Figure 62.36***).

Segments of the deep veins are hypoplastic or aplastic and there may be an associated obstruction of the lymphatics. The condition must be distinguished from the Parkes-Weber syndrome, in which there are multiple arteriovenous fistulae causing venous hypertension, ulceration and high-output cardiac failure.

Virtually all patients with Klippel–Trénaunay syndrome should be treated conservatively with compression hosiery; however, some will benefit from laser ablation of the naevus, stapling of the bones to avoid leg length discrepancy and occasional removal of large superficial varicose veins, provided the deep veins are patent. LMWH should be given to all patients having surgery as this syndrome is associated with an increased risk of VTE.

Figure 62.36 Two patients with Klippel–Trénaunay syndrome. **(a)** This patient has a longer leg and a capillary naevus; **(b)** this patient has a large lateral anomalous axial vein.

VENOUS ENTRAPMENT SYNDROMES

The axillary vein and the popliteal vein are the two veins that are most commonly compressed. The former is compressed at the thoracic outlet between the first rib and the clavicle, where it usually presents as an axillary vein thrombosis (see ***Axillary vein thrombosis***) (***Figure 62.37a***). The latter is compressed by an abnormal insertion of the gastrocnemius muscles. Entrapment may cause discomfort and swelling of the limb during exercise before thrombosis develops. Treatment is by surgical decompression, excising the first rib or dividing the abnormal musculature of the gastrocnemius insertion.

AXILLARY VEIN THROMBOSIS

Thrombosis of the axillary vein (Paget–Schrotter disease) may occur following excessive exercise in a patient with an anatomically abnormal thoracic outlet, but is also associated with excessive muscle bulk as found in weight lifters. The vein may be compressed by a cervical rib if this is present

George Budd, 1808–1882, Professor of Medicine, King's College Hospital, London, UK, described this syndrome in 1845.
Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France after the end of the First World War, in 1918), gave his account of this condition in 1898.
Frederick Parkes-Weber, 1863–1962, physician, The German Hospital, Dalston, London, UK.
Sir James Paget, 1814–1899, English surgeon and pathologist, best known for his description of Paget's disease of the bone.
Leopold von Schrotter, 1837–1908, Austrian physician and laryngologist, Chair of Laryngology, University of Vienna, Vienna, Austria.

(*Figure 62.37b*). The arm is swollen and painful and, at an early stage, the thrombus can be disrupted by thrombolysis delivered through one of the arm veins. The vein must then be imaged to see if there is any compression on elevation of the arm. If this is confirmed, thoracic outlet decompression can be carried out by resecting the cervical rib or first rib.

VENOUS INJURY

Blunt or penetrating trauma almost always damages some small and medium-sized veins, which can be safely ignored or ligated without causing any problems. Larger axial venous channels have in the past been ligated when injured, but it is now recognised that these axial veins should be repaired whenever possible to reduce subsequent morbidity (pain and swelling in the tissues being drained) and limb loss when associated with a concomitant arterial injury. Many venous injuries remain undiagnosed at the time of injury (e.g. crural vein damage associated with a fractured tibia) and only present many years later when post-thrombotic changes become apparent. Venous injuries occur from both civilian and military trauma but the incidence of venous military injuries has been particularly well documented. In total, 40–50% of arterial injuries have concomitant venous injuries, especially in the popliteal fossa.

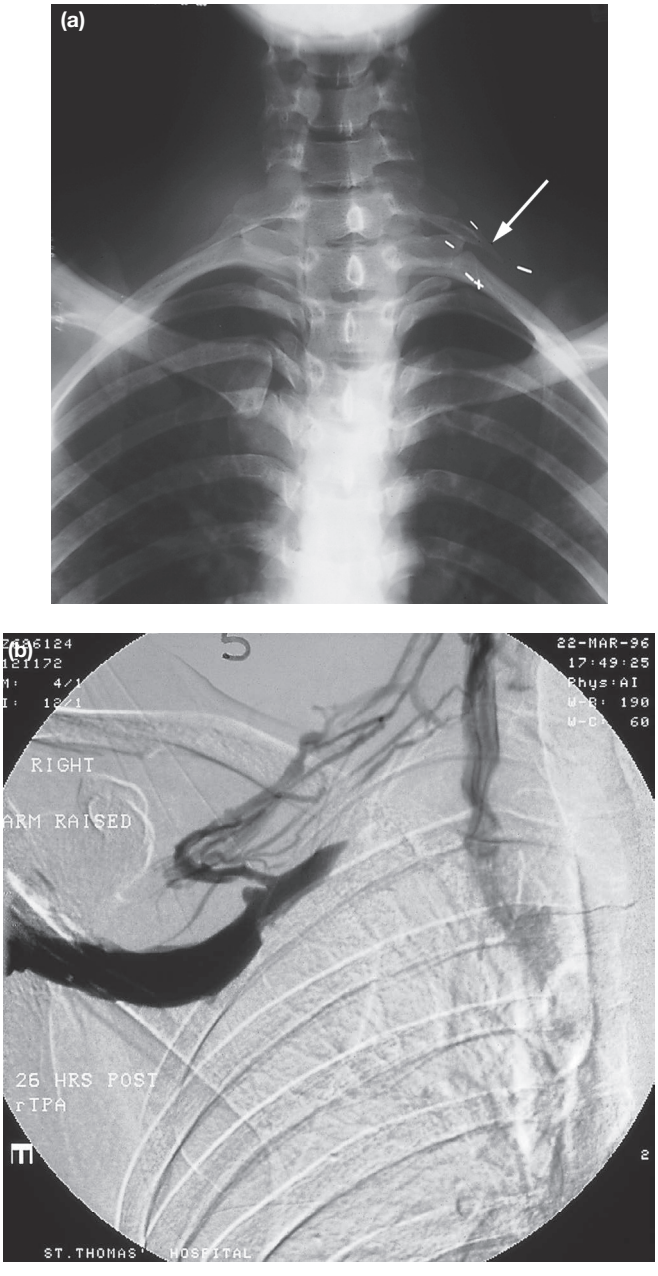

Figure 62.37 Thoracic outlet syndrome: **(a)** cervical ribs on plain radiograph; **(b)** elevation of the arm causes occlusion of the axillary vein with collaterals. The patient has had previous surgery to decompress the left side (arrow in **(a)**).

The mechanism may be laceration, contusion or avulsion (*Figure 62.38*). Iatrogenic injuries result from damage at the time of surgery and from punctures caused by catheter insertion. Thrombosis, haemorrhage and embolisation are all common complications and arteriovenous fistulae may develop when there is a local concomitant arterial injury.

Associated injuries to soft tissue, arteries and bones often overshadow the venous injury. Massive haemorrhage from the pelvic bones or the inferior vena cava can rapidly lead to hypovolaemic shock and death if left untreated. Haematomas are common and engorgement, cyanosis and swelling are also indicative of a major venous injury.

Management

As with all traumatic injuries, the management priorities are the assessment and management of issues affecting the airway, then breathing and then circulation. Venous injuries have the potential to threaten life through massive bleeding and patients require vascular access, circulatory support and blood products. Trauma patients with life-threatening haemorrhage are at risk of hypothermia, acidosis, functional and consumptive coagulopathy and paradoxical thrombosis, and these issues need to be prevented where possible and managed when present.

Venous pressures are low and so, where there is access to the site of injury, pressure will control bleeding and in most cases offer definitive management. Intervention is required where pressure cannot be applied, or where the loss of venous function itself threatens life or limb. Intervention can include reduction and stabilisation of a fracture (e.g. pelvis), endovenous embolisation or stent grafting.

A small proportion of venous injuries will require formal exploration and ligation or repair. Different types of repair are shown in *Figure 62.39*; the type of repair carried out depends on the extent of the venous injury, including how much venous wall has been lost or damaged. Lateral sutures and vein patches are ideal methods of repair and end-to-end anastomosis is satisfactory, provided that it is not carried out under tension. A jump graft may be required.

Vein replacement should be by autogenous tissue whenever possible, using vein harvested from another site, e.g. the internal jugular vein or the GSV from an undamaged limb. Artificial grafts, such as polytetrafluoroethylene (PTFE) grafts, are at risk of infection and have given poor results in recent conflicts. The use of anticoagulants and an arteriovenous fistula to reduce the risk of thrombosis in the vein graft are controversial and depend on the associated injuries that are present. In

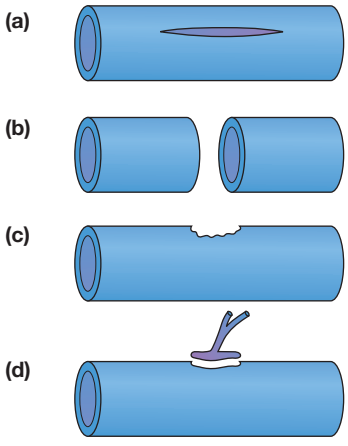

Figure 62.38 Types of venous damage: **(a)** incision; **(b)** transection; **(c)** irregular laceration; **(d)** avulsion of a tributary.

contaminated wounds, tetanus toxoid and antibiotics should be given. A fasciotomy should always be considered if there is a concomitant arterial and venous injury.

Prognosis

It is now recognised that repair of a major vein can be carried out with a 70–80% success rate, reducing the morbidity of a combined arterial and venous injury considerably (especially limb loss). Complex repairs should not, however, be carried out if a patient's life is at risk, when ligation may have to suffice in the short term.

VENOUS TUMOURS

Venous malformation cavernous angioma/haemangioma

These malformations are common, representing one end of a spectrum of arteriovenous malformations. They often affect the skin but also extend into the deep tissues, including bones and joints. They usually present with variable swelling and dilated veins beneath the skin. Occasionally, there is no visible mass and the complaint is one of pain. Haemorrhage and thrombophlebitis may exacerbate the pain. A soft compressible mass, which is venous in colour especially if it is under the skin, is usually present (***Figure 62.40a***). A dark-blue tinge is often apparent, even if the malformation is deeply situated. Nodules within the mass usually represent previous episodes of thrombosis. The size and extent of the haemangioma are best visualised by nuclear MR with a short tau inversion recovery (STIR) sequence (***Figure 62.40b***) or CT scanning with contrast enhancement. Venography rarely shows an abnormality, but direct puncture with contrast injection shows the connections of the malformation.

Treatment is a highly specialised area. Treatment options nowadays rarely initially involve surgical excision as once this is done future embolisation and sclerotherapy are very difficult. No treatment is entirely curative because it is difficult to remove all of the angiomatous tissue or sclerose the angioma completely. Sclerosis can be dangerous when the veins connect to the deep system, particularly near the central nervous system.

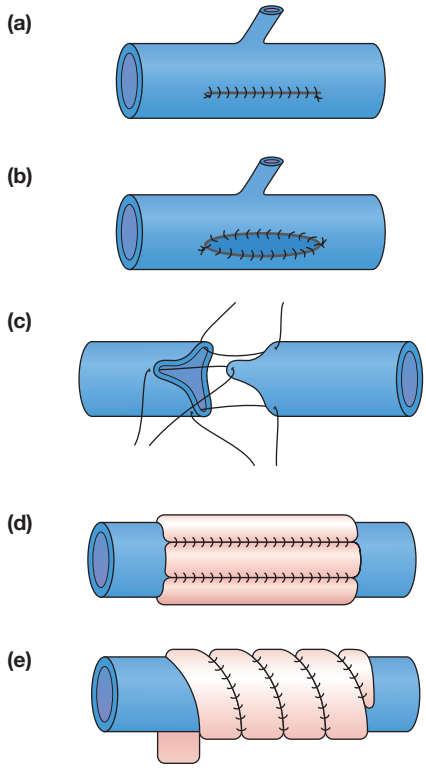

Figure 62.39 Types of venous repair: **(a)** lateral suture (risk of stenosis); **(b)** patch graft; **(c)** Carrel triangulation technique of venous anastomosis; **(d)** panel graft; **(e)** spiral graft.

Leiomyoma and leiomyosarcoma of the vein wall

These are extremely rare tumours that are usually slow growing. They present with pain and a mass with signs of venous obstruction, e.g. oedema and distended veins. Duplex scanning, CT (***Figure 62.41***) and magnetic resonance imaging (MRI) show a filling defect within the vein wall. Treatment is by resection with replacement by autogenous vein taken from another site. Rarely, a PTFE graft is required. When the tumour affects the vena cava it must be resected and replaced with a prosthetic graft.

Cystic degeneration

As in the peripheral arterial system, cystic degeneration of the vein wall is an uncommon cause of venous occlusion. It may be detected by ultrasound. The cyst may be deroofed or the venous segment excised.

Alexis Carrel, 1873–1944, a French surgeon who emigrated to work at the University of Chicago, Chicago, IL, USA. He was awarded the Nobel Prize in Physiology or Medicine in 1912 for pioneering vascular suturing techniques.

PART 11 | Abdominal

CHAPTER 63

History and examination of the abdomen

Learning objectives

To learn:
- The art and science of history-taking in a patient with abdominal complaints

To be able to:
- Recognise the organ or system responsible for the clinical features

To understand:
- The pathophysiological basis of common abdominal symptoms and signs as the pathway to clinical diagnosis

To be aware of:
- Leading questions and relevant physical signs based on the organ or system affected

INTRODUCTION

Abdominal symptoms are a frequent cause for surgical consultation. The underlying cause may be acute, presenting with the euphemistically termed 'acute abdomen'; subacute, indicating an evolving disorder; or longstanding, suggesting a functional or degenerative condition. Occasionally symptoms are due to disorders outside the abdomen, in which case the term 'referred' is used; for example, epigastric pain experienced as a result of a myocardial infarction.

At first presentation, a detailed clinical history and careful clinical examination are essential to establish a differential diagnosis, which, in turn, leads to appropriate triage into urgent and non-urgent investigation and subsequent treatment.

The advent of telemedicine and online remote consultation does not alter the basic art and science of consultation; however, the inability to perform a 'physical' examination may hamper arrival at a proper diagnosis. In such a scenario, a patient should be asked to come for a face-to-face consultation, physical examination and necessary investigations. It is vital to not miss a potentially seriously illness that needs urgent attention.

GATHERING INFORMATION

The experienced clinician will recognise the acuity and severity of the patient's condition even before a history has been taken. Initial observation provides clues to the direction that the history should take: general appearance, gait, position in bed, facial expression and tone of speech all provide useful hints. In an acute presentation, it is important to realise that the patient will feel anxious and vulnerable and may well be in severe pain; therefore, clinicians should introduce themselves, try to comfort the patient and gain the patient's confidence. Clinicians should put the patient at ease and seek permission to begin the consultation in ensured privacy. If a patient is still uncomfortable or reticent, the presence of a close family member as a chaperone can help. A tense patient without a relaxed abdominal wall will substantively affect the accuracy of the clinical examination. This is particularly important in a busy emergency department where the patient is only one among many.

Summary box 63.1

Importance of history and examination
- There is no substitute for a detailed history and thorough clinical examination
- The temptation to proceed to a diagnostic investigation such as abdominal ultrasound or computed tomography scan without clinical examination should be resisted

Obtaining a history

Presenting complaint

To establish the presenting complaint one should start with an open question inviting the patient to explain the reason for seeking medical advice. The patient must be allowed to explain the presenting complaint without interruption, after which carefully directed questions are used to further refine the history (Osler). Clues from these will allow identification of a

Sir William Osler, 1849–1919, Canadian Physician, initiated bedside clinical training for medical students at Johns Hopkins School of Medicine, Baltimore, MD, USA. 'Listen to the patient; he is giving you the diagnosis'.

likely organ or system responsible for the patient's symptoms, which then guides subsequent clinical examination and investigation to arrive at a probable diagnosis. History taking can be forwards and backwards, but its record should be structured.

In the acute situation, pain is the most common presenting feature. The classic features of site, nature, onset, duration, radiation and aggravating or relieving features of the pain should be established. In non-acute presentations, anorexia, weight loss, jaundice, altered bowel habit, blood loss and fatigue are all features that should be questioned.

Past medical history

The past history is important because it may have a bearing on the diagnosis and management. A history of previous similar episodes or past abdominal surgery often guides the diagnosis; for example, adhesive small bowel obstruction in a patient with a history of laparotomy or recurrent left iliac fossa pain in a patient with a past history of diverticulitis. Some symptoms and signs may be due to cardiac, respiratory, haematological conditions, such as abdominal pain in sickle cell crisis or acute epigastric pain in diabetic ketoacidosis.

Recurrent right iliac fossa pain may suggest a past history of appendicitis, Crohn's disease or in some regions amoebic typhlitis or ileocaecal tuberculosis. A positive history of tuberculosis can help in differential diagnoses in many patients. Efforts should be made to obtain previous medical records and investigations.

Drug history and allergies

Some drugs will have an effect on the symptoms and signs or may have to be discontinued before surgery. For example, a patient with bleeding who is taking a β-blocker will not have tachycardia proportionate to the blood loss; a patient taking long-term corticosteroids will need intravenous steroid supplementation to prevent an adrenal crisis in the perioperative period; a patient taking anticoagulant drugs may require reversal of the effects before surgical intervention. Patients with diabetes will require strict glycaemic control with sliding scale insulin in the perioperative period. Detailed enquiry about adverse reactions to anaesthetics or medications can prevent such problems later on.

Social history

The use of alcohol and illicit drugs, smoking and occupation are important. A history of family background and domestic support will guide the planning of discharge after surgery.

Family history

It is important to establish a family history of similar or related conditions, particularly cancer, inflammatory bowel disease, endocrine disease (e.g. hyperparathyroidism causing hypercalcaemia or renal calculi) and genetic disorders, including adverse reactions to anaesthetics or medications.

Review of the systems

A systems review should highlight any comorbid disease, such as cardiac, vascular, respiratory or endocrine problems; these have grave implications for the safety of any surgical intervention.

Summary box 63.2

Principles of history taking

- Identify the reason for consultation – the presenting complaint
- Determine the onset, duration and evolution of the symptoms
- Deduce the most likely organ or system affected
- Refine the history with relevant direct questions
- Establish relevant past, social, family, drug and allergy history
- Complete with a thorough review of other systems
- Devise a list of differential diagnoses

CLINICAL PRESENTATION OF ABDOMINAL PROBLEMS

Pain, weight loss, anorexia or vomiting, jaundice, abdominal bloating/distension, presence of a lump, alteration of bowel habit and blood loss or anaemia are the common clinical presentations of abdominal pathology. It is important to be vigilant about insidious presentations of malignancies. Classic examples are right colon cancer presenting with symptoms of anaemia, metastatic liver cancer with weight loss, gastric cancer with loss of appetite, ovarian cancer with abdominal distension and malignant obstruction of the extrahepatic biliary tree presenting with jaundice.

Abdominal pain

Pain is the most common of all abdominal symptoms and may be due to inflammatory, infective, obstructive, neurogenic, neoplastic or ischaemic pathology. Sometimes no organic cause can be found, a situation often labelled as 'functional or non-specific abdominal pain'. Improved understanding of pain pathways and the relationship with the gastrointestinal microbiome is likely to provide a more precise diagnosis, particularly in common 'functional' disorders such as non-ulcer dyspepsia and irritable bowel syndrome (IBS) (see ***Chapter 73***).

It is essential to establish the site, nature and radiation of the pain, the rapidity of onset and associated or relieving features such as food intake and or vomiting. Thus biliary colic will classically result in colicky pain in the right upper quadrant of the abdomen that radiates to the angle of the scapula and is associated with food intake (which results in cholecystokinin release and gallbladder contraction). The pain of acute appendicitis starts around the umbilicus and then shifts and localises to the right iliac fossa. Acute pancreatitis often has an abrupt onset of severe epigastric pain radiating to the back, which may be similar to pain emanating from peptic ulcer perforation or a leaking aortic aneurysm. Intestinal colic is most frequently associated with periumbilical pain and abdominal distension: the more distal in the intestine the pathology, the greater the degree of distension. Vomiting is an early feature of proximal small bowel obstruction, whereas absolute constipation is an early feature of colonic obstruction. Renal or ureteric colic is intense, located in the flanks and radiating towards the lower midline and scrotum. It is usually associated with either macroscopic or microscopic haematuria.

With regard to altered bowel habit, the onset, nature, duration, type of alteration (constipation or diarrhoea) and its relationship to abdominal pain will help to differentiate organic pathology causing obstruction or inflammation (colon cancer or inflammatory bowel disease [IBD]) from functional conditions such as IBS. When patients complain of diarrhoea, they may imply different meanings – some use the term for loose stools, others may mean frequent but normal stools. A longstanding increase in frequency of stools, with left-sided abdominal pain before defecation that eases after defecation, is suggestive of IBS. However, if such symptoms are of recent onset or are associated with blood or mucus in the stools, colonic carcinoma or IBD is more likely. A history of progressive change in bowel habit with an acute presentation with abdominal pain, distension and absolute constipation suggests acute-on-chronic intestinal obstruction, often from a stenotic left colon cancer. Marked distension with tenderness over the caecal area suggests a closed-loop obstruction with impending caecal rupture. Ileocaecal tuberculosis may present as a mass in the right iliac fossa with a ball of wind and gurgle suggestive of ileal stricture.

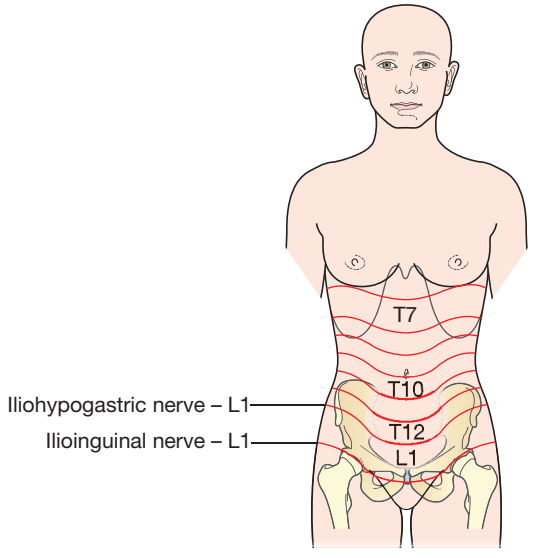

Figure 63.1 Distribution of the anterior abdominal wall dermatome and nerves.

Summary box 63.3

Classic presentations of abdominal pathology

- Obstructive and inflammatory pathology must be excluded in patients with abdominal pain and altered bowel habit as these require urgent care
- Closed-loop obstruction with tenderness in the right iliac fossa is indicative of imminent caecal rupture
- Caecal and ascending colon cancers classically present with anaemia
- Patients who have had previous abdominal surgery may have adhesions
- Check carefully for small incarcerated hernias, particularly femoral in obese patients as these may be hidden by 'abdominal panniculus'

PATHOPHYSIOLOGICAL BASIS OF COMMON ABDOMINAL SYMPTOMS AND SIGNS

The abdominal wall and parietal peritoneum are innervated by the somatic nervous system, whereas the abdominal organs and visceral peritoneum are innervated by the autonomic nervous system. Therefore pain may change in its character and distribution as the underlying pathology evolves. Visceral pain from the foregut is generally felt in the epigastrium, in the periumbilical area from the midgut and in the suprapubic area from the hindgut.

The skin and the muscles of the abdominal wall are supplied by the lateral and anterior cutaneous branches of the lower six intercostal nerves, the iliohypogastric nerve and the ilioinguinal nerve (***Figure 63.1***). The dermatome levels of the xiphoid process, umbilicus and pubis are T7, T10 and T12, respectively. The parietal peritoneum is supplied segmentally by the same nerves that innervate the overlying muscles. The central part of the diaphragmatic peritoneum is supplied by the phrenic nerve (C4); therefore, pain arising in this region is referred to the tip of the shoulder as it has the same segmental supply. The peripheral rim of the diaphragmatic peritoneum is supplied by the intercostal nerves. The obturator nerve is the principal nerve supply of the pelvic parietal peritoneum.

Pain from the viscera is principally due to ischaemia, muscle spasm or stretching of the visceral peritoneum. Unlike somatic pain, autonomic pain is deep and poorly localised. This pain is transmitted via sympathetic fibres and so is referred to the appropriate somatic distribution of that nerve root from T1 to L2. However, when an inflamed organ touches the parietal peritoneum, the pain becomes sharp and localises to the appropriate segmental dermatome of the abdominal wall. Referred pain due to irritation of the undersurface of the diaphragm by blood from a ruptured spleen can be felt at the left shoulder. Pain arising from the parietal peritoneum may radiate to the back or the front along the appropriate dermatome. This referral pattern is classically seen in acute cholecystitis when an inflamed gallbladder touches the parietal peritoneum. Pain then radiates round to the back along the involved dermatome. The overlying muscle and skin are supplied by the same nerve root, so, when the patient takes a deep breath, the tenderness in the right subcostal region is markedly increased, causing the patient to stop breathing; this is Murphy's sign. In children with abdominal pain who hold their right hip in a flexed position to obtain relief from the pain, one should suspect retrocaecal appendicitis causing irritation of the psoas muscle.

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA, described his sign in 1903. He was the son of immigrants fleeing the potato famine in Ireland. He was known as the 'stormy petrel' of American surgery.

Summary box 63.4

Nerves responsible for abdominal pain

- Abdominal wall and parietal peritoneum are supplied by the somatic nerves
- Abdominal organs and the visceral peritoneum are supplied by the autonomic nervous system
- Skin, muscles and parietal peritoneum are supplied by the iliohypogastric and ilioinguinal nerves and the lower six intercostal nerves
- Afferent pain fibres from the abdominal organs and visceral peritoneum travel with sympathetic nerves

Summary box 63.5

Specific characteristics of abdominal pain

- Visceral pain arises from ischaemia, muscle spasm or stretching of the visceral peritoneum
- Autonomic pain, deep and poorly localised, is referred to the equivalent somatic distribution of that nerve root from T1 to L2
- When an inflamed organ touches the parietal peritoneum, pain is then localised to the segmental dermatome of the abdominal wall
- The pain in the parietal peritoneum may radiate to back or front along the dermatome

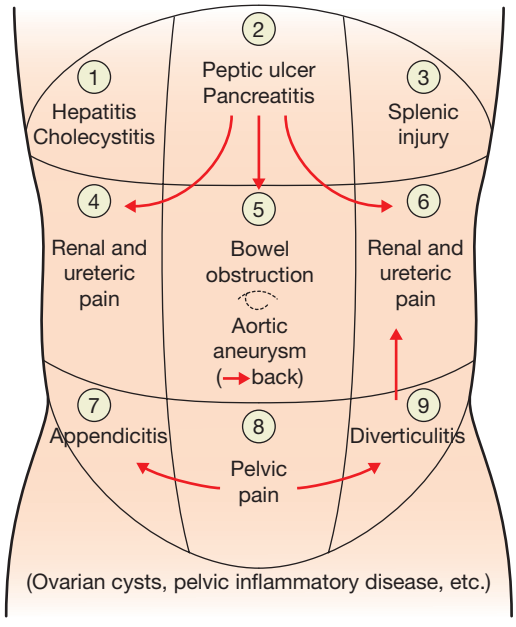

Figure 63.2 Nine sites of abdominal pain: 1, right subcostal; 2, epigastrium; 3, left subcostal; 4, right flank; 5, periumbilical; 6, left flank; 7, right iliac fossa; 8, suprapubic/hypogastrium; 9, left iliac fossa. (From Bailey and Love, 25th edn, courtesy of Mr Simon Paterson-Brown, Consultant Surgeon, Royal Infirmary of Edinburgh.)

Obstruction

Central colicky abdominal pain is a classic presentation of small bowel obstruction. The central distribution is because of the segmental nerve supply of the midgut. When the peristaltic waves hit an obstruction, the contractions increase to overcome the resistance, producing the colic. The pain reaches a crescendo and then disappears in minutes when the peristaltic wave passes. This is different from that of biliary colic. When the gallbladder contracts against a stone, pain is relatively insidious in onset and reaches its peak in about half an hour and then eases off. A basal pain persists between the bouts of colic. Pain of ureteric colic is intense, lasting 1–2 minutes along the line of the ureter.

Summary box 63.6

Colicky abdominal pain

- Pain of 'small bowel colic' comes in waves and disappears completely in minutes when the peristaltic wave ceases
- Pain of biliary colic is insidious in onset, reaches the peak in half an hour or so and does not ease off completely between spasms
- Pain of ureteric colic is intense, lasting 1–2 minutes

Rupture and perforation of organs

The urinary bladder, gallbladder and gastrointestinal tract are hollow organs that contain fluid. The gastrointestinal system also contains faeces, air and a high concentration of organisms. Trauma, ischaemia or tissue ulceration may cause perforation, with resulting leak of luminal contents with peritonitis and resulting in severe abdominal pain. This may be localised to the area immediately adjacent to the perforation (for example, in a localised perforation of an appendix) or more generalised. The initial site of onset of the pain may give a clue as to the organ involved and so help with the differential diagnosis. For example, the diagnosis of a perforated peptic ulcer is supported by a past history of ulcer-type pain followed by a sudden onset of upper abdominal pain. The urgency of the situation must not be missed as such a patient can deteriorate rapidly with septicaemia.

The abdomen is divided into nine areas for ease of description (***Figure 63.2***). These regions are demarcated by the midclavicular lines in the vertical axis and by the transpyloric and transtubercular lines in the horizontal axis. ***Figure 63.2*** also indicates some of the organs and pathological processes that commonly cause pain experienced in these regions.

EXAMINATION OF THE ABDOMEN

Abdominal examination must be preceded by a detailed general examination of the patient as a whole. Physical examination should be systematic using the following sequence: inspection, palpation, percussion and auscultation.

General examination

The patient must be lying flat with hips and knees extended but without causing distress (this may require provision of a pillow) and the abdomen should be adequately exposed.

While inspection of the abdomen is done in this position, for palpation hips and knees are flexed to ensure relaxation of abdominal muscles.

The examination should be performed sequentially, beginning with general inspection looking for evidence of weight loss, dehydration, pedal oedema, anaemia, jaundice or abnormal pigmentation. Examination of the hands may provide evidence of anaemia or chronic liver disease whereas examination of the head and neck may identify features indicative of liver disease or cervical lymphadenopathy (particularly left supraclavicular) suggestive of intra-abdominal malignancy. The patient's vital signs (heart rate, blood pressure, respiratory rate and body temperature) should be noted. In the elective setting the patient's weight and body mass index are also recorded.

Inspection

Scars, abdominal distension, visible peristalsis or abdominal masses, dilated veins, pulsation or abdominal wall swelling suggestive of hernia should all be carefully sought. The size and location of scars from previous surgery may provide some insight into the nature of the intervention that was performed (see ***Chapter 7***).

In an abdominal emergency look for Grey Turner's sign – skin discoloration of the flanks due to retroperitoneal haemorrhage in severe acute pancreatitis and leaking abdominal aortic aneurysm. Cullen's sign – discoloration around the umbilicus – may indicate severe acute pancreatitis, ruptured ectopic pregnancy or trauma to the liver. In these situations, blood tracks to the umbilicus along the ligamentum teres (***Figure 63.3***). These signs are better appreciated in a fair-skinned patient.

In a patient with acute abdominal pain, it is important to observe whether the abdominal wall moves with respiration. A thin patient with diffuse peritonitis may be unable to lie flat and the abdominal wall will have a 'scaphoid' appearance owing to protective contraction of the rectus abdominis muscles. It is often appropriate to ask the patient to cough gently – this will evoke sudden discomfort in the area of underlying peritoneal irritation (equivalent to eliciting rebound tenderness, but not as distressing for the patient). A visible 'cough impulse' will also help to identify an abdominal wall hernia, if present. A rounded, symmetrical contour of the abdomen with bulging flanks is seen in the presence of ascites. Visible abdominal masses, mobility on respiration and peristalsis are all best observed if the clinician kneels by the patient's bed so that the observer's eye is at the level of the patient's anterior abdominal wall. The same position is useful during palpation for abdominal masses (***Figure 63.4***).

Figure 63.3 Cullen's and Grey Turner's sign of skin discoloration of the flanks and around the umbilicus (courtesy of Mr Pradip Datta, Honorary Consultant Surgeon, Wick, Scotland).

Figure 63.4 Eye at the level of patient's abdominal wall.

In a thin patient, visible bowel loops give clues about the pathology: an overdistended, bean-shaped loop is seen in caecal volvulus, which characteristically points towards the left upper quadrant, and in sigmoid volvulus, which points towards the right upper quadrant.

Palpation

Palpation should be performed in a systematic manner, checking all nine regions of the abdomen (***Figure 63.2***). Palpation should start in the region furthest away from the site of pain and the patient instructed to let the examiner know if tenderness is elicited. The examination should be gentle and the hands warm. The patient's facial expression will immediately reveal discomfort. Superficial palpation is followed by deep palpation if tenderness will allow. To avoid 'poking' during palpation, the forearm is kept horizontal, the whole of the palm is kept lightly on the abdomen and hand movement is made only at the metacarpophalangeal joints; never at the interphalangeal

George Grey Turner, 1877–1951, Professor of Surgery, at the University of Durham (1927–1934) and at the Royal Postgraduate Medical School, Hammersmith Hospital, London, UK (1935–1946).

Thomas Stephen Cullen, 1868–1953, Professor of Gynecology, the Johns Hopkins University, Baltimore, MD, USA, described the sign in ruptured ectopic pregnancy in 1916.

joints of the fingers. Palpation during respiration is performed to identify the lower margins of the liver and spleen as they move with respiration. Palpation of the abdomen in a patient with ascites will often demonstrate a doughy feel in the tubercular abdomen.

Signs of parietal peritoneal irritation (tenderness, guarding, rebound tenderness, rigidity)

In the presence of abdominal pain, the degree of abdominal wall rigidity and involuntary guarding should be assessed. Guarding represents contraction of the abdominal wall muscles over the area of pain. This might occur 'voluntarily' when the patient wishes to avoid the pain from examination or 'involuntarily' when the muscles go into spasm as the inflamed viscus touches the parietal peritoneum. This produces a reflex spasm of the overlying abdominal wall muscles. The presence of rebound tenderness indicates underlying peritoneal inflammation and is examined best using gentle percussion, although pain on coughing is also found when there is rebound tenderness. When the underlying peritoneal inflammation becomes generalised, the abdomen is 'board-like rigid' to palpation, and selective tenderness can no longer be elicited. This sign represents widespread involuntary guarding.

Abdominal masses

A mass arising from the anterior abdominal wall will usually be mobile when the patient is relaxed. On contracting the abdominal wall muscles (ask the patient to lift his or her legs with the knees extended or perform Valsalva's manoeuvre for laterally placed swellings), lumps superficial to the abdominal wall muscles will become more obvious, and those attached to the deep fascia will become less mobile. Those arising within the muscle layer will become fixed and remain unchanged in size. Lumps arising deep to the abdominal wall (i.e. within the peritoneal cavity or behind the peritoneum) will become impalpable or less prominent on tensing the anterior abdominal wall muscles.

An intraperitoneal mass in contact with the diaphragm will move on respiration whereas retroperitoneal masses are usually fixed and do not move with respiration; an enlarged kidney is 'ballotable' and bimanually palpable. Normal aortic pulsations can be both seen and felt in a thin abdomen, but expansile pulsation is characteristic of an abdominal aortic aneurysm. This should be differentiated from transmitted pulsation of a mass sitting on the aorta (e.g. pseudocyst of the pancreas). When 'palpating during inspiration', the examining hand is placed distal to the normal site of the organ and is held there until the edge of the organ descends and touches the examiner's fingers. Liver, spleen, gallbladder and kidneys are best palpated during inspiration. An abdominal mass in a female, the lower limit of which cannot be distinguished, is likely to arise from the pelvis. If the mass can be moved in a transverse direction, it is likely to be a uterine or ovarian mass. The movement of a mesenteric cyst is perpendicular to the direction of attachment of the root of the mesentery.

Spleen

In a healthy patient the spleen is not normally palpable. An enlarged spleen descends downwards, forwards and medially. Palpation for an enlarged spleen is best performed in a supine patient. The examining hand should start in the right lower abdomen, with the tips of the fingers pointing upwards and pressed inwards. The patient is then asked to take a deep breath; if the spleen is enlarged the lower edge with the characteristic notch will touch the fingers. If it is not palpable, then the hand is gradually moved upwards in the direction of the position of the edge of the normal-sized spleen with each breath. If the spleen is still not palpable, the patient is moved to the right lateral position and the examination repeated.

Liver

In a supine patient, the hand is placed in line with the potential enlarged liver edge lateral to the rectus muscle. The patient is then asked to take a deep breath. If the liver is enlarged sufficiently below the costal margin, then surface irregularities can also be felt.

Percussion

Percussion helps to distinguish distension due to bowel gas from solid masses and free fluid in the abdomen. Percussion is most sensitive when the examiner moves from resonant parts of the abdomen to dull areas. In patients with free fluid in the peritoneal cavity, percussion from the centre to the periphery reveals dullness of flanks. Shifting dullness is elicited if the patient is re-examined lying on his or her side. The margin of dullness is then found to shift when the patient has moved. Free fluid can also give rise to 'fluid thrill'; this is feeling the vibrations from a tap in one flank on the other flank while pressure is kept on the midline to prevent vibrations through the abdominal wall.

Percussion is also a very sensitive and refined method of testing for rebound tenderness. If the patient winces with pain on abdominal percussion it denotes underlying peritonitis.

Auscultation

High-pitched bowel sounds are heard during the early stages of mechanical intestinal obstruction. Aortic and iliac bruits are heard when blood flows through a stenosis. A succussion splash is a sound like 'shaking a half-filled bottle with water' and is found most often in patients with gastric stasis due to gastric outlet obstruction. In generalised peritonitis and paralytic ileus, bowel sounds will not be heard or be very few and far between.

Inspection of hernia sites, examination of genitalia, inspection of anal region and digital rectal examination

Abdominal examination is not complete until all external hernia sites and the anal area have been carefully inspected,

Antonio Maria Valsalva, 1666–1723, Professor of Anatomy, Bologna, Italy, of whom Morgagni wrote 'there is nobody of those times who goes ahead of him, very few who are his equals'.

the genitalia, renal angles and the thoracic and lumbar spine are examined and a digital rectal examination performed. A vaginal examination may also be needed in females. Details of these clinical examinations are covered in the respective chapters.

VALUE OF OBSERVATION AND REVIEW

In the case of acute abdominal pain, there will be a subset of patients in whom, after full clinical assessment, the surgeon remains uncertain about the need for an urgent operation. This is probably the most difficult group to deal with compared with those in whom an urgent operation is either clearly required or clearly not required, and undoubtedly the one in which the majority of errors occur. These include rare causes of abdominal pain and vomiting such as metabolic diseases (diabetic ketoacidosis, diabetic gastroparesis, porphyria, hyperparathyroidism etc.), referred pain from the spine, heart and lungs and functional pain. Further urgent investigations are obviously needed in this group and these are discussed in some detail elsewhere in this book. However, while these are taking place, regular review of the patient is essential, preferably by the same clinician who initially examined the patient so as not to miss any subtle changes or worsening of the situation. Such a period of observation is an integral part of the early management of patients with acute abdominal pain.

PART 11 | Abdominal

CHAPTER 64

The abdominal wall, hernia and umbilicus

Learning objectives

To know and understand:

- Basic anatomy of the abdominal wall and its weaknesses
- Causes of abdominal hernia
- Types of hernia and classifications
- Clinical history and examination findings in hernia
- Complications of abdominal hernia
- Non-surgical and surgical management of hernia, including mesh
- Complications of hernia surgery
- Other abdominal wall conditions

THE ABDOMINAL WALL

Basic anatomy and function related to pathology

The abdominal wall is a complex structure composed primarily of muscle, bone and fascia. Its major function is to protect the enclosed organs but it must also enable mobility and be able to flex, extend, rotate and vary its capacity. Flexibility requires elasticity and stretch, which compromise abdominal wall strength.

The roof of the abdomen is formed by the diaphragm separating the thoracic cavity above, with negative pressure, from the abdomen below, with positive pressure. Weakness of the diaphragm can lead to much of the bowel being drawn into the chest down this pressure gradient. The bony pelvis forms the floor of the cavity but a muscular central portion, the perineum, may also weaken and allow rectum, bladder and gynaecological organs to bulge downwards, a condition called prolapse.

The overall design of the abdominal muscles is best seen on transverse section through the mid-abdomen (***Figure 64.1***). Posteriorly the muscles are strong, further supported by the vertebral column, ribs and pelvis. Two regions called the posterior triangles represent areas of weakness, which can lead to rare lumbar hernias. Laterally there are three thin muscle layers, the fibres of which criss-cross for strength and flexibility.

Anteriorly the two powerful rectus abdominis muscles extend vertically from ribs to pelvis. Herniation through these strong muscles does not occur naturally but their central join, the linea alba, is an area of weakness that may result in epigastric or umbilical herniation. Divarication of the recti is the condition where the linea alba stretches laterally as the two rectus muscles separate. It occurs predominantly in the upper abdomen in middle-aged, overweight men (***Figure 64.2***) and also as a result of pregnancy in women, where it is primarily below the umbilicus. Divarication is not a hernia and does not require treatment, although some surgeons do offer repair for purely cosmetic reasons.

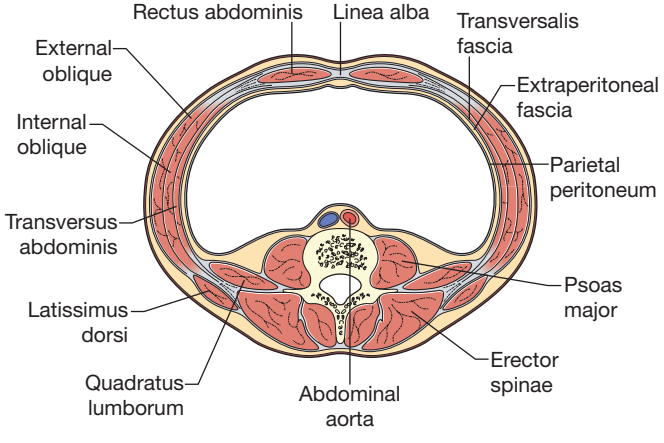

Figure 64.1 A cross-section of the mid-abdomen showing the muscular anatomy.

ABDOMINAL HERNIA

A hernia is an abnormal protrusion of an organ or tissue through an opening in the layer that normally confines it. There are many varieties of hernia arising through areas of weakness in the abdominal wall. Because they 'push' from the inside to the outside, an abdominal hernia takes with it all the coverings of the abdominal wall, although they may be thinned and attenuated. However, not all abdominal hernias have a peritoneal sac: many epigastric hernias, for example, arise in the interstitial layers and only draw peritoneum into the protrusion as a secondary phenomenon when they become larger.

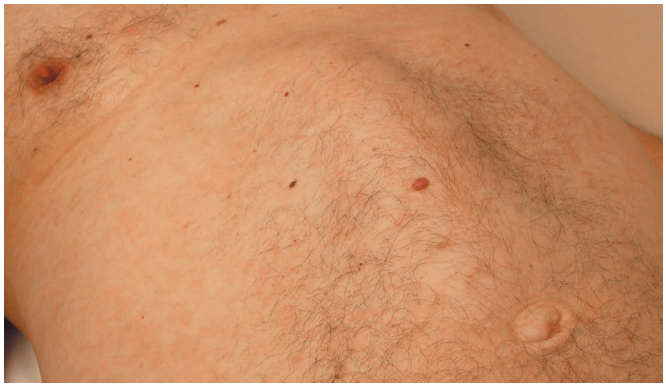

Figure 64.2 Divarication of the recti. Note a coexisting small umbilical hernia.

Anatomical causes of abdominal wall herniation

These may be classified as areas of natural weakness due to absence of muscle, natural defects that allow structures to enter or leave the abdomen, developmental abnormalities and disruptions of the abdominal wall as a result of injury. The only natural weaknesses caused by inadequate muscular strength are the lumbar triangles (see ***Lumbar hernia***) and the posterior wall of the inguinal canal (***Figure 64.3***).

Many structures enter and leave the abdominal cavity, creating weakness that can lead to hernia formation. The most common example is the inguinal canal, along which, in males, the testis and its associated vessels descend from the abdomen to scrotum at the time of birth. In females the round ligament traverses the inguinal canal. The resultant weakness may lead to an indirect inguinal hernia. The risk of inguinal hernia is related to the anatomical shape of the pelvis and is greater in patients with a wider and shorter pelvis. Other examples of inherent areas of weakness include the oesophageal hiatus, the femoral canal and the umbilical cicatrix.

Failure of normal development may lead to congenital hernias. The most common is an indirect inguinal hernia arising through failure of the processus vaginalis to close. As the testis (or round ligament) descends, it pulls a tube of peritoneum along with it. This tube should naturally fibrose and become obliterated, but, if it fails to do so, a hernia may develop. Recent studies have shown that calcitonin gene-related peptide and hepatocyte growth factor influence the closure of the processus, raising the possibility of a hormonal cause of hernia development.

Other examples of congenital herniation include Morgagni and Bochdalek hernias of the diaphragm and some umbilical hernias. In neonates these are often seen in association with other congenital abnormalities.

Weak areas of the abdominal wall may also arise from direct injury. A surgical scar, even with perfect wound healing, has only 70% of the initial muscle strength, resulting in incisional herniation in at least 10% of laparotomy incisions. Smaller laparoscopic port-site incisions have a hernia rate of 1%. Increasing use of the laparoscopic surgical approach should lead to a fall in the incidence of incisional hernia.

Muscle damage by blunt trauma or tearing of the abdominal muscles is rare but is seen after exceptional force, such as high-speed motor vehicle accidents (***Figure 64.4***).

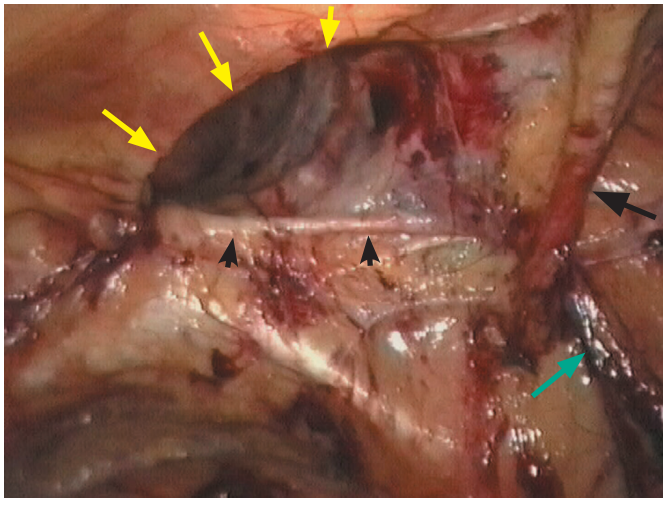

Figure 64.3 A right direct inguinal hernia defect (yellow arrows) is above the inguinal ligament (arrowheads). The round ligament (green arrow) enters the deep inguinal ring just lateral to the inferior epigastric vessels (black arrow).

Summary box 64.1

Causes of hernia

- Anatomical weakness
- Developmental failures
- Genetic weakness of collagen
- Sharp and blunt trauma
- Weakness due to ageing and pregnancy
- Primary neurological and muscle diseases

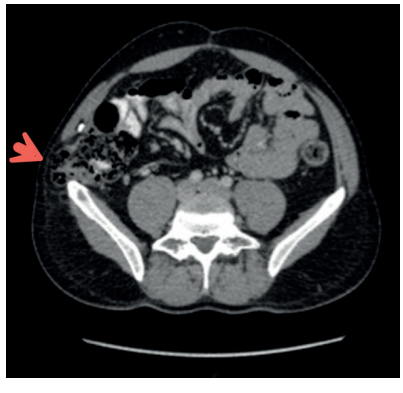

Figure 64.4 Traumatic hernia in the right iliac fossa (arrow) following a motor vehicle accident in which the lateral muscles, along with a tiny sliver of bone, were torn off the iliac crest.

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy.
Vincent Alexander Bochdalek, 1801–1883, Professor of Anatomy, Prague, Czech Republic.

Pathophysiology of hernia formation

A normal abdominal wall has sufficient strength to resist high abdominal pressure and prevent herniation of content. Many patients will first notice a hernia after excessive straining, the strain bringing the hernia to the attention of the patient, rather than being the cause.

There is good evidence that hernia is a 'collagen disease' and is due to an inherited imbalance in the types of collagen. This is supported by histological evidence and relationships between hernia and other diseases related to collagen, such as aortic aneurysm. In extreme collagen disorders, such as Ehlers–Danlos syndrome, successful long-term repair of a hernia can be very difficult. Hernia is more common in smokers as smoking is linked to impaired collagen maturation.

Hernias are more common in elderly people owing to degenerative weakness of muscles and fibrous tissue. Incisional hernias are more common after wound complications and in patients with a high body mass index; however, a major risk factor is the surgeon and the way the abdominal wall was closed.

Common principles in abdominal hernia

An abdominal wall hernia has two essential components: a defect in the wall and the content, i.e. tissue that has been forced outwards through the defect. The weakness may be through fascia and muscle, or through fascia alone, such as an epigastric hernia. It may have a bony component, such as a femoral hernia. The weakness in the wall is usually the narrowest part of the hernia, which expands into the subcutaneous fat outside the muscle. The defect varies in size and may be very small or indeed very large. The nature of the defect is important to understanding the risk of hernia complications. A small defect with rigid walls traps the content and prevents it from freely moving in and out of the defect, increasing the risk of complications.

The content of the hernia may be tissue from the extraperitoneal space alone, such as fat within an epigastric hernia or urinary bladder in a direct inguinal hernia. However, if a hernia enlarges then peritoneum may also be pulled into the hernia secondarily along with intraperitoneal structures such as bowel or omentum; a good example is a '**sliding type**' of inguinal hernia. More commonly, when peritoneum is lying immediately deep to the abdominal wall weakness, pressure forces the peritoneum through the defect and into the subcutaneous tissues. This '**sac**' of peritoneum allows bowel and omentum to pass through the defect. In most cases, the intraperitoneal organs can move freely in and out of the hernia, a '**reducible**' hernia; however, if adhesions form or the defect is small, bowel can become trapped and unable to return to the main peritoneal cavity, an '**irreducible**' hernia, with higher risk of further complications. The narrowest part of the sac, at the abdominal wall defect, is called the '**neck**' of the sac.

When tissue is trapped inside a hernia it is in a confined space. The narrow neck acts as a constriction ring impeding venous return and increasing pressure within the hernia. Resulting tension leads to pain and tenderness. If the hernia contains bowel then it may become '**obstructed**', partially or totally. If the pressure rises sufficiently, arterial blood is not able to enter the hernia and the contents become ischaemic and may infarct. The hernia is then said to have '**strangulated**'. The wall of the bowel perforates, releasing infected, toxic bowel content into the tissues and ultimately back into the peritoneal cavity. The risk of strangulation is highest in hernias that have a small neck of rigid tissue, leading first to irreducibility and on to strangulation. The term '**incarcerated**', literally 'in prison', means that a hernia is not only irreducible but also potentially developing strangulation.

Summary box 64.2

Types of hernia by complexity

- Occult – not detectable clinically
- Reducible – a swelling that appears and disappears
- Irreducible – a swelling that cannot be replaced in the abdomen, at risk of complications
- Incarcerated – irreducible, trapped, risk of strangulation
- Strangulated – acutely painful swelling with tissue ischaemia: requires emergency surgery
- Infarcted – when contents of the hernia have become gangrenous: high mortality

Figure 64.5 A gangrenous Richter's hernia from a case of strangulated femoral hernia.

In a special circumstance (Richter's hernia) only part of the bowel wall enters the hernia (***Figure 64.5***). It may be small and difficult or even impossible to detect clinically. Bowel obstruction may or may not be present but the bowel wall may still become necrotic and perforate with life-threatening consequences. Femoral hernia may present in this way, often with diagnostic delay and high risk to the patient.

Edvard Ehlers, 1863–1937, dermatologist, Frederiks Hospital, Copenhagen, Denmark.
Henri-Alexandre Danlos, 1844–1912, dermatologist, Hôpital Saint Louis, Paris, France.
August Gottlieb Richter, 1742–1812, surgeon, Göttingen, Germany.

An interstitial hernia occurs when the hernia arises entirely between the musculofascial layers of the abdominal wall muscle and does not contain a peritoneal sac. This is commonly seen with small Spigelian hernias (see ***Spigelian hernia***).

An internal hernia describes bowel entrapment within the peritoneal cavity. This can occur in naturally existing spaces such as the foramen of Winslow or the paraduodenal and paracaecal fossae, around adhesive bands or through iatrogenic defects in the mesentery.

Clinical history and diagnosis in hernia cases

Patients are usually aware of a lump on the abdominal wall under the skin. Self-diagnosis is common. The hernia is usually painless but patients may complain of an aching or heavy feeling. Sharp, intermittent pains suggest pinching of tissue at the hernia neck. Severe pain should alert the surgeon to a high risk of strangulation. One should determine whether the hernia reduces spontaneously or needs to be helped. The patient should be asked about symptoms that might suggest bowel obstruction.

Once the clinician is satisfied that a swelling is indeed a hernia, it is important to know if this is a primary hernia, a recurrent hernia or an incisional hernia after previous surgery. Recurrent and incisional hernias are more difficult to treat and may require a different surgical approach.

General questions about the cardiac and respiratory systems are necessary to assess a patient's anaesthetic risk. Intake of anticoagulants such as warfarin and apixaban or antiplatelet medication such as aspirin or clopidogrel is important because this impacts on future surgery. Many hernia operations can be performed as a day case or single overnight stay, so that suitability for such treatment needs to be assessed, including home support, distance from the hospital, mobility levels, etc. (see ***Chapter 22***).

Examination for hernia

The patient should be examined lying down initially and then standing, as this will usually increase hernia size. Some hernias will only be apparent with the patient standing. The patient may be asked to cough or to perform the Valsalva manoeuvre to make the hernia appear. Divarication is best seen by asking a supine patient to simply lift his/her head off the pillow. Finally, it should be remembered that if a patient describes an intermittent swelling but the surgeon finds no hernia on examination, there still may be a hernia present.

The overlying skin is usually of normal colour. If there is overlying cellulitis then the hernia content is strangulating and the case should be treated as an emergency.

In most cases an expansile cough impulse is felt if gentle pressure is applied to the lump and the patient is asked to cough; however, there may be no cough impulse when the neck is tight and the hernia irreducible. This is typical of a femoral hernia, where lack of an impulse leads the clinician to misdiagnose a lymph node. A cough impulse can also be appreciated in a saphena varix (see ***Chapter 62***).

If a groin hernia is found on one side, the other side must also be examined as occult contralateral hernias are present in up to 20% of patients.

If a hernia does not reduce spontaneously, the surgeon should ask the patient to attempt reduction because he/she may be well practised in this task, and the surgeon might cause unnecessary discomfort. If neither the patient nor the surgeon can reduce the hernia, the treatment is more urgent.

Summary box 64.3

Checks

- Reducibility
- Cough impulse
- Tenderness
- Overlying skin colour changes
- Multiple defects/contralateral side
- Signs of previous repair
- Scrotal content for groin hernia
- Associated pathology

Summary box 64.4

Examination

- A swelling with a cough impulse is not necessarily a hernia
- A swelling with no cough impulse may still be a hernia but consider other diagnoses

Investigations for hernia

For most hernias, the diagnosis is made on clinical examination. However, the patient may have symptoms suggesting a hernia but no hernia is found, or the patient may have a swelling suggestive of hernia but with clinical uncertainty. It is important to be certain that any symptoms described are due to a hernia and not to coexisting pathology, particularly when the major symptom is pain. Soft, reducible hernias are rarely painful. There may also be a requirement for more detailed information than can be found by examination alone. An ultrasound scan may be helpful in cases of irreducible hernia when the differential diagnosis includes a mass or fluid collection, enlarged lymph node or saphena varix or when the nature of the hernia content is in doubt. It is non-invasive, dynamic and low cost but highly operator dependent. Ultrasonography may be useful in the early postoperative period to distinguish a haematoma or seroma from an early recurrence.

Computed tomography (CT) is helpful in complex ventral and incisional hernias, determining the number and size of muscle defects, identifying the content, giving some indication

Adriaan van den Spiegel, 1578–1625, Flemish anatomist who practised in Padua, Italy.
Jacob Benignus Winslow, 1669–1764, Danish-born anatomist, Jardin du Roi, Paris, France
Antonio Maria Valsalva, 1666–1723, Professor of Anatomy, Bologna, Italy.

of presence of adhesions and excluding other intra-abdominal pathology such as ascites, occult malignancy and portal hypertension. By showing the surrounding muscle layers CT helps planning abdominal wall reconstruction.

Magnetic resonance imaging (MRI) can help in the diagnosis of sportsman's (Gilmore's) groin, where pain is the presenting feature and the surgeon needs to distinguish an occult hernia from an orthopaedic injury.

Laparoscopy itself may be used. In incisional hernia, initial laparoscopy may determine whether a laparoscopic approach is feasible or not. In inguinal hernia repair by the transabdominal route, initial laparoscopy can determine the presence of an occult contralateral hernia. However, laparoscopy will not identify intraparietal hernias such as lipomas of the spermatic cord and some epigastric and Spigelian hernias.

Summary box 64.5

Investigations

- Plain radiograph – of little value
- Ultrasound scan – low cost, operator dependent
- CT scan – ventral and incisional hernia
- MRI – good in sportsman's groin with pain
- Laparoscopy – useful to identify occult defects but not interstitial hernias

Management principles

An abdominal wall hernia does not necessarily require repair. A patient may request surgery for relief of symptoms or for cosmesis. The surgeon should recommend repair when complications are likely, the most worrying being bowel obstruction and strangulation. These are most likely in narrow-necked hernias; for this reason all femoral hernias should be repaired, as should symptomatic or irreducible hernias unless coexisting medical factors place the patient at very high risk. Increasing difficulty in reduction and increasing size are also indications for surgery. Surgery should be offered to younger adult patients as symptoms and complications are likely over time.

Summary box 64.6

Management

- Not all hernias require surgical repair
- Small hernias can be more dangerous than large
- Pain, tenderness, skin changes and difficulty reducing imply high risk of strangulation
- Femoral hernia should always be repaired

In elderly patients a policy of 'watchful waiting' in asymptomatic inguinal hernia appears generally safe, with an annual crossover to surgery because of symptoms developing of around 10%. A truss can be used to control a hernia but nowadays few surgeons recommend this approach. Small umbilical and epigastric hernias may also be managed conservatively as they cause few symptoms and usually contain fat or omentum with a very low risk of complications.

Large incisional hernias, particularly recurrent, present a major problem. Surgical repair is a complex procedure with significant risk of complications and later recurrence. When the neck is wide, the risk of strangulation is low. In obese and elderly patients, these risks may outweigh the benefits of surgery and it is common for surgeons to adopt a conservative approach.

A patient who presents with acute pain in a hernia, particularly if it is irreducible, should be offered urgent surgery. It may be reducible by taxis (gentle forceful reduction, perhaps requiring analgesia and/or sedation) and sometimes, after admission to hospital and adequate analgesia, the hernia will reduce as a result of muscle relaxation. In either case, the likelihood of similar episodes is very high and surgery should be recommended at the next available opportunity.

Surgical approaches to hernia

In general, modern surgical repairs follow these principles:

- Reduction of the hernia contents into the abdominal cavity with excision of any non-viable tissue and bowel repair if necessary.
- Excision and closure of the peritoneal sac if present (though small sacs may be reduced intact).
- Closure of the hernia defect if possible.
- Reinforcement of the abdominal wall with mesh (though non-mesh repairs are an option).
- If necessary, excise redundant skin to improve cosmetic outcome.

Reduction of hernia content is essential for a successful repair. Excision and closure of the peritoneal sac is ideal but not essential. During intraperitoneal onlay mesh laparoscopic repair of incisional hernia, for example, surgeons will often leave the sac *in situ* after reducing the hernia contents, and simply fix a mesh over the defect. Leaving the peritoneal sac *in situ* risks the accumulation of serous fluid formation within the sac (seroma). This can arise after all forms of hernia repair. In open repair of lateral (indirect) inguinal hernia, most surgeons excise the peritoneal sac but small sacs can be simply pushed back through the deep inguinal ring, which is said to reduce postoperative pain. Similarly, in laparoscopic repair of inguinal hernias, surgeons simply pull the sac back into the abdominal cavity from within and do not excise it.

Closure of the hernial defect is ideal but may not be possible when the defect is large, the surrounding tissues are rigid (such as the femoral canal) or structures traversing the defect must be retained (such as the spermatic cord traversing the deep inguinal ring). Plastic surgical techniques have been developed to 'borrow' tissue from elsewhere in order to cover large muscle defects, but usually at the cost of leaving a weak area elsewhere. The repair of large and complex hernias using a variety of such specialised techniques has led to some surgeons declaring a specialist hernia interest.

Jerry Gilmore, 1942–2019, surgeon, London, UK, gave his name to a syndrome of chronic groin pain in professional footballers.

Closure of the hernia defect alone is associated with a high recurrence rate. Additional reinforcement of the repair with a non-absorbable mesh reduces but does not prevent recurrence. With improved techniques and new meshes it is hoped that recurrence after surgery will fall further. Mesh repair has become so important in hernia surgery that some understanding of mesh technology is essential for the modern surgeon.

Mesh in hernia repair

The term 'mesh' refers to prosthetic material, either a net or a flat sheet, that is used to strengthen a hernia repair. Mesh can be used to:

- bridge a defect: the mesh is simply fixed over the defect as a tension-free patch;
- plug a defect: a plug of mesh is pushed into the defect;
- augment a repair: the defect is closed with sutures and the mesh added for reinforcement.

Simple bridging of a hernia defect relies on a generous overlap of the mesh onto strong tissues around the defect in order to reduce the risk of recurrence. Mesh plug repairs have been used in small defects, especially where tissue overlap is hard to achieve, but have been largely abandoned because collagen deposition often produces a fibrous mass, a 'meshoma', that may cause chronic pain. Other complications include mesh migration, erosion into adjacent organs and fistula formation. Primary closure of the hernia defect with the addition of mesh for reinforcement placed in a tension-free manner is currently regarded as optimal. Suturing a mesh edge to edge into the defect (inlay), with no overlap, is not recommended.

Mesh types

Gross structure

Net meshes are woven or knitted. Sheet meshes are not porous but may be perforated with multiple holes. Net meshes allow native tissue ingrowth between the strands so that the mesh becomes integrated into host tissues within a few months. Initial fixation of such mesh is by glue, sutures or tacks/staples, which may or may not be absorbable; in some cases, such as extraperitoneal repair of inguinal hernias, no mesh fixation may be required at all. 'Sheet' meshes do not allow host tissue ingrowth but eventually become encapsulated by host fibrous tissue. They always require strong, non-absorbable fixation to prevent mesh migration.

Synthetic mesh

Most meshes used today are synthetic polymers of polypropylene, polyester or polytetrafluoroethylene (PTFE), but there may be other chemical additives and meshes may have a composite structure such as those with anti-adhesive barriers. Meshes for hernia repair are generally non-absorbable and designed to provoke tissue ingrowth that leads to the formation of a tissue barrier. Polypropylene is an inert, hydrophobic, monofilament material so does not generate an immune response and tends to resist bacterial ingrowth. Polyester mesh is similar but hydrophilic, and is said to encourage microvascular ingrowth. PTFE meshes are flat sheets, quite inert and resistant to both tissue ingrowth and adhesion formation (***Figure 64.6***).

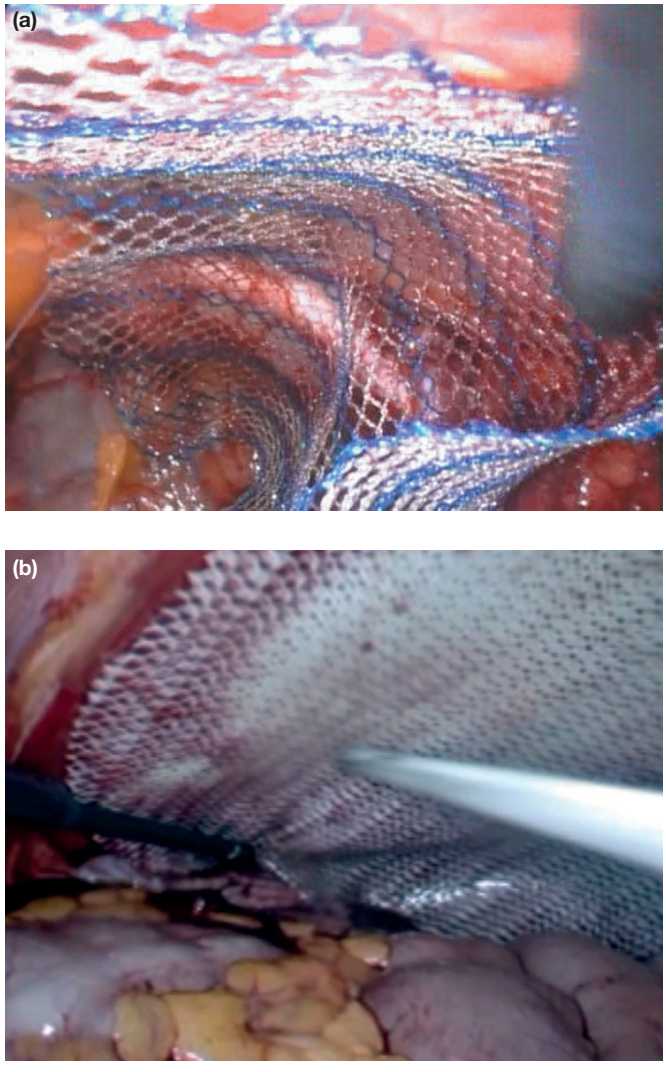

Figure 64.6 (a) Polypropylene mesh in totally extraperitoneal inguinal hernia repair. The blue lines are added purely to help the surgeon orientate the mesh. **(b)** Polyester mesh in an epigastric hernia repair.

Weight and porosity

Synthetic meshes are very strong; early meshes were much stronger than a human abdominal wall, so they are considered to be 'over-engineered'. All meshes provoke a fibrous reaction. More dense or heavyweight meshes provoke a greater reaction, leading to collagen contraction and mesh stiffening, which is associated with impaired elasticity/mobility of the abdominal wall, foreign body sensation and pain.

The term 'mesh shrinkage' is often used to describe this progressive decrease in mesh size over time, but the mesh itself does not shrink; instead, it is simply the natural progressive contraction of the fibrous tissue that has grown into the mesh. Thus 'mesh contracture' is a more accurate term. This process can lead to hernia recurrence if the mesh no longer covers the defect. Meshes can contract in area by more than 50%. Meshes with thinner strands and larger spaces (pores) between them are preferred because they have better tissue integration, less contracture, less foreign body reaction, more flexibility and improved comfort.

Current opinion avoids the use of stiff, heavyweight mesh and favours a pore size of at least 1 mm in all directions in order to promote collagen ingrowth that is not only strong but also elastic.

Biological mesh

So-called 'biological meshes' are sheets of sterilised, decellularised, connective tissue derived from a variety of sources, including human or animal dermis, bovine pericardium or porcine intestinal submucosa. They provide a 'scaffold' to encourage neovascular ingrowth, fibroblast infiltration and new collagen deposition. In theory host enzymes eventually break down the biological implant and replace it with normal host fibrous tissue. The rates of enzymatic degradation and collagen deposition vary between products and also depend on the local environment of the mesh. In the presence of infection, for example, some biological meshes break down more rapidly and weaken before remodelling can occur, leading to early hernia recurrence. Others are more resistant to breakdown, particularly those with chemical cross-linking between the fibrous strands. The choice of biological mesh depends on the clinical situation for which it is to be used. They are expensive, and their precise role in abdominal wall hernia repair has yet to be fully established.

Absorbable meshes

Synthetic absorbable meshes such as those made from polyglycolic acid, collagen or polyhydroxybutyrate may be used in temporary abdominal wall closure and for short-term buttressing suture lines but are not recommended in hernia repair as they are absorbed too quickly and induce only minimal collagen deposition. In recent years a number of synthetic, slowly absorbable meshes have been developed. These are designed to be gradually degraded by the body and replaced with strong native collagenous fibrosis in order to create a lasting repair. The long-term outcomes of repairs using these meshes are as yet unknown.

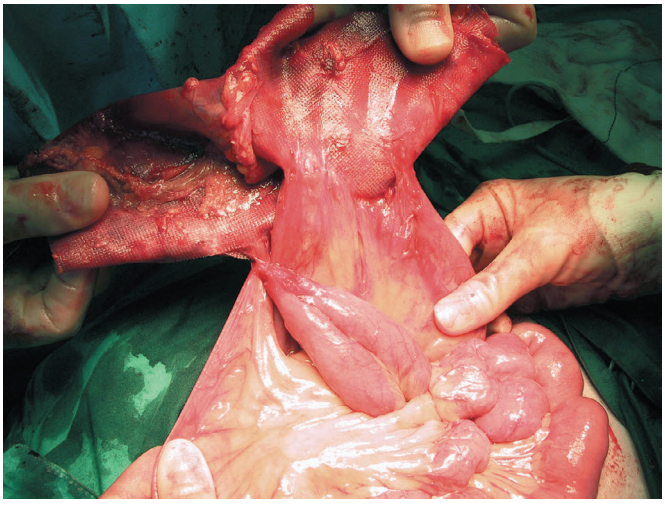

Figure 64.7 Adhesions to intraperitoneal mesh causing bowel obstruction.

Tissue-separating meshes

Most standard meshes induce fibrosis and, if placed within the peritoneal cavity, promote unwanted adhesions. A number of meshes have been designed for intraperitoneal use. Most of these have two very different surfaces, one being sticky and one slippery. Good adherence and host-tissue ingrowth is required on the parietal (fascia/muscle/peritoneum) side of the mesh, but the opposite (bowel) side needs to prevent adhesions to the abdominal contents. Usually, one side of the mesh is coated by material that prevents adhesions, such as polycellulose, collagen or PTFE. However, none of these materials is 100% effective at preventing adhesions and consequently intraperitoneal placement of mesh is associated with bowel obstruction, mesh erosion and fistulation (***Figure 64.7***). Surgeons now try to avoid intraperitoneal mesh placement whenever possible.

Summary box 64.7

Mesh characteristics

- Net (woven or knitted) or sheet
- Synthetic or biological – mainly synthetic
- Large pore, small pore – large pore causes less fibrosis and pain
- If for intraperitoneal use – non-adhesive surface on one side
- Non-absorbable or absorbable – mainly non-absorbable

Positioning the mesh

The strength of a mesh repair depends on host-tissue ingrowth. Meshes should be laid in a tension-free manner on a firm, well-vascularised tissue bed with generous overlap of the hernia zone. The mesh can be placed:

- on top of the muscle/fascia in the subcutaneous space (onlay);
- within the defect (inlay);
- immediately deep to the muscle layers in the abdominal wall (sublay);
- extraperitoneally;
- intraperitoneally.

Each of these planes may be used with both open and laparoscopic techniques (***Figure 64.8***). Onlay meshes may become

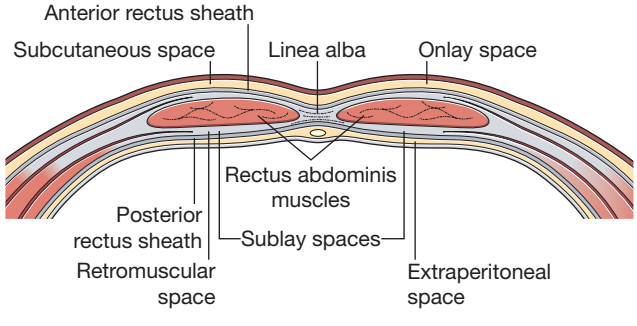

Figure 64.8 Diagrammatic representation of the various layers into which meshes are placed in ventral hernia repair.

exposed in the event of wound breakdown, and the elevation of skin flaps to allow wide overlap can lead to skin ischaemia and/or seroma formation. Inlay meshes are not recommended as they are effectively no more than a suture repair at each mesh–tissue interface. Meshes placed deep to the abdominal wall muscle layers have a mechanical advantage over onlay positioning as the abdominal pressure helps to keep the mesh in place; both sublay and extraperitoneal mesh placement techniques are generally preferred. Intraperitoneal mesh is associated with complications described earlier and many surgeons now try to avoid this.

Limitations to the use of mesh

The presence of infection limits the use of mesh. If a mesh becomes infected then it usually needs to be removed, although some infected situations can be salvaged using a combination of debridement, appropriate antibiotics and modern vacuum-assisted dressings.

Meshes are expensive, especially biological, biodegradable or those for intraperitoneal use. Price or novelty is not always an indicator of quality or safety and a simple, non-absorbable, large-pore synthetic mesh is nowadays seen as the safest implant.

SPECIFIC HERNIA TYPES

Hernia sites are shown in ***Figure 64.9***.

Inguinal hernia

Inguinal hernia, often referred to as a 'rupture' by patients, is the most common hernia in men and is around 10 times more common in men than in women. There are two basic types that are fundamentally different in anatomy, causation and complications. However, they are anatomically very close to each other, the surgical repair techniques are very similar and ultimate reinforcement of the weakened anatomy is identical, so they are often referred to together as inguinal hernia.

Summary box 64.8

Inguinal hernia

- Types – indirect (lateral, or oblique) or direct (medial)
- Origin – congenital or acquired
- Anatomy – inguinal canal
- Diagnosis – usually clinical but radiological in special circumstances
- Surgery – open or minimally invasive (laparoscopic/robot assisted)

Congenital inguinal hernias are of the indirect type, whereas the acquired hernias may be either indirect or direct.

Anatomy of the inguinal canal

As the testis descends from the abdominal cavity to the scrotum it passes through a defect in the transversalis fascia called the deep inguinal ring, just deep to the abdominal muscles. This ring lies midway between the anterior superior iliac spine and the pubic tubercle, approximately 2–3 cm above and marginally lateral to the femoral artery pulse in the groin. The inferior epigastric vessels lie just medial to the deep inguinal ring, passing from the iliac vessels to rectus abdominis. Muscle fibres from the innermost two layers of the lateral abdominal wall, the transversus muscle and the internal oblique muscle, arch over the deep inguinal ring from lateral to medial before descending to become attached to the pubic tubercle. These two muscles fuse and become tendinous, forming the conjoint tendon. Below this arch there is no muscle but only transversalis fascia and external oblique aponeurosis, resulting in an area of weakness (***Figure 64.10***).

The testis proceeds medially and downwards along the inguinal canal. Anterior to the canal is the aponeurosis of the external oblique muscle, the fibres of which run downwards and medially. The testis finally emerges through an inverted V-shaped defect in the aponeurosis, the superficial inguinal ring, and descends into the scrotum.

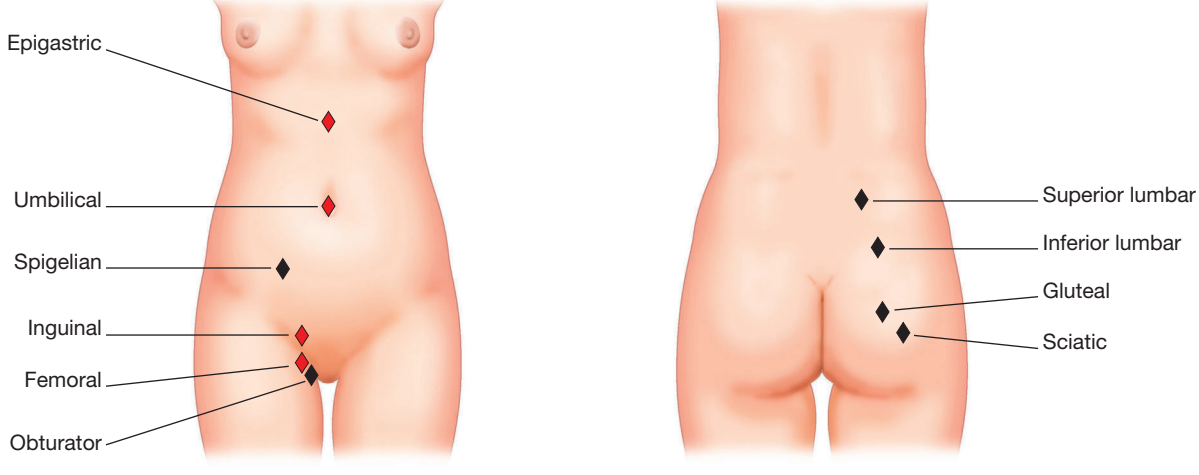

Figure 64.9 Diagram to show the sites of abdominal wall hernias: common in red and rare in black. Incisional and parastomal hernias can be found at various sites.

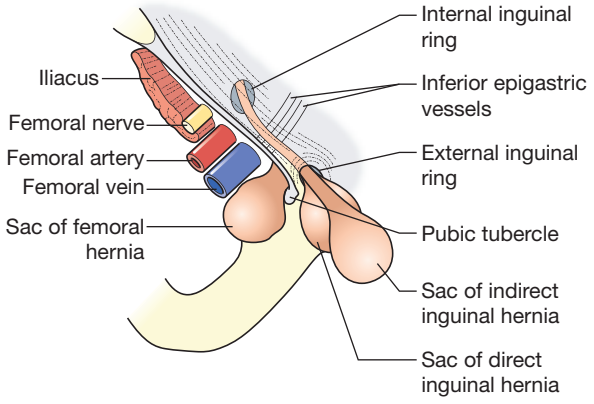

Figure 64.10 The close relationships of direct inguinal, indirect inguinal and femoral hernias.

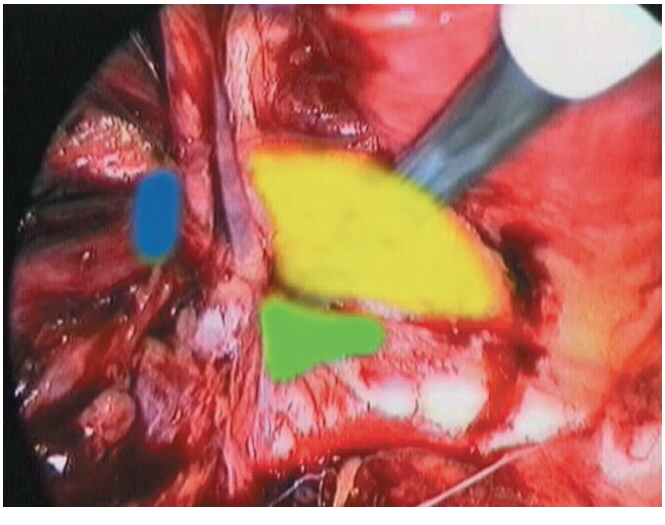

The inguinal canal is roofed by the conjoint tendon; its posterior wall is transversalis fascia, the anterior wall is the external oblique aponeurosis and the floor is the free inferior edge of the external oblique aponeurosis, rolled inwards thickened to become the inguinal (Poupart's) ligament. The inguinal canal in males contains the testicular artery, veins, lymphatics and the vas deferens all covered in cremasteric muscle. In females, the round ligament descends through the canal to end in the labia majora. Three important nerves, the ilioinguinal, the iliohypogastric and the genital branch of the genitofemoral nerve, also pass through the canal.

As the testis descends, a tube of peritoneum is pulled with the testis and wraps around it ultimately to form the tunica vaginalis. This peritoneal tube should obliterate, possibly under hormonal control, but it commonly fails to do so completely. As a result, bowel within the peritoneal cavity can pass inside the tube towards the scrotum. Inguinal hernias in neonates and children are always of this congenital type. However, in other patients, the muscles around the deep inguinal ring can prevent a hernia from developing until later in life, when, under the constant positive abdominal pressure, the deep inguinal ring and muscles are stretched and a hernia becomes apparent. As the hernia increases in size, the contents are directed down into the scrotum. These hernias can become massive and may be referred to as a scrotal hernia. An indirect hernia is lateral because its origin is lateral to the inferior epigastric vessels. It is also oblique as the hernia passes obliquely from lateral to medial through the abdominal muscle layers. An indirect hernia can pass all the way down to the scrotum, following the line of the processus vaginalis, while this is not possible with a direct hernia.

The second type of inguinal hernia, referred to as direct or medial, is always acquired. It is a result of stretching and weakening of the abdominal wall just medial to the inferior epigastric vessels, an area known as Hesselbach's triangle, the three sides of which are the inferior epigastric vessels laterally, the lateral edge of rectus abdominis muscle medially and the inguinal ligament below (the iliopubic tract) (***Figure 64.11***). This area is weak because the abdominal wall at this point consists of only transversalis fascia covered by the external oblique aponeurosis.

A direct medial hernia is more likely in elderly patients. It is broadly based and therefore unlikely to strangulate. The bladder can be pulled into a direct hernia (***Figure 64.12***).

Inguinal hernias are sometimes referred to as 'sliding' in type. These are acquired indirect hernias arising at the deep inguinal ring lateral to the inferior epigastric vessels. Retroperitoneal fatty tissue is pushed downwards along the inguinal canal. As more tissue enters the hernia, peritoneum is pulled with it, thus creating a sac. However, the sac has formed secondarily, distinguishing it from a classic indirect hernia. On the left side, sigmoid colon may descend into a sliding hernia and

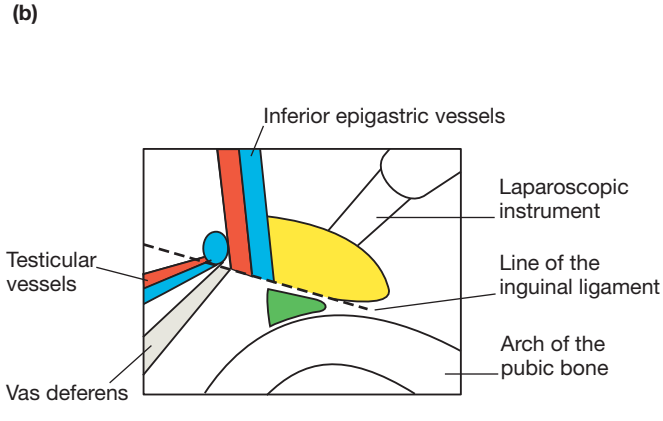

Figure 64.11 (a) Laparoscopic view of the left inguinal region with hernia defects highlighted: yellow, Hesselbach's triangle (medial or direct inguinal); blue, lateral or indirect inguinal; green, femoral. **(b)** Diagrammatic representation of **(a)**.

Francois Poupart, 1661–1709, physician and anatomist, Hôtel Dieu, Reims, France, described the inguinal ligament in 1705 although it had been described in 1561 by **Gabrielle Fallopius**, 1523–1563, Professor of Anatomy, Padua, Italy.
Franz Kaspar Hesselbach, 1759–1816, surgeon and anatomist, Würzburg, Germany.

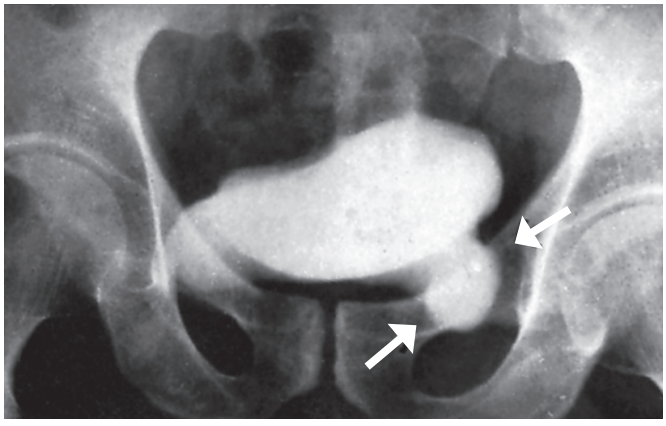

Figure 64.12 A cystogram showing that part of the urinary bladder has descended into a left direct inguinal hernia (arrows).

the caecum may do so on the left. Surgeons need extra caution during repair because the bowel may form part of the sac itself and can be damaged during the dissection.

Occasionally, both lateral and medial hernias are present in the same patient (pantaloon hernia).

Classification

Many ways to classify inguinal (and femoral) hernias have been described. The European Hernia Society has recently suggested a simplified system of:

- primary or recurrent (P or R);
- lateral, medial or femoral (L, M or F);
- defect size in fingerbreadths (assumed to be 1.5 cm), with three sizes of one fingerbreadth or less, between one and three fingerbreadths and three or more fingerbreadths.

A primary indirect inguinal hernia with a 3-cm defect size would be PL2.

Diagnosis of an inguinal hernia

In most cases, the diagnosis of an inguinal hernia is simple. Often the hernia will reduce on lying and reappear on standing. With the patient lying down, the patient is asked to reduce the hernia if it has not spontaneously reduced. If the patient cannot then the surgeon gently attempts to reduce the hernia. Once reduced, the surgeon identifies the bony landmarks of the anterosuperior iliac spine and pubic tubercle, from which the location of the deep inguinal ring can be found just above the midpoint of the inguinal ligament. Gentle pressure is applied at this point and the patient asked to cough. If the hernia is controlled with pressure on the deep inguinal ring then it is likely to be indirect/lateral; if the hernia appears medial to this point despite local pressure, then it is direct/medial. Other examination techniques have been suggested but even experienced surgeons find it difficult to distinguish lateral and medial hernias with certainty (***Figure 64.13***).

Diagnostic difficulties

Confirmation of the diagnosis may not be possible when the patient describes an intermittent swelling but nothing is found on examination. Surgeons will often accept the diagnosis on history alone but re-examination at a later date or investigation by ultrasound scan may be requested.

If an inguinal hernia becomes irreducible and tense there may be no cough impulse. Differential diagnosis would include a groin lymph node mass, psoas abscess, subcutaneous soft tissue mass (e.g. lipoma) or an abdominal mass. Such cases may require investigation by either ultrasonography or CT.

Large scrotal hernias may be misdiagnosed as a hydrocele or other testicular swelling. The surgeon should be able to identify the upper limit of a swelling that arises from within the scrotum, but a large scrotal hernia has no upper limit because it extends back along the inguinal canal to the peritoneal cavity. In cases of doubt, ultrasonography or CT should establish the diagnosis.

As inguinal hernia is so common, less experienced clinicians might suggest this diagnosis when referring cases of femoral hernia or Spigelian hernia. A saphena varix may present as a groin swelling that increases in size on standing and with a definite cough impulse and be misdiagnosed as a hernia, particularly in pregnant women.

It is essential in men to examine the scrotal contents to exclude other pathologies and to check that the patient has both testes. It is also important to examine the opposite side because contralateral hernia is common. A patient with a single hernia has a 50% lifetime risk of developing a hernia on the other side. Some surgeons have suggested that patients should be offered bilateral repair, especially if laparoscopic surgery is planned, but this is not widespread practice at present.

Figure 64.13 Oblique left inguinal hernia that became apparent when the patient coughed and persisted until it was reduced when he lay down.

Investigations for inguinal hernia

Most cases require no diagnostic tests but ultrasonography, CT and MRI are occasionally used and show excellent anatomical detail but may miss groin hernias because they tend to reduce spontaneously in supine patients.

Management of inguinal hernia

It is safe to recommend no active treatment in cases of early asymptomatic direct hernia, particularly in elderly patients who do not wish for surgical intervention. These patients should be warned to seek early advice if the hernia increases in size or becomes symptomatic. Surgical trusses are not recommended. Elective surgery for inguinal hernia can be undertaken under local, regional or general anaesthesia with minimal risk, even in high-risk patients.

Herniotomy

In children who have lateral hernias with a persistent processus vaginalis, it is sufficient just to excise and close the sac. This is called a herniotomy (see ***Chapter 18***). In adult surgery, herniotomy alone has a high recurrence rate and some form of muscle-strengthening repair (herniorrhaphy) is recommended.

Open suture repair

In 1890, Edoardo Bassini described a suture repair for inguinal hernia that remained the basis of open repair for over 100 years (***Figure 64.14***). The surgeon enters the inguinal canal by opening its anterior wall, the external oblique aponeurosis. The spermatic cord is dissected free and the presence of a lateral or a medial hernia is confirmed. The sac of a lateral hernia is separated from the cord, opened and any contents reduced. The sac is then sutured closed at its neck and excess sac removed. If there is a medial hernia then the sac is inverted and the transversalis fascia is suture plicated. Sutures are now placed between the conjoint tendon above and the inguinal ligament below, extending from the pubic tubercle to the deep inguinal ring. The posterior wall of the inguinal canal is thus strengthened.

Over 150 modifications to Bassini's operation have been described with little or no benefit except for the Shouldice modification. In this operation, the transversalis fascia is opened by a central incision from the deep inguinal ring to the pubic tubercle and then closed to create a two-layered posterior wall (double breasting). The external oblique is closed in a similar fashion. Expert centres have reported lifetime failure rates of less than 2% after Shouldice repair but it is a technically demanding operation that, in most hands, gives results similar to those of a Bassini repair.

Today, when a Bassini-type operation is done, most surgeons use a continuous, non-absorbable nylon or polypropylene suture that is darned between the conjoint tendon and inguinal ligament (Maloney). This operation gives excellent results and is the most common operation performed in countries where mesh is too expensive.

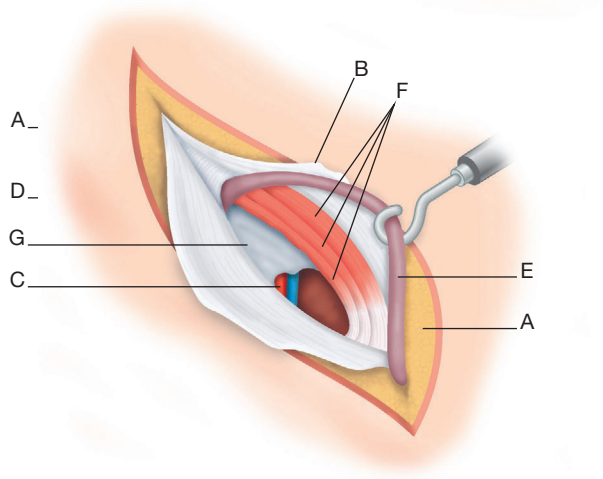

Figure 64.14 Inguinal canal anatomy as shown in Bassini's original diagram (1890). A, subcutaneous fat; B, external oblique aponeurosis (opened); C, inferior epigastric vessels; D, Poupart's (inguinal) ligament; E, spermatic cord retracted; F, the conjoint tendon (triple layer of lesser oblique, transversus abdominis and Cooper's (cremasteric) fascia); G, transversalis fascia.

Desarda has described an operation where a 1- to 2-cm strip of external oblique aponeurosis lying over the inguinal canal is isolated from the main muscle, but left attached both medially and laterally. It is then sutured to the conjoint tendon and inguinal ligament, reinforcing the posterior wall of the inguinal canal. As the abdominal muscles contract, this strip of aponeurosis tightens to add further physiological support to the posterior wall. This operation is currently seen as equivalent to Shouldice repair.

Open flat mesh repair

Synthetic mesh has been used since the 1950s to reinforce hernia repair, and in the 1980s Lichtenstein described a tension-free, simple, flat, polypropylene mesh repair for inguinal hernia (***Figure 64.15***). The initial part of the operation is identical to Bassini's. Once the hernia sac has been removed and any medial defect closed, a piece of mesh measuring 8 × 15 cm is placed over the posterior wall, behind the spermatic cord, and is slit to wrap around the spermatic cord at the deep inguinal ring. Loose sutures hold the mesh to the inguinal ligament and conjoint tendon. Two major advantages are claimed: lower hernia recurrence rates and accelerated postoperative recovery. Randomised trials show that hernia recurrence within the first 2 years is lower but acute pain scores are similar. Recent research comparing Lichtenstein's repair with laparoscopic surgery has identified chronic pain as the most common complication of open flat mesh repair with rates reported as

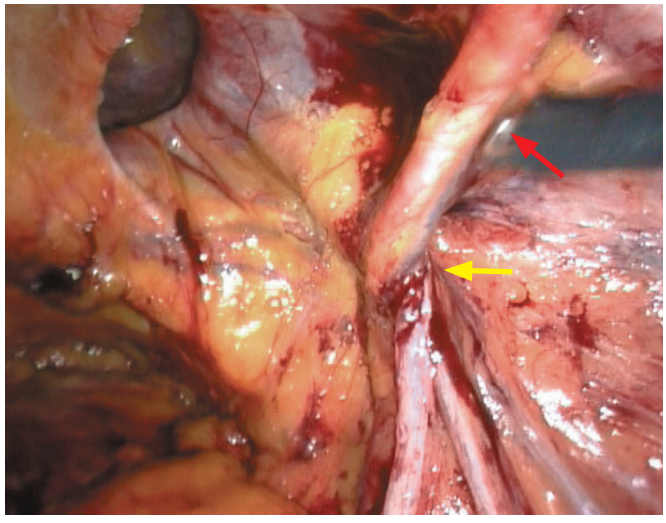

Figure 64.16 Right medial/direct inguinal hernia: laparoscopic view. Note the inferior epigastric vessels (red arrow) and contents of the spermatic cord passing through the deep ring (yellow arrow).

high as 20%. Nevertheless, today, Lichtenstein's repair is the most common operation for inguinal hernia in resource-rich countries.

Open plug/device/complex mesh repair

Shaped mesh plugs have been developed in an attempt to improve on simple flat mesh repair. They are simple to insert and require little if any fixation. However, they can become solid (meshoma) and migrate/erode into adjacent structures such as the urinary bladder. Other meshes have been designed to be placed beneath the transversalis fascia. There is little evidence that any of these techniques are superior to Lichtenstein's operation and use is not recommended in the 2018 European Hernia Society groin hernia guidelines.

Open preperitoneal repair

The preperitoneal approach was first described by Annandale in 1880, but was largely discarded until the 1950s when Stoppa described it with mesh reconstruction through a midline incision. It is useful when multiple attempts at open standard surgery have failed and the hernia(s) keeps recurring. It has been largely superseded by the totally extraperitoneal laparoscopic approach, which is modelled on Stoppa's operation.

Laparoscopic inguinal hernia repair

Two techniques are described and have been extensively studied: the totally extraperitoneal (TEP) and the transabdominal preperitoneal (TAPP) approach. In both, the aim of surgery is to reduce the hernia and hernia sac from within the abdomen and place a 10 × 15 cm mesh (or larger) in the preperitoneal plane, just deep to the abdominal wall extending medially into the retropubic space and at least 5 cm lateral to the deep inguinal ring (***Figure 64.16***). The mesh covers Hesselbach's triangle, the deep inguinal ring and the femoral canal. In TEP, the surgeon develops the extraperitoneal plane just deep to the abdominal muscles, taking care not to enter the peritoneal cavity. In TAPP, the surgeon enters the peritoneal cavity first and incises the peritoneum above the hernia defect to open up the extraperitoneal space as in TEP.

Compared with an open approach, the laparoscopic approach is associated with reduced pain both immediately after surgery and up to 5 years later, more rapid return to full activity and a reduced incidence of wound complications such as infection, bleeding and seroma. Laparoscopic surgery is of particular benefit in bilateral hernias and in patients with hernia recurrence after open surgery. The proportion of cases performed laparoscopically is slowly rising, but there is a long learning curve.

The increasing use of robot-assisted laparoscopic inguinal hernia surgery is evident. To date, little additional patient benefit has been noted, although the enhanced surgical view of the robot and the ergonomic comfort for the surgeon are compelling reasons to utilise this platform. The cost of using a robot for simple inguinal repair remains hard to justify.

Tailored approach

A number of surgical approaches and operations are available, as noted in ***Summary box 64.9.*** No one operation suits all hernias. Taking into account the surgeon's skills, equipment available, patient type and hernia characteristics will aid a preoperative discussion as to which repair is best, or indeed whether no operation at all is the best management plan.

Thomas Annandale, 1838–1907, Regius Professor of Surgery, Edinburgh, UK.
Rene Stoppa, 1921–2006, surgeon, Amiens, France.

Summary box 64.9

Operations for inguinal hernia

- Herniotomy
- Open suture repair
  - Bassini
  - Shouldice
  - Desarda
  - Maloney darn
- Open flat mesh repair
  - Lichtenstein
- (Open complex mesh repair – not recommended
  - Mesh plugs
  - Hernia systems)
- Open preperitoneal repair
  - Transinguinal, Stoppa repair
- Laparoscopic/robot-assisted repair
  - TEP
  - TAPP

Emergency inguinal hernia surgery

Approximately 5% of inguinal hernias present as an irreducible, painful lump that may progress to strangulation and possible bowel infarction. Time is critical in the presence of ischaemic bowel. The principles of surgery are the same as in an elective setting. Open or laparoscopic surgery is possible depending on the local facilities, the surgeon's skills and the patient's characteristics. Approximately 20% of patients who present as an emergency require bowel resection. This may require conversion to a midline laparotomy, which adds significantly to postoperative morbidity and mortality. Surgical site infection may complicate emergency cases but, unless there is significant infection/contamination, use of synthetic mesh is acceptable as long as the operation is covered by appropriate antibiotics.

Complications of inguinal hernia surgery

Despite inguinal hernia repair being a common procedure, postoperative complications are common. Immediate complications include bleeding or haematoma (usually from subcutaneous vessels but occasionally from accidental damage to the inferior epigastric or iliac vessels). Urinary retention may require catheterisation. Infusion of local anaesthetic may lead to femoral nerve blockade that will resolve over some hours.

Within the first week, pain, bruising and swelling are common while seroma formation and wound infection are less frequent. Seroma is due to an inflammatory response to dissection, sutures or mesh and is more common if the peritoneal sac is left *in situ*. In most cases the fluid resolves spontaneously but may require aspiration. After laparoscopic surgery, a seroma may be misdiagnosed as an early recurrence. Despite the potential of bacterial contamination of a groin incision and use of mesh, routine use of antibiotics is not recommended in recent guidelines.

In the longer term, hernia recurrence and chronic pain are the main concerns. No operation can be guaranteed to be recurrence free and good centres aim for a 5-year recurrence rate of less than 5%. Mesh repairs have lower recurrence rates than suture repairs, but there is no difference between the various mesh repairs and no difference between open and laparoscopic surgery. There is very strong evidence that specialist hernia surgeons have lower recurrence rates and chronic pain rates whatever technique they use.

Chronic pain, defined as pain persisting for more than 3 months after surgery, is common after all forms of surgery and possibly affects as many as 20% of patients after groin hernia repair. It is less common and less severe after laparoscopic surgery. Different types of pain have been described but the most severe is neuralgic pain due to nerve irritation. This may be the result of nerve injury at the time of operation or chronic irritation of nerves by suture material or mesh. Chronic pain has become one of the main areas of focus when comparing inguinal hernia outcomes. Patients at higher risk of chronic pain include females, the young, those with a painful hernia, those with a chronic pain syndrome, those with an exaggerated response to a heat stimulus and those with certain psychological tendencies. In addition, the handling of the nerves at open surgery is thought to be important. The variation of anatomy of the three nerves should be considered during the dissection, keeping nerves contained within their connective tissue surroundings when possible. In laparoscopic surgery, placing sutures or staples/tacks into the retroperitoneal area should be avoided for fear of causing nerve injury. If a nerve requires to be sacrificed, this should be done as proximally as practicable and the nerve end buried within the muscle belly.

Rarely, damage to the testicular artery can lead to testicular infarction, perhaps the most serious complication of inguinal hernia surgery in a young man. There is no evidence that hernia surgery has an effect on male fertility despite extensive study in this area.

Summary box 64.10

Complications

- Early: pain, bleeding/haematoma, urinary retention
- Medium: seroma, wound infection
- Late: chronic pain, testicular atrophy

Sportsman's groin

This specific entity is well described and presents with severe pain in the groin area, often extending into the upper thigh and the scrotum in men. It is seen in both men and women who play contact sports such as football and rugby. The pain can be debilitating and prevent the patient from exercising. On examination there may be some tenderness in the region of the inguinal canal, over the pubic tubercle and over the insertion of the thigh adductor muscles. Tightening the hip flexor or thigh adductor muscles against resistance may reproduce the pain. Usually no hernia is present.

In most cases, the pain is due to adductor strain or pubic symphysis diastasis. However, some believe that it can be due to muscle tearing (Gilmore's groin) or stretching of the

posterior wall of the inguinal canal. Other causes of pain should be excluded, such as hip, pelvic or lumbar spinal disease and bladder/prostate problems. MRI is most likely to detect a musculoligamentous problem but ultrasonography or laparoscopy may be used to exclude an underlying hernia.

Hernia surgery should be a last resort and the patient should be warned of a significant risk of failure to relieve the pain. The same is true for patients with groin pain and no obvious hernia, even if a small hernia is noted on groin ultrasound.

Femoral hernia

Basic anatomy

The external iliac artery and vein pass below the inguinal ligament to become the common femoral vessels in the leg. The vein lies medially and the artery is lateral to the vein, with the femoral nerve lateral to the artery. They are enclosed in a fibrous sheath. Just medial to the vein is a small space containing fat and some lymphatic tissue (node of Cloquet). It is this space, the femoral canal, that is exploited by a femoral hernia. The boundaries of the femoral canal are the femoral vein laterally, the inguinal ligament anteriorly, the pelvic bone covered by the iliopectineal ligament (Astley Cooper's) posteriorly and the lacunar ligament (Gimbernat's) medially. This is a strong curved ligament with a sharp unyielding edge that impedes reduction of a femoral hernia (***Figure 64.17***).

The female pelvis has a different shape from the male, increasing the size of the femoral canal and the risk of hernia. In old age, the femoral defect enlarges further and femoral hernia is commonly seen in thin, elderly women.

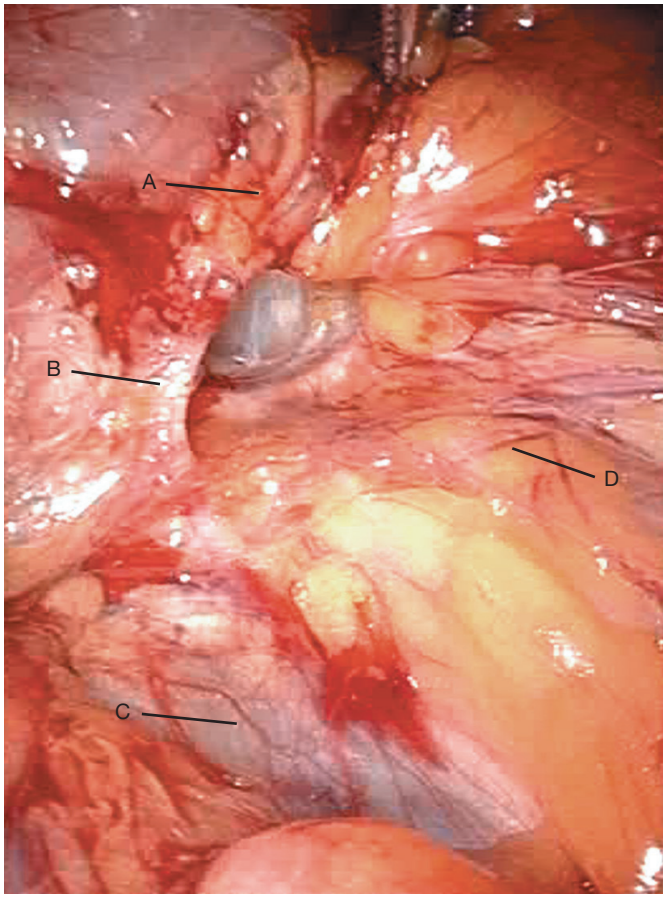

Figure 64.17 Right femoral hernia: laparoscopic view. The slightly oblique inguinal ligament can be seen superolaterally above the defect. The external iliac vein is not seen. A, inguinal ligament; B, lacunar ligament; C, arch of pubic bone; D, fatty tissue overlying iliac vessels.

Summary box 64.11

Femoral hernia

- Less common than inguinal hernia
- More common in women than in men
- Easily missed on examination
- 50% present as an emergency with very high risk of strangulation

Diagnosis of femoral hernia

Diagnostic error is common and often leads to delay in diagnosis and treatment. The hernia appears below and lateral to the pubic tubercle and lies in the upper leg rather than in the lower abdomen. Inadequate exposure of this area during routine examination leads to failure to detect the hernia. The hernia often rapidly becomes irreducible and loses any cough impulse owing to the tightness of the neck. It may only be 1–2 cm in size and can easily be mistaken for a lymph node. As it increases in size, it is reflected superiorly and becomes difficult to distinguish from a medial direct hernia, which arises only a few centimetres above the femoral canal.

Summary box 64.12

Differential diagnosis

- Inguinal hernia
- Lymph node
- Saphena varix
- Femoral artery aneurysm
- Psoas abscess
- Rupture of adductor longus with haematoma

Investigations

In routine cases, no specific investigations are required. However, if there is uncertainty then ultrasonography or CT should be requested. In the emergency patient, bowel obstruction is often present and a plain radiograph is likely to show this. All patients with unexplained small bowel obstruction should undergo careful examination for a femoral hernia.

Jules Germain Cloquet, 1790–1883, Professor of Anatomy and Surgery, Paris, France.
Manoel Louise Antonio don Gimbernat, 1734–1816, Professor of Anatomy, Barcelona, Spain.

It is now common to perform CT scanning in cases of bowel obstruction primarily to exclude malignancy, but it can identify an obstructing femoral hernia missed by clinicians.

Surgery for femoral hernia

There is no alternative to surgery for femoral hernia and it is wise to treat such cases with some urgency. There are three open approaches and appropriate cases can be managed laparoscopically.

Low approach (Lockwood)

This is the simplest operation for a femoral hernia but suitable only when there is no risk of bowel resection. It can easily be performed under local anaesthesia. A transverse incision is made over the hernia. The sac of the hernia is opened and its contents reduced. The sac is also reduced and non-absorbable sutures are placed between the inguinal ligament above and the pectineal ligament overlying the pubic bone below. A small incision can be made in the medial lacunar ligament to aid reduction but there may be an abnormal branch of the obturator artery just deep to it, which can bleed. The femoral vein, lateral to the hernia, needs to be protected. Some surgeons place a mesh plug into the hernia defect for further reinforcement.

The inguinal approach (Lotheissen)

The initial incision is identical to that of Bassini's or Lichtenstein's operation into the inguinal canal. The spermatic cord (or round ligament) is mobilised and the transversalis fascia opened from the deep inguinal ring to the pubic tubercle, avoiding injury to the inferior epigastric vessels. This gains entry into the extraperitoneal space. A femoral hernia lies immediately below this incision and can be reduced by a combination of pulling from above and pushing from below. If necessary, the peritoneum can be opened to deal with the contents. Once reduced, the neck of the hernia is closed with sutures or a mesh plug, protecting the external iliac vein throughout; alternatively, a sheet of flat mesh may be laid over the defect in the extraperitoneal plane. The layers are closed as for inguinal hernia and the surgeon may place a mesh into the inguinal canal to protect against development of an inguinal hernia.

High approach (McEvedy)

This more complex operation is ideal in the emergency situation where the risk of bowel strangulation is high. It requires regional or general anaesthesia. Although McEvedy described a paramedian incision, most surgeons nowadays use the Nyhus modification, which is a transverse incision just above the inguinal canal, centred on the lateral border of the rectus muscle. The anterior rectus sheath is incised and the rectus muscle retracted. The surgeon proceeds deep to the muscle in the preperitoneal space. The femoral hernia is reduced and the sac opened to allow careful inspection of the hernia contents. In dubious cases, the bowel is replaced into the peritoneal cavity for 5 minutes and then re-examined. The femoral defect is then closed with sutures or mesh.

This approach allows a generous incision to be made in the peritoneum, which aids inspection of the bowel and facilitates bowel resection. Bowel resection is not possible via the low (Lockwood) approach because the completed anastomosis will not be able to be returned to the abdominal cavity through the narrow femoral canal. The preperitoneal approach may be extended to gain access to repair bilateral femoral hernias through a single incision (Henry).

Laparoscopic approach

Both the TEP and TAPP approaches can be used for a femoral hernia and a standard mesh inserted in the extraperitoneal plane. This is ideal for reducible femoral hernias presenting electively, but there are increasing reports of the laparoscopic approach in the emergency setting, mainly with the TAPP approach.

In women, the laparoscopic approach is recommended because of the increased early recurrence observed in women, thought to relate more to misdiagnosis of the hernia (inguinal versus femoral) than true recurrence. The laparoscopic approach allows good visualisation of all the hernia orifices, removing any diagnostic uncertainty.

VENTRAL HERNIA

This term refers to hernias of the anterior abdominal wall. Inguinal and femoral hernias are not included, however lumbar hernia is included despite being dorsolateral. The European Hernia Society classification (2009) distinguished primary ventral from incisional hernia but did not include parastomal hernia, which is included in this section.

Summary box 64.13

Primary ventral hernias
- Umbilical
- Epigastric
- Spigelian
- Lumbar
- Traumatic

'Secondary' ventral hernias
- Incisional
- Parastomal

Umbilical hernia

The umbilical defect is present at birth but closes as the stump of the umbilical cord heals, usually within a week of birth. This process may be delayed, leading to the development of herniation in the neonatal period. The umbilical ring may also stretch and reopen in adult life.

Charles Barrett Lockwood, 1856–1914, surgeon, St Bartholomew's Hospital, London, UK.
George Lotheissen, 1868–1941, surgeon, the Kaiser Franz Joseph Hospital, Vienna, Austria.
Peter George McEvedy, 1890–1951, surgeon, Ancoats Hospital, Manchester, UK.
Lloyd Milton Nyhus, 1923–2008, Chief of Surgery, University of Illinois, Chicago, IL, USA.
Arnold K Henry, 1886–1962, Professor of Surgery, Cairo, later Anatomy Professor, Royal College of Surgeons in Ireland, Dublin, Ireland.

Umbilical hernia in children

This common condition occurs in up to 10% of infants, with a higher incidence in premature babies. The hernia appears within a few weeks of birth and is often symptomless, but increases in size on crying and assumes a classic conical shape. Sexes are equally affected but the incidence in black infants is up to eight times higher than in white. Obstruction and/or strangulation is extremely uncommon below the age of 3 years.

Treatment

Conservative treatment is indicated under the age of 2 years when the hernia is symptomless. Parental reassurance is all that is necessary as 95% will resolve spontaneously. If the hernia persists beyond the age of 2 years surgical repair is indicated.

Surgery

A small, curved incision is made immediately below the umbilicus. The neck of the sac is defined, opened and any contents are returned to the peritoneal cavity. The sac is closed and redundant sac excised. The defect in the linea alba is closed with interrupted sutures of slowly absorbable material.

Summary box 64.14

Umbilical hernia in children

- Common in infants and most resolve spontaneously
- Rarely strangulate

Umbilical hernia in adults

Conditions that cause stretching and thinning of the midline raphe (linea alba), such as pregnancy, obesity and liver disease with cirrhosis and ascites, predispose to reopening of the umbilical defect. In adults, the defect can be not only through the umbilicus but also in the median raphe (linea alba) immediately adjacent to (most often above) the true umbilicus. The latter are commonly called 'paraumbilical' hernias; however, under current guidelines, any hernia in the immediate vicinity of the umbilicus can now be called 'umbilical'. Small umbilical hernias often contain extraperitoneal fat or omentum. Larger hernias can contain small or large bowel. Because the hernia neck is relatively narrow in relation to the size of the sac, they are prone to become irreducible, obstructed and strangulated.

Clinical features

Umbilical hernias are commonly seen in overweight men with a thinned and attenuated midline raphe or in postpartum women with a weakened abdominal wall. The bulge is typically slightly to one side of the umbilical depression, creating a crescent-shaped appearance to the umbilicus (***Figure 64.18***). Women are affected more than men. Most patients complain of pain due to tissue tension or symptoms of intermittent bowel obstruction. In large hernias, the overlying skin may become very thin; while overlying skin irritation and ulceration may be seen, spontaneous rupture is extremely rare.

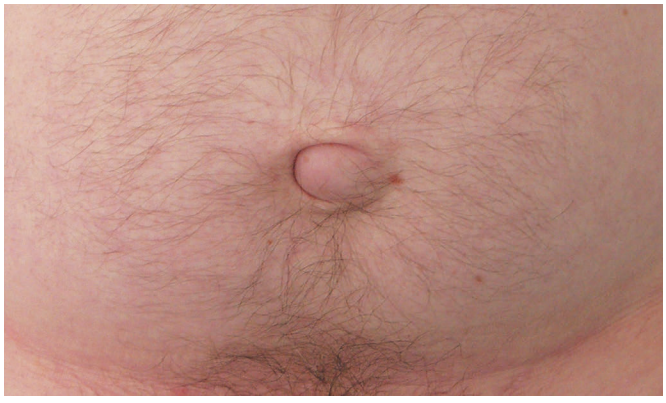

Figure 64.18 A small adult umbilical hernia.

Treatment

As a result of the high risk of strangulation, surgery should be advised in cases where the hernia contains bowel. Small hernias may be left alone if they are asymptomatic, but they may enlarge and require surgery at a later date. Surgery may be performed open or laparoscopically.

Open umbilical hernia repair

Very small defects less than 1 cm in size may be closed with a simple suture repair as long as the fascia is not closed under tension. An alternative technique utilises a darn suture where a non-absorbable, monofilament suture is criss-crossed across the defect and anchored firmly to the fascia all around. For defects up to 2 cm in diameter a transverse incision is made and the hernia sac dissected, opened and its contents reduced. The peritoneum is closed. The defect in the linea alba is extended in a transverse direction and the fascial edges are closed in an overlapping style with the superior flap on top ('waistcoat over trousers') (Mayo). Non-absorbable sutures are used and the skin is closed in a routine manner, but redundant skin may need to be excised to achieve a better cosmetic result. The Mayo repair remains popular for defects up to 2 cm, but the larger the defect the more tissue tension. Current evidence advises the use of mesh even in small defects, and certainly for all defects larger than 2 cm, owing to the high likelihood of recurrence (***Figure 64.19***).

Special circumstances

Women often develop umbilical hernias during pregnancy and may present in the early postpartum period. There is often a degree of rectus divarication. They should be advised to exercise specifically for this condition, lose weight and increase their abdominal muscle tone before operation should be considered as these may resolve completely within a few months. It is strongly recommended to avoid surgery for umbilical hernia repair before or during pregnancy.

William James Mayo, 1861–1939, surgeon, the Mayo Clinic, Rochester, MN, USA, described this operation in 1901. He and his brother **Charles Horace Mayo** (1865–1939) joined their father's (William Worrall Mayo) private practice in Rochester. This practice became the Mayo Clinic.

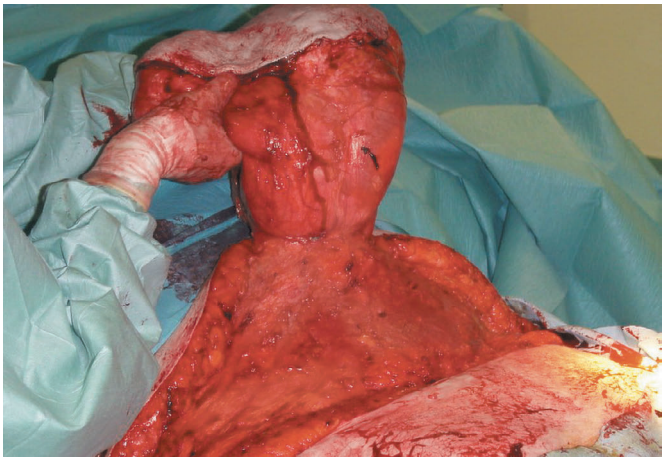

Figure 64.19 A massive umbilical hernia, intraoperative view.

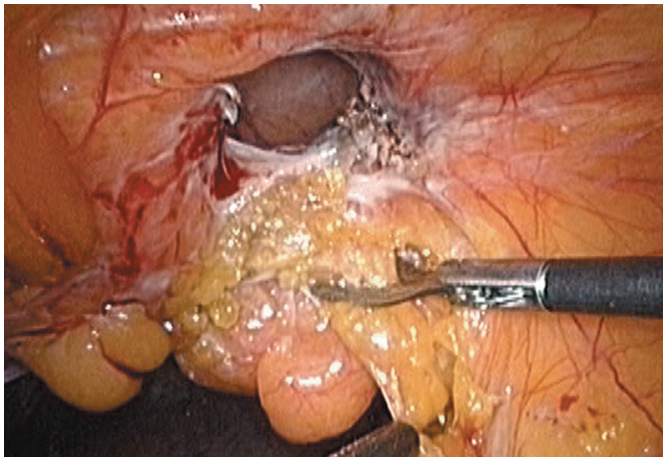

Figure 64.20 Umbilical defect: laparoscopic view, before the bulky falciform ligament has been taken down to create a smoother surface for mesh placement.

Patients with liver cirrhosis have extremely high mortality and morbidity after primary ventral hernia repair, especially with Child's B and C disease. Patient selection is very important, with appropriate hepatology support if surgery is contemplated. Fascial repair is best done with fine continuous sutures to minimise the risk of post-operative ascites leakage.

Laparoscopic umbilical hernia repair

A camera port and two working ports are placed laterally on the abdominal wall, well away from the defect. The contents of the hernia are reduced by traction and external pressure. The falciform ligament above and the median umbilical fold below may need to be taken down to create a smooth, firm surface for mesh placement (***Figure 64.20***). A disc of non-adherent mesh, designed for intraperitoneal use, is introduced and positioned on the undersurface of the abdominal wall, centred on the defect. It is then fixed to the peritoneum and posterior rectus sheaths using staples, tacks or sutures. This is a simple and secure repair, which achieves generous overlap without surgical damage to umbilicus and surrounding fascia. However, it requires specialised equipment and expensive tissue-separating mesh and brings with it all the potential problems of intraperitoneal mesh, including bowel adhesion, erosion and fistulation. Intraperitoneal meshes can cause severe pain lasting for 24–48 hours after surgery, which can mimic peritonitis. The tacks or sutures used to fix the mesh can be a source of chronic or long-lasting pain. However, this approach is associated with fewer wound complications than open repair and allows large pieces of mesh to be used, so should be considered for obese patients, those with concomitant rectus divarication and those with multiple ventral hernia defects.

Emergency repair of umbilical hernia

Incarceration, bowel obstruction and strangulation are frequent because of the narrow neck and the fibrous edge of the defect in the midline raphe. Delay to surgery can lead to gangrene of the omentum or bowel. Large hernias are often multiloculated and there may be strangulated bowel in one component when other areas are clinically soft and a non-tender hernia. Multiloculated hernias are however more common as incisional then primary ventral. Most emergency repairs are performed by open surgery. In the presence of established strangulation mesh should be avoided as the risk of infection is too high; the focus of the operation should be to deal with the strangulated tissue, so a suture repair is advised with a more definite repair to be performed at a later date if necessary.

Epigastric hernia

These hernias arise through the midline raphe (linea alba) anywhere between the xiphoid process and the umbilicus. They begin with a transverse split in the midline raphe so the defect is elliptical and usually less than 1 cm in diameter. The hernia commonly contains only extraperitoneal fat, which gradually enlarges, spreading in the subcutaneous plane to resemble the shape of a mushroom (***Figure 64.21***). When very large they may contain a peritoneal sac but rarely any bowel. More than one hernia may be present. Indeed, the most common cause of 'recurrence' is failure to identify a second defect at the time of original repair.

Clinical features

The patients are often fit, healthy men, but they are also seen in older, overweight men and women especially after multiple pregnancies. The hernia can be very painful even when the swelling is small owing to the fatty contents becoming nipped sufficiently to produce partial strangulation. It may be locally tender. It is unlikely to be reducible because of the narrow neck and may resemble a lipoma. A cough impulse may or may not be felt.

Charles Gardner Child, 1908–1991, Chair of the Departments of Surgery at Cornell University, Ithaca, NY (1947–1953), Tufts University, Boston, MA (1953–1974), and the University of Michigan, Ann Arbor, MI (1978–1983), USA.

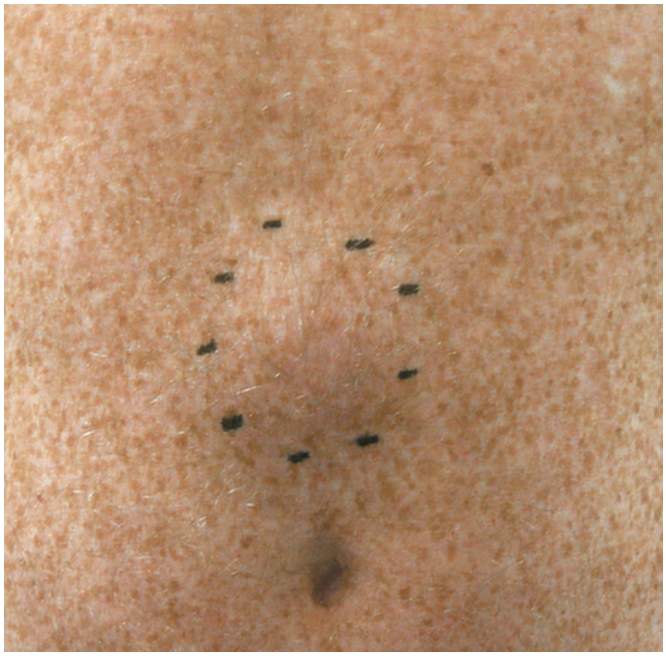

Figure 64.21 Epigastric hernia.

Treatment

Very small epigastric hernias have been known to disappear spontaneously, probably because of infarction of the fat. Small- to moderate-sized hernias without a peritoneal sac are not inherently dangerous and surgery should be offered only if the hernia is sufficiently symptomatic. Hernias containing bowel should always be repaired.

Surgery

This may be open or laparoscopic. At open surgery, a vertical or transverse incision is made over the swelling and down to the linea alba. Protruding extraperitoneal fat can simply be pushed back through the defect or excised. Often a small vessel is present in the hernia content that can cause troublesome bleeding. Small defects in the linea alba may be closed with non-absorbable sutures in adults and absorbable sutures in children; however, in larger hernias and when a peritoneal sac is present, the surgical approach is similar to that described for an umbilical mesh repair.

Laparoscopic repair is also very similar to that for umbilical hernia except that the defect is hidden behind the falciform ligament, which must first be taken down from the undersurface of the abdominal wall to allow the margins of the defect to be exposed. It is very important to fully reduce the fatty contents, as simply placing a mesh under the linea alba may leave the patient with a palpable lump if the hernia contents are extraperitoneal fat.

Spigelian hernia

These hernias are uncommon although probably underdiagnosed. They affect men and women equally and are most common in elderly people. They have also been described in infants, reflecting incomplete differentiation of the mesenchymal layers within the abdominal wall. They arise through a defect in the aponeurosis of transversus abdominis (Spigelian fascia) and may advance through the internal oblique to spread out deep to the external oblique aponeurosis. Most Spigelian hernias appear below the level of the umbilicus near the edge of the rectus sheath, but they can be found anywhere along the Spigelian line (***Figure 64.22***). There is a common misconception that they protrude below the arcuate line as a result of deficiency of the posterior rectus sheath at that level, but in fact the defect is almost always above the arcuate line. In young patients they usually contain extraperitoneal fat only, but in older patients there is often a peritoneal sac and they can become very large.

Clinical features

Young patients usually present with intermittent pain, due to pinching of the fat, similar to an epigastric hernia. A lump may or may not be palpable because the fatty hernia is small and the overlying external oblique is intact. Older patients generally present with a reducible swelling at the edge of the rectus sheath and may have symptoms of intermittent obstruction. The diagnosis should be suspected because of the location of the symptoms and is confirmed by CT. Ultrasonography has the advantage that it can be performed in the upright patient because no defect may be visible with the patient lying down.

Treatment

Surgery is recommended because the narrow and fibrous neck predisposes to strangulation. Surgery can be open or laparoscopic. At open surgery a skin crease is made over the hernia, but no abnormality will be seen until the external oblique is opened. The sac and contents are dealt with and the small defect in the Spigelian fascia is repaired by suture or mesh laid deep to the external oblique aponeurosis. The plane of the mesh can be extended medially into the posterior rectus sheath if required. The external oblique aponeurosis is closed over the mesh.

Figure 64.22 Spigelian hernia in the left iliac fossa. Note the scar from a previous left inguinal hernia repair.

Laparoscopy is useful if no sac is palpable, but, in young patients with a hernia containing only extraperitoneal fat, no hernia will be seen from within the peritoneum. In such cases, the peritoneum can be incised and the extraperitoneal plane explored for the small defect, which can then be closed by either suture or mesh. When an intraperitoneal sac is present, laparoscopic repair can be performed using either the intraperitoneal onlay of mesh (IPOM) or, more commonly now because of the risks of intraperitoneal mesh, the TAPP technique.

Summary box 64.15

Spigelian hernia

- Rare
- Often misdiagnosed
- High risk of complications

Lumbar hernia

Most primary lumbar hernias occur through the inferior lumbar triangle of Petit, bounded below by the crest of the ilium, laterally by the external oblique muscle and medially by latissimus dorsi (***Figure 64.23***). Less commonly, the sac comes through the superior lumbar triangle, which is bounded by the twelfth rib above, medially by sacrospinalis and laterally by the posterior border of the internal oblique muscle (***Figure 64.24***). Primary lumbar hernias are rare, but may be mimicked by incisional hernias arising through flank incision operations.

Figure 64.23 Inferior lumbar hernia, which contained caecum, appendix and small bowel. Note the filarial skin rash on the buttocks (courtesy of VJ Hartfield, formerly of south-east Nigeria).

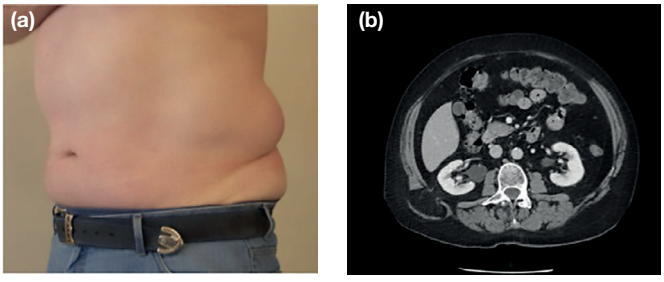

Figure 64.24 (a) Left superior lumbar hernia, containing only extraperitoneal fat. **(b)** Computed tomography scan of a similar but right-sided superior lumbar hernia. Emerging just below the twelfth rib, it is level with the right kidney and the right lobe of the liver.

Differential diagnosis

A lumbar hernia must be distinguished from:

- a lipoma;
- an incisional hernia, such as from a renal operation;
- a cold (tuberculous) abscess pointing to this position;
- a pseudohernia due to local muscular paralysis. Lumbar pseudohernia can result from any interference with the nerve supply of the affected muscles, the most common cause being injury to the subcostal nerve during a kidney operation.

Treatment

The natural history is for these hernias to increase in size and surgery is recommended. Lumbar hernias can be approached by open or laparoscopic surgery. The defects can be difficult to close with sutures alone and mesh is recommended.

The TAPP laparoscopic approach is gaining popularity for small hernias. With the patient in a semilateral position ports are inserted well away from the defect. The peritoneum is incised above the hernia and dissected back to expose the muscle defect. The content, often extraperitoneal fat, is reduced and a mesh fixed with ample overlap. The peritoneum can then be resutured or tacked back to cover the mesh.

Lumbar incisional hernias can be approached in the same way; however, large ones can be very difficult, especially if there is a component of neuropathic muscle atrophy causing a diffuse bulge (pseudohernia).

Traumatic hernia

These hernias arise through non-anatomical defects caused by injury. They can be classified into three types:

1. Hernias through abdominal stab wound sites. These are effectively incisional hernias.
2. Hernias protruding through splits or tears in the abdominal muscles after blunt trauma (***Figure 64.4***).
3. Abdominal bulging secondary to muscle atrophy that

Jean Louis Petit, 1674–1750, Director of the Academie de Chirurgie, Paris, France.

occurs as a result of nerve injury or other traumatic denervation. Akin to the lumbar pseudohernia seen after open nephrectomy, these can also arise after rib fractures with damage to the intercostal nerves.

Clinical features

Traumatic hernias present as any other hernia. The key to the aetiology is in the history and the non-anatomical location of the hernia.

Treatment

Surgery may be justified if the hernia is sufficiently symptomatic or if investigations suggest a narrow neck and hence a risk of obstruction or strangulation. CT scanning is useful to define the tissue layers that have been damaged in order to plan repair. Stab wound traumatic hernias are straightforward to repair. Diffuse abdominal bulges are more difficult to correct and require some form of plication of the stretched musculofascial layer with mesh reinforcement to prevent further bulging in the future. Some bulging may persist, however.

Figure 64.25 A large incisional hernia involving the full length of the incision.

Incisional hernia

These arise through a defect in the musculofascial layers of the abdominal wall at the site of a postoperative scar. Thus, they may appear anywhere where a laparotomy has been made.

Incidence and aetiology

Incisional hernias have been reported in 10–50% of laparotomy incisions and 1–5% of laparoscopic port-site incisions. Factors predisposing to their development include patient factors (genetic collagen disorders, obesity, general poor healing due to malnutrition, immunosuppression or steroid therapy, chronic cough, cancer), wound factors (poor quality tissues, wound tension, wound infection) and surgical factors (inappropriate suture material, poor closure technique).

An incisional hernia usually starts as disruption of the musculofascial layers of a wound in the early postoperative period. This may progress rapidly to full thickness wound dehiscence, usually heralded by a serosanguineous discharge around the sixth postoperative day, but more commonly the event passes unnoticed if the overlying skin wound has healed securely. A visible swelling may take weeks, months or years to appear. Many incisional hernias may be preventable by ensuring healthy wound edges, minimal wound tension and good surgical technique as described by the European Hernia Society abdominal wall closure guidelines. The small-stitch, small-bite technique is recommended, and the role of prophylactic mesh in high-risk patients is also a current area of research.

Clinical features

Incisional hernias commonly appear as a localised swelling involving part of a surgical scar but may present as a diffuse bulging of the whole length of the incision (***Figure 64.25***). Alternatively there may be several discrete hernias along the length of the incision, but even with apparently singular hernias unsuspected defects are frequently found at operation (***Figure 64.26***). Incisional hernias tend to increase steadily in size with time, and the overlying skin may become thin and atrophic. Local trauma and microvascular damage to skin may lead to ulceration. Episodes of intestinal obstruction are common because there are usually coexisting internal

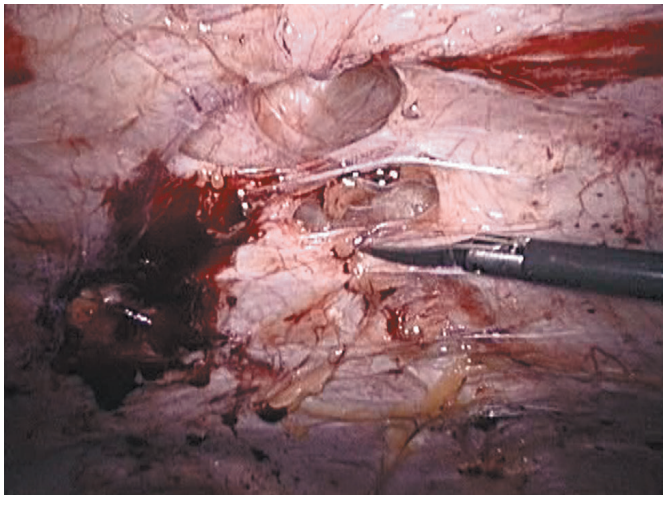

Figure 64.26 Multiple defects along the line of the scar, seen at laparoscopy.

Summary box 64.16

Incisional hernia

- Incidence 10–50% after surgery
- Aetiology includes patient, wound and surgeon factors
- Wide variation in size
- Multiple defects within the same scar are very common
- Obstruction is common but strangulation is rare
- Open and laparoscopic repairs possible

adhesions, but strangulation is less frequent because most incisional hernias are shallow and wide-necked. As with any hernia type, strangulation is most likely when the fibrous defect is small and the sac is large.

Treatment

Asymptomatic incisional hernias may not require treatment. The wearing of an abdominal binder or belt often provides symptomatic relief and may prevent the hernia from increasing in size. Many patients with an incisional hernia have other comorbidities and discussion around the balance of benefits and risks of surgery is important. The decision to operate and choice of technique should always be agreed between the patient and the surgeon and patients' preferences need to be respected. Repair of large and/or complex incisional hernias can be extremely challenging; in such cases advice from, or referral to, a colleague with a special interest in abdominal wall reconstruction should be considered.

Each patient undergoing an elective incisional hernia repair should be optimised for surgery. In many centres, patients undergo formal multidisciplinary team assessment and this is likely to become the standard of care in the coming years. So-called 'prehabilitation' includes weight loss if the patient is obese, smoking cessation, fitness improvement and core strength exercising. Loss of 7% of total bodyweight achieves a significant improvement in metabolic state, and 5 kg of body weight is said to create about one extra litre of space inside the adult male abdomen (0.5 litres in women).

Prevention of incisional hernia

The risk of incisional hernia may be reduced by improving the patient's general condition preoperatively where possible, e.g. smoking cessation, weight loss for obesity or improving nutritional status in undernourished individuals. Closing the fascial layers with good technique and materials is important. For years it has been advised that sutures should be 1 cm back from the wound edge and 1 cm apart, but recent work has shown that lower incisional hernia rates and reduced infection rates are gained when smaller and closer bites are used: 5 mm apart and 5–8 mm back from the wound edge, with care taken to incorporate fascia only in the suture bites (no muscle) and to minimise excessive suture tension. A 2/0 slowly resorbable suture is also recommended rather than traditional heavier and/or non-absorbable materials (see ***Chapter 7***).

There is no evidence that interrupted sutures are better or worse than continuous. However, if continuous suturing is used, the tissue bites must not be too near the fascial edge or pulled too tight because they may cut out. The optimal ratio of suture length to wound length is 4:1. If a ratio of less than this is achieved, the suture bites are likely to be too far apart and/or too tight (and vice versa).

Drains should be brought out through separate incisions and not through the wound itself because this prevents fascial apposition and increases the risk of hernia formation.

Studies in obese patients undergoing bariatric surgery have suggested that placement of a prophylactic mesh in patients at high risk of incisional hernia formation will substantially reduce that risk. Use of prophylactic mesh may reduce the risk of parastomal herniation, which occurs in up to 50% of patients.

Principles of surgical repair

For repair of most incisional hernias, both open and laparoscopic options are available. A number of principles apply, irrespective of the technique used. First, the repair should cover the whole length of the previous incision. Second, approximation of the musculofascial layers should be done with minimal tension; third, prosthetic mesh should be used to reduce the risk of recurrence. Mesh may be contraindicated in a contaminated field, e.g. in the event of perforation of strangulated bowel, but mesh may still be used in a clean-contaminated field, such as after an elective bowel resection, if strict hygiene measures are observed and appropriate prophylactic antibiotics are given.

Open repair

The previous incision is opened along its full length to reveal any clinically unsuspected defects. The hernial sac, its neck and the margins of the defect are fully exposed. The sac can be opened, contents reduced, local adhesions divided and any redundant sac excised to allow safe fascial closure.

Simple suture techniques without the use of prosthetic mesh for reinforcement, even with the overlapping repair of Mayo or the layered closure of da Silva, are not recommended because of the unacceptable risk of recurrence. However, they may be the only option in the presence of gross contamination, where mesh is contraindicated. Mesh should ideally be used in a tension-free manner to augment primary fascial closure and not used to 'bridge' a gap between fascial edges as the unsupported mesh centrally will inevitably bulge outwards postoperatively, giving the appearance of recurrence. However, if the mesh-to-defect area ratio is sufficiently large, i.e. there is sufficient circumferential overlap of mesh in relation to the size of the defect, then a bridging repair is generally secure. Mesh can be placed in one of several planes, as for primary ventral hernia repair. The simplest approach is an onlay mesh but this carries the risk of mesh exposure and contamination in the event of wound infection or wound breakdown. Furthermore, placement of a large onlay mesh requires elevation of large skin flaps, which increases the risk of wound seroma and overlying skin ischaemia. Intraperitoneal mesh placement is difficult at open surgery and mesh in direct contact with the intra-abdominal organs is prone to complications such as adhesive bowel obstruction, erosion into adjacent organs and bowel fistulation. The retromuscular plane is preferred by many surgeons.

Laparoscopic repair

Great advances have been made in applying laparoscopic techniques to incisional hernia repair. Laparoscopy and division of adhesions is initially performed, hernia contents are reduced and the fibrous margins of the hernia defect(s) are exposed. Often the falciform ligament and median umbilical fold need

Alcino Lazaro da Silva, contemporary, surgeon, Vitoria, Brazil.

to be taken down. Some surgeons prefer to close the fascial defect(s) with sutures before reinforcing with mesh, while others simply 'bridge' the defect with no attempt at closure. Larger defects are more difficult to close, but bridging large defects is associated with bulging of the mesh postoperatively, often referred to as 'pseudo-recurrence' (***Figure 64.27***). Only small hernias can be safely fixed without closing the defect, as the large mesh to defect area ratio will help to minimise mesh bulging and recurrence.

The mesh is placed directly onto the peritoneum deep to the abdominal wall muscles, fixed in place with tissue glue, sutures or staple/tacks and is known as an IPOM repair. Special meshes with anti-adhesion coatings must be used, so-called 'tissue separating' meshes, and these are generally expensive.

In the presence of dense peritoneal adhesions, the laparoscopic surgeon needs to take great care because injury to the bowel is possible and may not be recognised. If occult bowel injury does occur it can lead to postoperative peritonitis.

Parastomal hernia

When surgeons create a stoma, such as a colostomy or ileostomy, they are effectively creating a hernia by bringing bowel out through the abdominal wall. The muscle defect created tends to increase in size over time and can ultimately lead to massive herniation around the stoma. The rate of parastomal hernia is over 50%. For patients, it is very difficult to manage a stoma that is lying adjacent to or atop a large hernia. The stoma may intermittently obstruct and appliance bags fit poorly leading to leakage.

The ideal surgical solution for the patient is to rejoin the bowel and remove the stoma altogether, but this is not always possible. The stoma may be re-sited but parastomal hernia will occur at the same rate at the new location, so it is no longer recommended. Numerous techniques have been described to repair parastomal hernia but failure rates remain high. Mesh repairs are associated with a lower recurrence rate but also with occasional bowel erosion and infection. Meshes are best placed in the retromuscular space but intraperitoneal mesh placement is also popular (Sugarbaker). Laparoscopic repair is also possible, using a modified Sugarbaker technique or by using a large mesh with a central hole ('keyhole' technique).

Recent reports have described the use of prophylactic mesh insertion at the time of formation of the stoma. A large-pore polypropylene mesh is inserted in the retromuscular space so that the bowel passes through a hole in the centre of the mesh. Using this technique, parastomal hernia rates may be reduced significantly.

Rare external hernias

Perineal hernia

Primary perineal hernias are very rare. The majority of perineal hernias encountered are some form of incisional hernia arising after previous pelvic floor surgery or trauma. This type of hernia includes:

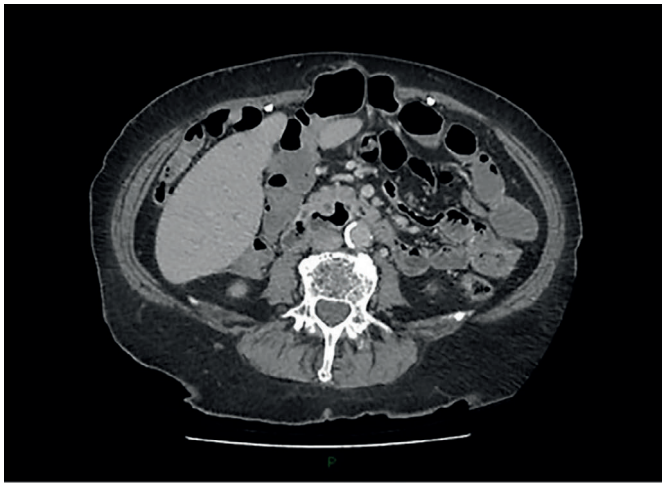

Figure 64.27 Abdominal computed tomography scan showing mesh bulge (pseudo-recurrence) 2 years after a laparoscopic repair of incisional hernia. The two white dots are metal tacks still in place, fixing the mesh to the underside of the abdominal wall.

- postoperative hernia through a perineal scar, typically after excision of the rectum;
- median sliding perineal hernia, which is a complete prolapse of the rectum;
- anterolateral perineal hernia, which occurs in women and presents as a swelling of the labium majus;
- posterolateral perineal hernia, which passes through the levator ani to enter the ischiorectal fossa.

A combined abdominoperineal operation is generally employed. The hernia is exposed by an incision directly over it. The sac is opened and its contents are reduced. The sac is cleared from surrounding structures and the wound closed. With the patient in semi-Trendelenburg position, either laparoscopically or at open surgery, the abdomen is opened and the mouth of the sac exposed. The sac is inverted, ligated and excised, and the pelvic floor repaired by muscle apposition and, if indicated, buttressing of the repair with prosthetic mesh or tissue flap with the involvement of plastic surgeons.

Obturator hernia

Obturator hernia, which passes through the obturator canal, occurs six times more frequently in women than in men. Most patients are older than 60 years. Any swelling is liable to be overlooked because it is covered by pectineus. It seldom causes a palpable lump but, if the limb is flexed, abducted and rotated outwards, the hernia sometimes becomes apparent. The leg is usually kept in a semiflexed position and movement increases the pain. In more than 50% of cases of strangulated obturator hernia, pain is referred along the obturator nerve by its geniculate branch to the knee. On vaginal or rectal examination the hernia can sometimes be felt as a tender swelling in the region of the obturator foramen.

These hernias are most frequently diagnosed on a CT scan, usually requested to investigate pelvic pain or bowel

Paul H Sugarbaker, contemporary, surgeon, Washington Cancer Institute, Washington, DC, USA.

obstruction. Obturator hernias have often undergone strangulation, frequently of the Richter type, by the time of presentation. Occasionally, asymptomatic obturator hernia defects are noted at laparoscopy on the lateral pelvic wall, under the pubic arch.

Surgery is indicated. The diagnosis is rarely made preoperatively and so it is often approached through a laparotomy incision. The full Trendelenburg position is adopted. The constricting agent is the obturator fascia, which can be stretched by inserting the operator's index finger, or suitable forceps, through the gap in the fascia. The content is reduced. If incision of the fascia is required, it is made parallel to the obturator vessels and nerve. The contents of the sac are dealt with in a standard manner. The defect cannot simply be closed because one margin is bone and the obturator nerve and vessels run through it. It is best repaired using a flat mesh laid over the defect in the extraperitoneal plane. In the absence of mesh or in an infected field, the broad ligament can be sutured over the defect or used as a plug.

Laparoscopic TAPP repair may also be performed again using a mesh. As with other extraperitoneal mesh repairs, mesh fixation is often not required. Alternatively, to avoid nerve injury, tissue glue can be used to fix a mesh over the defect. Note that it can be very difficult to reduce an incarcerated hernia laparoscopically and it is easy to damage the bowel with traction.

Gluteal and sciatic hernias

Both of these hernias are very rare. A gluteal hernia passes through the greater sciatic foramen, either above or below piriformis. A sciatic hernia passes through the lesser sciatic foramen. Differential diagnosis must be made between these conditions and:

- a lipoma or other soft-tissue tumour beneath gluteus maximus;
- a tuberculous abscess;
- a gluteal aneurysm.

All doubtful swellings in this situation can be characterised with CT scanning but, if in doubt, they should be explored by operation. After reduction of the hernia contents, complete closure of the defect may not be possible because of the unyielding bony and ligamentous margins of the hernia orifices. Bridging mesh may be useful but should not be placed directly on top of major nerves or vessels in the vicinity for fear of causing local irritation and neuralgic pain.

UMBILICAL CONDITIONS IN THE ADULT

Chronic infection in the umbilical area is common, particularly in patients with poor hygiene due to a plug of keratin causing chronic irritation. It is often encountered during elective surgery and may complicate the insertion of a laparoscope port at the umbilicus. Occasionally, a rapid-onset, superficial cellulitis occurs even after minor surgery in this region. It is normally due to a streptococcal infection and is treated with appropriate antibiotics. Pre-existing infection should be treated before surgery where possible.

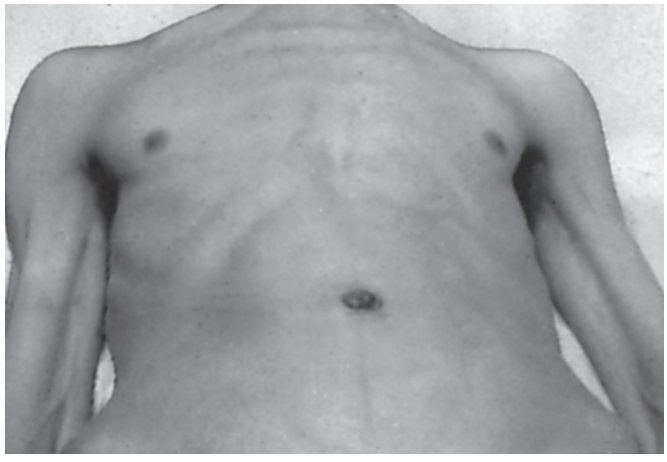

Figure 64.28 Secondary nodule at the umbilicus: Sister Joseph's nodule.

A chronic sinus may arise following umbilical hernia repair owing to infection of a mesh or non-absorbable suture material used. Antibiotics may help but usually the mesh or suture will need to be removed with a risk of recurrence of the hernia.

In utero the umbilicus is connected to the gut by the vitellointestinal duct. In most patients the duct becomes totally obliterated. The bowel end of the duct may persist as Meckel's diverticulum. More rarely, the umbilical end persists, leading to chronic faeculent discharge. Rarely endometriosis can present with cyclical bleeding from the umbilicus.

The urachus is a connection between the urinary bladder and umbilicus. It usually involutes but may present in later life as a result of increased pressure in the bladder usually due to prostatic hypertrophy. The cause of obstruction should be dealt with initially, but if the problem persists then surgical excision of the patent urachus might be considered.

If tumour presents at the umbilicus it is most probably due to spread from the internal organs along internal ligaments, e.g. from the liver along the falciform ligament. A malignant mass at the umbilicus is called a Sister Joseph's nodule. It usually indicates very advanced malignant disease and surgery probably has little to offer (***Figure 64.28***). Malignancy at the umbilicus is rare; however, primary squamous carcinoma may occur and malignancy may develop in a urachal remnant. Local excision is required.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery, successively at Rostock (1875–1882), Bonn (1882–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Johann Frederick Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described his diverticulum in 1809 although **Alexis Littre**, 1658–1726, surgeon and lecturer in anatomy, Paris, France, described Meckel's diverticulum in a hernial sac in 1700, 81 years before Meckel was born.

Sister Mary Joseph (nee Julia Dempsey), Nursing Superintendent, St Mary's Hospital, Rochester, MN, USA, observed that patients with terminal cancer sometimes developed a red papular lesion in the umbilicus. She and William Mayo published this observation in 1928; however, it was Hamilton Bailey who coined the term '**Sister Mary Joseph's nodule**' in 1949.

GENERAL INFECTION OF THE ABDOMINAL WALL

The skin of the abdominal wall, similar to all skin, is prone to develop superficial infection that may be spontaneous, due to minor trauma or infection of skin lesions such as an epidermoid cyst. Although antibiotics will suffice in most patients, if an abscess develops then surgical drainage may be required.

The close proximity of bowel and bowel organisms opens the abdominal wall to attack from a wide range of highly virulent bacteria. Most commonly, these are released during abdominal surgery such as appendicectomy and hence the need for appropriate antibiotic prophylactic cover.

Synergistic gangrene

This rare condition is due to the synergistic action of non-haemolytic streptococci and staphylococci causing rapid tissue necrosis and overwhelming systemic infection (***Figure 64.29***). It requires immediate administration of high-dose, broad-spectrum antibiotics in combination with early debridement of any non-viable tissue. Hyperbaric oxygen therapy has been advocated.

Other forms of severe abdominal wall infections occur, generally known as necrotising fasciitis (also known as Fournier's gangrene). All of these conditions have a high associated morbidity and mortality. They occur more frequently in diabetic, debilitated or immunocompromised patients but can occasionally occur in healthy patients. The necrosis spreads rapidly through the subcutaneous layers of the abdominal wall and may extend into the chest, axilla, thigh and perineum. Necrotising fasciitis is characterised by systemic features of septic shock, a high temperature, a foul smell and occasionally crepitus in the skin, indicating gas-producing bacteria. Prompt diagnosis and aggressive surgical debridement within hours of onset are the keys to success, with repeated debridements under anaesthesia over several days until all of the necrotic and infected tissues have been cleared. If the patient survives, extensive skin grafting is usually required.

Patients with lymphatic oedema of the abdominal wall may present with redness and tenderness, suspicious for necrotising fasciitis. This important diagnosis needs to be excluded, but cellulitis secondary to lymphatic stasis is more likely to be the cause.

Cutaneous fistula

Because of the thickness of the abdominal wall, it is rare for abdominal inflammatory conditions to discharge spontaneously through the wall to the skin. Chronic intraperitoneal abscesses arising after occult bowel perforation, appendicitis, diverticulitis and cholecystitis are the most likely sources. CT will locate the internal abscess and suggest the likely origin. Treatment is usually by CT- or ultrasonography-guided drainage but the surgeon may be called on to remove the source organ (source control). Malignancy in its later stages can occasionally erode through the abdominal wall. Crohn's disease also has a tendency to fistulate into adjacent organs and may develop an enterocutaneous fistula.

Figure 64.29 Bacterial synergistic gangrene of the chest and abdominal wall. The area has become gangrenous and looks like suede leather.

Abdominal compartment syndrome

Surgeons are increasingly aware of the harmful effect of high intra-abdominal pressures that can occur in severe intra-abdominal sepsis, such as pancreatitis and also following aortic aneurysm rupture. High pressure leads to reduced blood flow and tissue ischaemia, which contributes to multiorgan failure. Although the abdominal wall has elasticity, if intra-abdominal volume increases as a result of fluid, gas, pus, tissue oedema, etc., the maximal capacity may be reached and pressure rises to a critical level. Intra-abdominal pressure >20 mmHg, as measured via a catheter in the urinary bladder, is diagnostic and requires intervention to avoid organ failure.

Occasionally, such as after surgery for severe intraperitoneal sepsis, there is so much retroperitoneal swelling and/or oedema of the bowel that the surgeon cannot close the abdomen. In such cases it is often wise to leave the incision open, cover the abdominal contents with mesh or a saline-soaked dressing and plan to return at a future date to close the defect. This is called a laparostomy. Vacuum-assisted dressings assist in managing the large amounts of wound exudate. The patient may require repeated trips to the operating theatre, gaining a little more fascial apposition each time, before the wound can be finally closed.

Neoplasms of the abdominal wall

As the abdominal wall is composed of muscle, fascia and bone, benign and malignant tumours can arise from each, although these are rare.

Jean Alfred Fournier, 1832–1915, French syphilologist and founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, along with Leon Ginzburg and Gordon Oppenheimer described regional ileitis in 1932.

Desmoid tumour

This is usually considered by pathologists to be a hamartoma and is more common in women. Some, however, believe it to be a fibroma and possibly the result of repeated trauma. Desmoids also occur in familial adenomatous polyposis. Histologically, they contain plasmodial cell masses resembling giant cells. They undergo central myxomatous change. Surgical excision with a wide margin is required to prevent local recurrence, which is a frequent problem.

ACKNOWLEDGEMENT

The authors are grateful to Andrew C de Beaux MBChB MD FRCS FEBS AWS, Consultant General and Upper GI Surgeon, Royal Infirmary of Edinburgh, Edinburgh, UK, for his input to this chapter.

PART 11 | Abdominal

CHAPTER 65

The peritoneum, mesentery, greater omentum and retroperitoneal space

Learning objectives

To understand:

- The development and anatomy of the mesentery and peritoneum
- Surgical conditions of the peritoneum, mesentery, greater omentum and retroperitoneal space

DEVELOPMENT OF THE MESENTERY AND PERITONEUM

Early in development, the human abdomen comprises a wall and enclosed space (coelom). A partition (mesentery) subdivides the cavity into left- and right-sided spaces (***Figure 65.1***). The mesentery comprises a cell body (mesodermal mesentery) lined on either side by a sheet of mesothelial cells (***Figure 65.2***). At first the cell body is continuous with the posterior abdominal wall, and the mesothelial covering of the mesentery is continuous with that lining the inner surface of the posterior abdominal wall. Soon after this arrangement has developed, the cell body of the mesentery separates from the posterior abdominal wall but remains in contact with it (***65.1***). The surface mesothelium of the mesentery remains in continuity with that of the posterior abdominal wall (***Figure 65.2***).

The mesentery remains continuous throughout development, following birth and into adult life (***65.2***). Early during development, the mid-region of the mesentery forms a fold that subdivides the mesentery into upper (pre-fold), mid- (fold) and lower (post-fold) regions (***Figure 65.1***). The upper region develops as a sack overlapping the mid-region. As it develops, the spleen, stomach and liver emerge.

The mid-region fold has left and right sides (on either side of the midline). The mid-region nearest the posterior abdominal wall is termed the central zone (***Figure 65.1***). The remainder of the fold is termed the peripheral zone. Soon after the mid-region fold first emerges, the sides of the periphery (but not of the central zone) switch position relative to the superior mesenteric artery (SMA). After the switch, the original right side of the mid-region commences on the right side centrally but continues peripherally on the left of the SMA. The original left side commences peripherally on the right side of the vessel then returns centrally on the left of the SMA (***Figure 65.1***). Failure of switch formation occurs in malrotation (see ***Rotational disorders***).

During development of the upper region of the mesentery, the region of the mesodermal mesentery that is nearest the posterior abdominal wall adheres to the wall (***65.1***). This process progresses from the midline laterally to the left. Adhesion of both displaces the mesothelial junction between the mesentery and the adjacent posterior abdominal wall (***Figure 65.2***). At completion of development the posterior wall of the upper region (the dorsal mesogastrium) is fully adherent to the abdominal wall of the left upper quadrant (LUQ). The spleen is located at the lateral part of the upper region sac, in the LUQ. The original mesothelial junction remains as the peritoneal reflection linking the surface lining the mesenteric domain (in this case the spleen) with the surface lining of the adjacent non-mesenteric domain (in this case the LUQ).

During development of the mid-region fold, the region of the mesodermal mesentery that is nearest the posterior abdominal wall (i.e. the central zone) progressively adheres to the posterior abdominal wall. With continued adhesion, the periphery of the mid-region fold also adheres (***65.2 and 65.3***). Adhesion occurs inferolaterally to the right, and from the central to peripheral zones. The mesothelial junction between the mid-region mesentery and abdominal wall is displaced in tandem, inferolaterally to the right. At completion of development the mid-region fold is adherent to the posterior abdominal wall at the right mesocolon. The original mesothelial junction is at the periphery of the fold and persists as a peritoneal reflection bridging the surface lining of the mesenteric and non-mesenteric domains (***Figure 65.2***) (***65.3***). Incomplete adhesion of the mid-region fold is associated with increased mobility of the ileocaecal region and volvulus (see ***Volvulus of the intestine and adjoining mesentery***).

During development of the lower region of the mesentery, the part nearest the posterior abdominal wall progressively adheres to the wall (***65.1***). This proceeds from the midline laterally to the left. The overlying mesothelial junction is displaced in tandem (***Figure 65.2***). At completion of development, the lower region has fully adhered at the left mesocolon, medial mesosigmoidal and mesorectal levels. The lateral part of the mesosigmoid remains mobile. The mesothelial junction remains as a peritoneal reflection bridging the surface lining of the mesenteric and adjacent non-mesenteric domain

(▶ *65.3*). Incomplete adhesion (and hence anchorage) of the lower region is associated with sigmoid volvulus (see ***Volvulus of the intestine and adjoining mesentery***).

ANATOMY OF THE MESENTERY AND PERITONEUM

All abdominal digestive organs develop *in* or *on* the mesentery and then remain directly connected to it (***Figure 65.3***). In the adult setting, these collectively comprise a discrete anatomical unit, the mesenteric domain (***Figure 65.4***). All genitourinary organs develop on and remain on the musculoskeletal mainframe of the abdomen. In the adult, these are collectively termed the non-mesenteric domain. Thus, the adult abdomen comprises two discrete anatomical compartments: the mesenteric and non-mesenteric domains (***Figure 65.5***) (▶ *65.2*).

When development is complete, the mesentery and conjoined digestive organs (intestine, pancreas, spleen and liver) have taken shape and adherence to the posterior abdominal wall is nearly complete. The dorsal mesogastrium, mesoduodenum, right and left mesocolon and mesorectum are

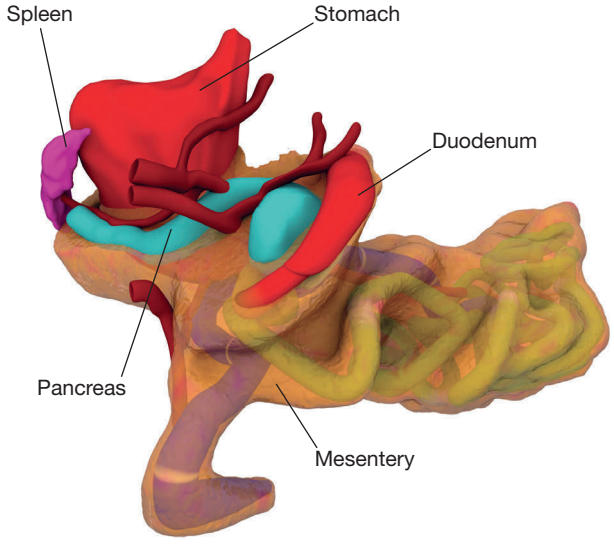

Figure 65.3 The right lateral aspect of the mesentery during development. The mesentery has been sectioned to expose the developing stomach (red), pancreas (light blue) and major blood vessels.

anchored to the subjacent abdominal wall (or pelvic sidewall) (***Figure 65.4***). The small intestinal region of mesentery, transverse mesocolon and lateral mesosigmoidal mesentery are not adherent and thus are mobile.

Adhesion of the mesentery to the abdominal wall anchors the mesenteric to the non-mesenteric domain, maintained by peritoneal reflection at the periphery of the mesenteric domain (***65.1 and 65.3***). At the periphery, the peritoneal reflection bridges the surface lining of the mesenteric and non-mesenteric domains (***Figure 65.6***). The peritoneum thus comprises visceral peritoneum (corresponding to the surface lining of the mesenteric domain), parietal peritoneum (corresponding to the surface lining of the non-mesenteric domain) and the reflection joining both. Peritonitis refers to inflammation of any region (see ***Peritonitis***).

The surface contours generated by the organisation of the domains and the peritoneum explains the sacs, recesses, fossae and pouches in which abnormal fluid collections arise in the abdomen (***65.3***). On completion of development, the free (non-adherent) surface of each organ of the mesenteric domain is peritonealised. The opposing adherent surface is not peritonealised.

In the male, the peritoneal cavity is normally closed. In the female, the peritoneal cavity is open to the environment at the fimbrial entrance to the fallopian tubes. In both sexes (but more frequently in the male) a peritoneal tube (processus vaginalis) can persist at the deep inguinal ring and predispose to inguinal hernia formation.

The interface between adherent regions of the mesenteric and non-mesenteric domains is termed the retroperitoneal space (***65.4***). The retroperitoneal space normally contains connective tissue fascia. The space (and fascia) continues into the thorax superiorly and into the pelvis inferiorly. The retroperitoneum is deep to the retroperitoneal space. It includes the kidneys, ureters, gonadal vessels, lumbosacral plexus and the musculoskeletal frame of the posterior abdominal wall.

The arterial inflow to the mesenteric domain is limited to the coeliac trunk and superior and inferior mesenteric arteries. The venous drainage of the mesenteric domain occurs via the hepatic veins at the junction of these and the inferior vena cava. In between the arterial inflow and venous drainage, the vasculature of the abdominal digestive organs is entirely intramesenteric and aligned with the mesenteric regional anatomy (***65.5***). The limited routes of arterial inflow and venous drainage have significant implications when these are affected by pathology (discussed in ***Vascular abnormalities of the mesentery***).

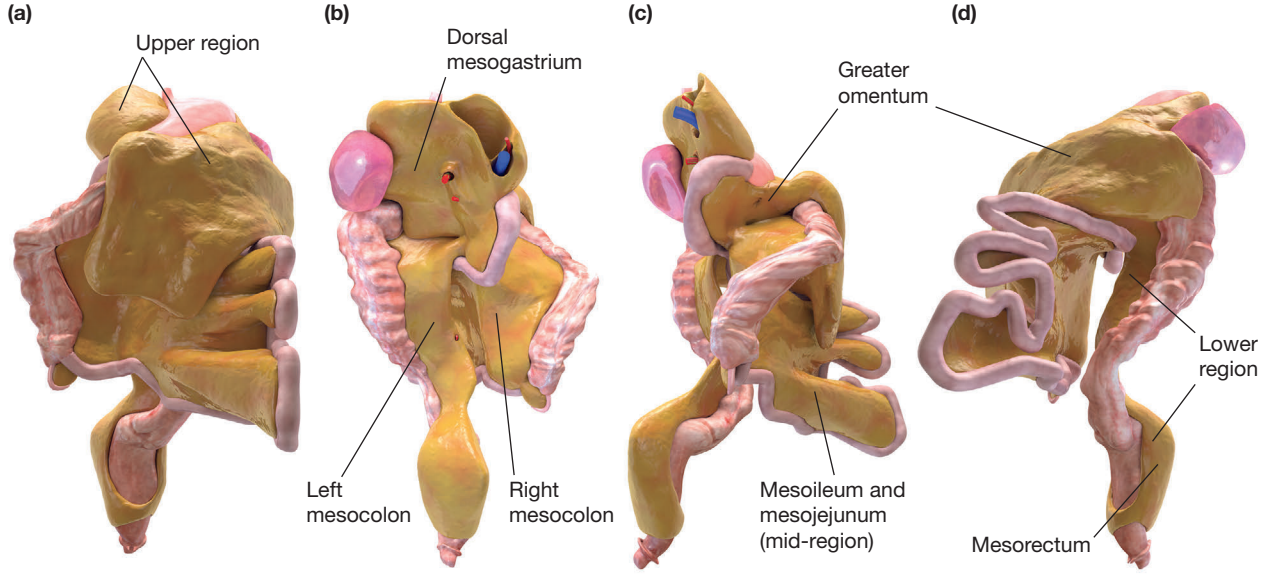

Figure 65.4 The mesentery. **(a–d)** The adult mesentery (and mesenteric domain) as seen from anterior **(a)**, posterior **(b)**, right posterolateral **(c)** and left anterolateral **(d)** perspectives.

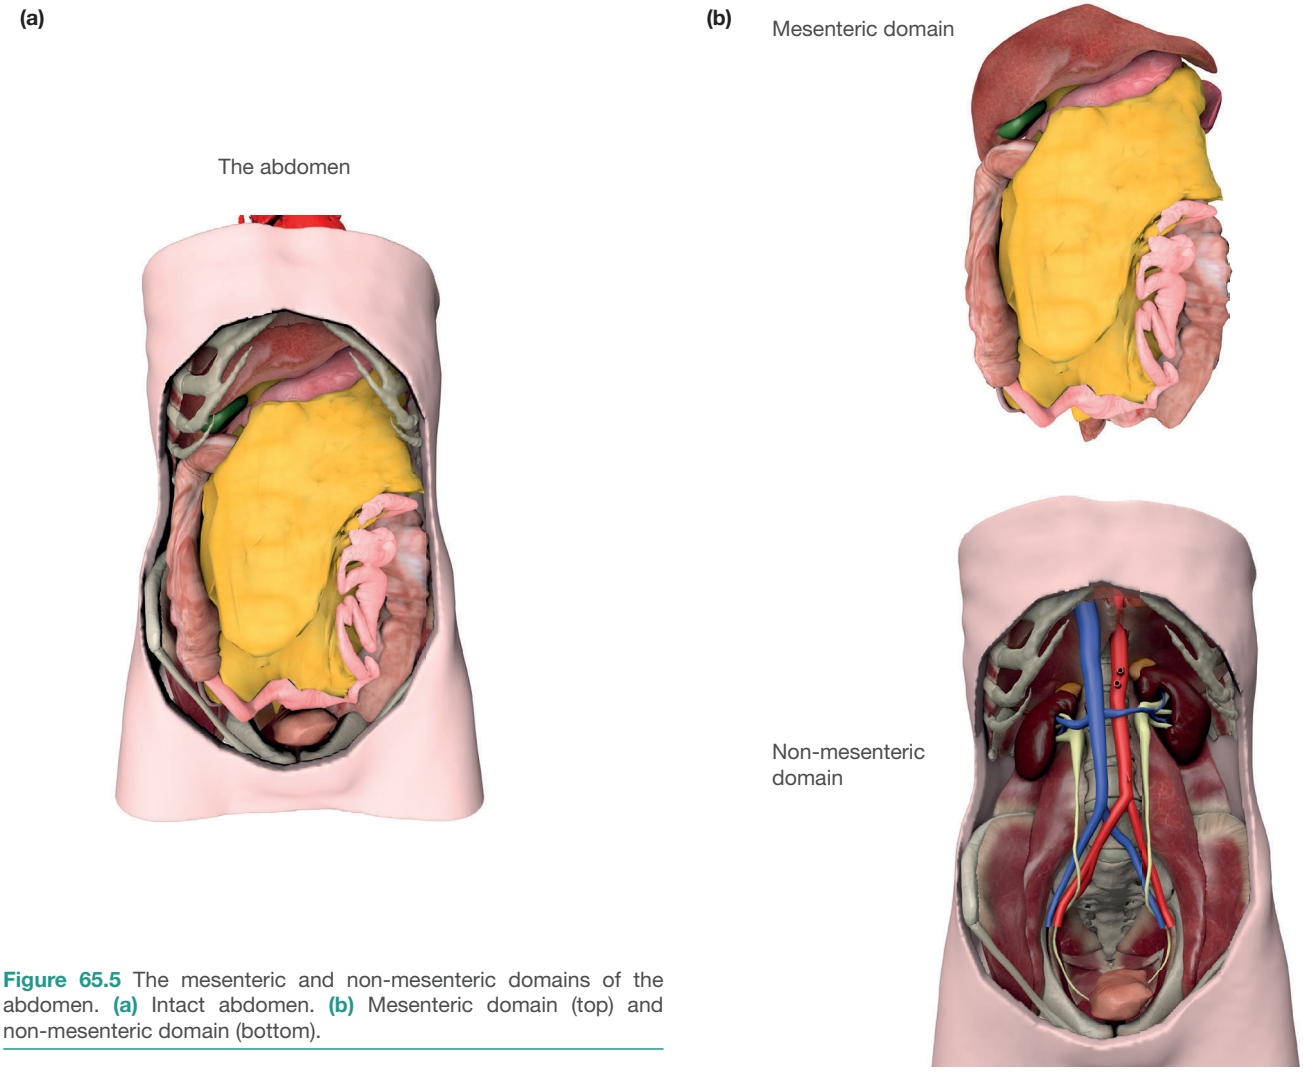

Figure 65.5 The mesenteric and non-mesenteric domains of the abdomen. **(a)** Intact abdomen. **(b)** Mesenteric domain (top) and non-mesenteric domain (bottom).

A knowledge of the anatomical relationships between the mesenteric and non-mesenteric domains provides the student of abdominal surgery with a roadmap by which to perform safe and optimal abdominal surgery. The above description is termed the mesenteric model of abdominal anatomy. It is a model that matches observations during development with clinical observations *in vivo* and with radiological depictions of the abdomen. It provides the anatomical context on which surgical diseases of the abdomen and pelvis arise. Given this, it is rapidly substituting the peritoneal model in reference anatomical texts.

THE PERITONEUM

The peritoneal cavity is the largest cavity in the body, the surface area of its lining membrane (2 m^2 in an adult) being nearly equal to that of the skin (*65.3*). The peritoneal membrane is composed of flattened polyhedral cells (mesothelium), one layer thick, resting on a thin layer of fibroelastic tissue. Beneath the peritoneum, supported by a small amount of areolar tissue, lies a network of lymphatic vessels and a rich plexus of capillary blood vessels from which all absorption and exudation must occur. In health, only a few millilitres of peritoneal fluid are found in the peritoneal cavity. The fluid is pale yellow, somewhat viscid and contains lymphocytes and other leukocytes; it lubricates the viscera, allowing easy movement and peristalsis. The parietal portion is richly innervated and, when irritated, causes severe pain that is accurately localised to the affected area. The visceral peritoneum, in contrast, is poorly innervated and irritation causes pain that is usually poorly localised to the midline.

Summary box 65.1

Functions of the peritoneum

In health

- Visceral lubrication
- Fluid and particulate absorption

In disease

- Pain perception (mainly parietal)
- Inflammatory and immune responses
- Fibrinolytic activity

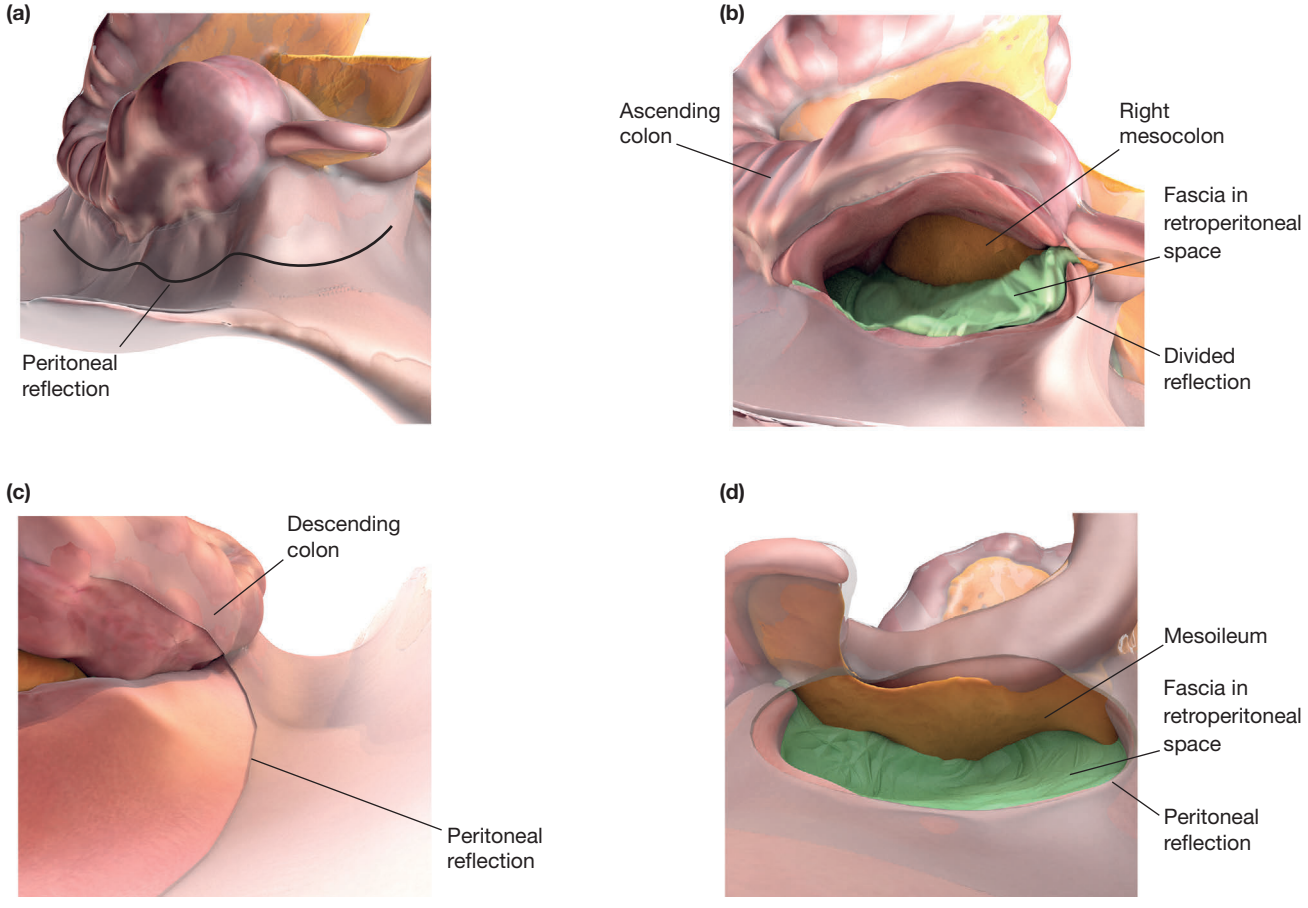

Figure 65.6 The reflection at the periphery of the mesenteric domain, i.e. the junction between the mesenteric and non-mesenteric domains. (Reproduced with permission from Coffey JC, Lavery I, Sehgal R (eds). *Mesenteric principles of gastrointestinal surgery: basic and applied principles.* Boca Raton: CRC Press, 2017.)

The peritoneum has the capacity to absorb large volumes of fluid; however, the peritoneum can also produce large volumes of fluid (ascites) and an inflammatory exudate when injured (seen in peritonitis). During expiration, intra-abdominal pressure is reduced and peritoneal fluid, aided by capillary attraction, travels in an upward direction towards the diaphragm. Particulate matter and bacteria are absorbed within a few minutes into the lymphatic network through a number of 'pores' in the diaphragmatic peritoneum. The circulation of peritoneal fluids may be responsible for the occurrence of abscesses anatomically remote from primary disease. The two sites most prone to collection are the pelvis and subdiaphragmatic areas, reflecting the effects of gravity while standing and lying, respectively.

PERITONITIS

Peritonitis is inflammation of the peritoneum and can be categorised as localised or diffuse, acute or chronic or according to the primary underlying pathology. In the clinical setting, the most useful categorisation of peritonitis is based on whether it is localised or diffuse.

Summary box 65.2

Causes of peritoneal inflammation

- Bacterial, gastrointestinal and non-gastrointestinal
- Chemical, e.g. bile, barium
- Allergic, e.g. starch peritonitis
- Traumatic, e.g. operative handling
- Ischaemia, e.g. strangulated bowel, vascular occlusion
- Miscellaneous, e.g. familial Mediterranean fever

Summary box 65.3

Paths to peritoneal infection

- Gastrointestinal perforation, e.g. perforated ulcer, appendix, diverticulum
- Transmural translocation (no perforation), e.g. pancreatitis, ischaemic bowel, primary bacterial peritonitis
- Exogenous contamination, e.g. drains, open surgery, trauma, peritoneal dialysis
- Female genital tract infection, e.g. pelvic inflammatory disease
- Haematogenous spread (rare), e.g. septicaemia

Localised peritonitis

This is where a localised area of the peritoneum has become inflamed. If the parietal peritoneum is involved, the patient complains of pain (somatic pain) in the area affected. Vital signs may be normal, but tachycardia and pyrexia are common. The characteristic signs are involuntary guarding (reflex abdominal wall contraction to reduce further peritoneal irritation) and rebound tenderness (worsening of pain on lifting the examining hand off the abdominal wall). Collectively these signs and symptoms are termed *peritonism* and the patient is described as *peritonitic* (see ***Chapter 63***).

If inflammation arises under the diaphragm, shoulder tip ('phrenic') pain may be felt. This is referred pain to the C5 dermatome. In cases of pelvic peritonitis, e.g. from an inflamed appendix or salpingitis, abdominal signs may be limited; deep-seated tenderness may be detected by digital rectal or vaginal examination. Signs may be limited in obese patients or in patients on immunosuppressive medications.

The aim is to diagnose the underlying cause and guide treatment. Diagnosis of the underlying condition is made through a combination of history and physical examination, supplemented by laboratory and radiological investigations. Laboratory biomarkers will support a diagnosis of acute inflammation, but are rarely diagnostically specific. The investigation of choice is computed tomography (CT) scanning. Modalities such as ultrasound can be used but lack specificity except in the case of tubo-ovarian pathology (see ***Chapter 87***). Laparoscopy may be required if the above investigations are inconclusive.

The aims of treatment are to remove the underlying cause and to lavage or dilute residual contamination. At surgery the inflamed peritoneum appears reddened, thickened and has a velvety texture. Plaques of yellow/white fibrin may be apparent, causing loops of intestine (and mesentery) to adhere to themselves and to the parietes. There is a reactionary, serous exudate (rich in leukocytes and plasma proteins) that gradually becomes turbid in appearance. The fluid may transform to frank pus if not evacuated.

Diffuse (generalised) peritonitis

This normally signifies the occurrence of a life-threatening pathology. It means that regions (not just focal areas) of the parietes (parietal peritoneum) are inflamed. It normally arises as a result of pressure-related perforation of a viscus (e.g. in the setting of an obstructed colon), when large volumes of blood abruptly enter the peritoneal cavity (ruptured aortic aneurysm) or when substantial volumes pour incessantly (albeit not under pressure) into the peritoneal cavity (e.g. perforated duodenal ulcer or anastomotic leak).

The patient may describe acute or gradual onset abdominal pain of considerable intensity. The pain may be localised at first and then become diffuse. The patient is gravely ill looking (Hippocratic facies) and usually lies as still as possible to minimise fluid movement within the peritoneal cavity. The entirety of the abdominal musculature undergoes a reflex contraction and feels board-like on palpation ('board-like' rigidity). In a thin patient, contraction of the rectus abdominis muscles may be reflected in a scaphoid appearance of the abdomen (see ***Chapter 63***). A generalised ileus occurs and the abdomen may become distended.

Vital signs are usually deranged. In advanced cases the patient is hypotensive, tachycardic and pyrexial. At first the patient may seem confused, drowsy and disoriented. If the underlying pathology is not corrected the patient will lose consciousness. Signs may be limited in obese patients or in patients on immunosuppressive medications.

Investigation and treatment must be undertaken expediently as the time available to salvage may be limited. Investigations aim to identify the underlying cause and to guide treatment. An erect chest radiograph can be useful in identifying subdiaphragmatic gas (***Figure 65.7***). If a patient is particularly unwell and a CT is not available, then a lateral decubitus radiograph serves the same purpose as an erect radiograph (provided the patient has been appropriately positioned for long enough for the gas to rise within the peritoneal cavity).

Summary box 65.4

Clinical features of peritonitis

- Abdominal pain, worse on movement, coughing and deep respiration
- Constitutional upset: anorexia, malaise, fever, lassitude
- Gastrointestinal upset: nausea +/– vomiting
- Pyrexia (may be absent)
- Raised pulse rate
- Tenderness +/– guarding/rigidity/rebound of abdominal wall
- Pain/tenderness on rectal/vaginal examination (pelvic peritonitis)
- Absent or reduced bowel sounds
- 'Septic shock' (systemic inflammatory response syndrome [SIRS] and multiorgan dysfunction syndrome [MODS]) in later stages

Summary box 65.5

Management of peritonitis

General care of patient

- Correction of fluid and electrolyte imbalance
- Insertion of nasogastric drainage tube and urinary catheter
- Broad-spectrum antibiotic therapy
- Analgesia
- Vital system support

Surgical treatment of cause when appropriate

- 'Source control' by removal or exclusion of the cause
- Peritoneal lavage +/– drainage

Hippocrates of Kos, Greek physician and surgeon, and by common consent 'the father of medicine', was born on the island of Kos, off Turkey, about 460 BCE and probably died in 375 BCE.

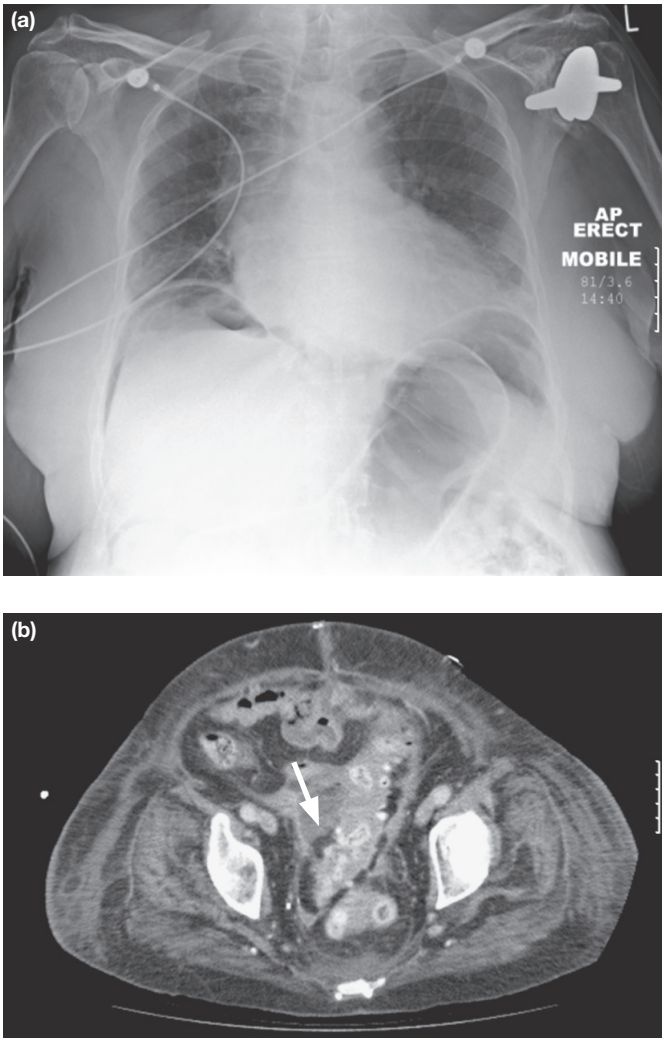

Figure 65.7 Intraperitoneal perforation. **(a)** Erect chest radiograph demonstrating air under the diaphragm on the right side. **(b)** Axial computed tomography image showing a segment of sigmoid diverticulosis with localised perforation (arrow).

Acute bacterial peritonitis

Acute bacterial peritonitis most commonly arises from perforation of a viscus of the alimentary tract. Other routes of infection can include the female genital tract and exogenous contamination. Less common forms involve a primary 'spontaneous' peritonitis due to streptococcal, pneumococcal or *Haemophilus* infection.

Non-gastrointestinal causes of acute bacterial peritonitis

Pelvic infection via the Fallopian tubes is responsible for a high proportion of 'non-gastrointestinal' infections. The most common offending organisms are *Chlamydia* spp. and gonococci. These organisms lead to a thinning of cervical mucus and allow bacteria from the vagina to pass into the uterus and oviducts, causing infection and inflammation. A variant of transperitoneal spread of such organisms is perihepatitis, which can cause scar tissue to form on Glisson's capsule, a thin layer of connective tissue surrounding the liver (Fitz-Hugh–Curtis syndrome). Fungal peritonitis is rare but may complicate severely ill patients.

Biliary peritonitis

Biliary peritonitis is mostly seen after cholecystectomy and arises from slippage of a clip off the cystic duct, drainage of bile from an accessory cystic duct or perforation of the common bile or hepatic duct (see ***Chapter 71***). It can also arise after hepatectomy or duodenal surgery, although this is unusual if a drain has been placed at the time of surgery.

Investigation follows the principles and steps described in ***Peritonitis***. The natural course of biliary peritonism varies depending on the volume of contamination. In severe contamination the patient will be extremely unwell and urgent intervention is required.

Localised collections can be treated by percutaneous insertion of a drain followed by endoscopic retrograde pancreatography (ERCP) to identify the source of bile leak. ERCP enables placement of a stent across the source of the leak. Diffuse or high-volume contamination, or the presence of multiple separate locules, normally mandates surgical exploration with the aim being lavage and drainage.

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP; sometimes called primary bacterial peritonitis) is an acute bacterial infection of ascitic fluid. There is often a history of cirrhosis and ascites. The clinical picture is highly variable as the patient may be asymptomatic. The course can be prolonged.

The diagnosis is made by paracentesis and should be considered in cirrhotic patients and those with ascites even when there is a low index of suspicion. The diagnosis is confirmed by finding an increased neutrophil count of 250/mm^3 in aspirated ascitic fluid. Culture of ascites is negative in as many as 60% of patients with clinical manifestations of SBP. When culture is positive the most common pathogens include Gram-negative bacteria, usually *Escherichia coli*, and Gram-positive cocci (mainly streptococci and enterococci).

Empirical treatment of SBP must be initiated immediately after diagnosis and before the results of culture have been received. Although the choice of antibiotic may vary, a third-generation cephalosporin, e.g. cefotaxime, is a reasonable first-line treatment that avoids the renal toxicity of aminoglycosides. Alternatives are amoxicillin/clavulanic acid and quinolones such as ciprofloxacin.

Francis Glisson, 1597–1677, Regius Professor of Medicine, Cambridge, UK.
Fitz-Hugh–Curtis syndrome: named after the two physicians, **Thomas Fitz-Hugh, Jr** 1894–1963, physician, University of Pennsylvania, Philadelphia, PA, USA, and **Arthur Hale Curtis** 1881–1955, gynecologist, Chicago, IL, USA, who first reported this condition in 1934 and 1930, respectively.

Primary pneumococcal peritonitis

The incidence of pneumococcal peritonitis has declined greatly and the condition is now rare. It may complicate nephrotic syndrome or cirrhosis in children; however, otherwise healthy children may also be affected. In girls, the route of infection may be via the vagina and Fallopian tubes, while a blood-borne route secondary to respiratory tract or middle-ear disease is also possible.

The clinical onset is usually sudden, with pain usually localised to the lower half of the abdomen. The temperature is raised to 39°C or more and there is usually frequent vomiting. After 24–48 hours, profuse diarrhoea is characteristic. There is usually increased frequency of micturition. The last two symptoms are caused by severe pelvic peritonitis. On examination, peritonism is usually diffuse but less prominent than in cases of a perforated viscus, leading to peritonitis.

An underlying pathology must always be excluded before primary peritonitis can be diagnosed with certainty. Causative organisms include *Haemophilus* spp., group A streptococci and a few Gram-negative bacteria. Idiopathic streptococcal and staphylococcal peritonitis can also occur in adults.

After starting antibiotic therapy and correcting dehydration and electrolyte imbalance, early surgery is required unless spontaneous infection of pre-existing ascites is strongly suspected, in which case a diagnostic peritoneal tap is useful. Laparotomy or laparoscopy may be used. Assuming that no other cause for the peritonitis is discovered, some of the exudate is aspirated and sent to the laboratory for microscopy, culture and sensitivity tests. Thorough peritoneal lavage is carried out and the incision closed. Antibiotics and fluid replacement therapy are continued and recovery is usual.

Tuberculous peritonitis

Intra-abdominal tuberculosis (TB) is common in resource-poor countries; however, the incidence is rising in resource-rich countries as a consequence of migration and immunosuppression. *Mycobacterium avium intracellulare* is becoming increasingly prevalent with the widespread increase in human immunodeficiency virus (HIV) co-infection. The abdomen is involved in approximately 11% of patients with extrapulmonary TB and includes intraperitoneal, gastrointestinal tract and solid organ disease forms. TB peritonitis requires specific mention because it is often diagnosed late, resulting in undue patient morbidity and mortality.

TB can spread to the peritoneum through the gastrointestinal tract (typically the ileocaecal region) via mesenteric lymph nodes or directly from the blood, usually from the 'miliary' (***Figure 65.8a***) but occasionally from the 'cavitating' form of pulmonary TB, lymph and the Fallopian tubes; 50–80% of patients with abdominal TB can be expected to have peritoneal involvement.

The most common form of TB peritonitis is the wet, ascitic-type disease (90%), which is characterised by generalised or loculated ascites. Multiple tubercle deposits are present on both layers of the peritoneum. In the less common form fibrotic fixed loops of bowel and omentum are matted together and may present with subacute intestinal obstruction. Ascites is not present in the dry, plastic type. Presentation is often insidious with abdominal pain, weight loss and abdominal distension. Distinction from diffuse peritoneal metastases is difficult and may require biopsy.

Diagnosis is via abdominal ultrasonography or CT to detect ascites and lymphadenopathy with/without diffuse thickening of the peritoneum, mesentery and/or omentum (***Figure 65.8b,c***). Ascitic fluid is typically a straw-coloured exudate (protein >25–30 g/L) with white cells >500/mL and lymphocytes >40%. Unfortunately, diagnostic smears for acid-fast bacilli are often not diagnostic and culture may take up to 4–8 weeks. Laparoscopy and peritoneal biopsy may thus be helpful to couple typical appearances with histology. The value of new laboratory investigations such as the Xpert® MTB/RIF assay and the interferon-gamma release assay in diagnosing extrapulmonary TB remains to be determined; however, measurement of adenosine deaminase activity in ascitic fluid has a high sensitivity and specificity in diagnosing peritoneal TB.

TB management is principally supportive (nutrition and hydration) and medical (systemic anti-TB therapy, noting that multidrug resistance may be higher for abdominal than for pulmonary TB), although surgery may be required for specific complications such as intestinal obstruction.

Summary box 65.6

Tuberculous peritonitis

- Acute (may be clinically indistinguishable from acute bacterial peritonitis) and chronic forms
- Abdominal pain, sweats, malaise and weight loss are frequent
- Ascites common, may be loculated
- Caseating peritoneal nodules are common – distinguish from metastatic carcinoma and fat necrosis of pancreatitis
- Intestinal obstruction may respond to anti-TB treatment without surgery

Familial Mediterranean fever

Familial Mediterranean fever (FMF; synonym familial paroxysmal polyserositis) is an autosomal recessive inherited autoinflammatory syndrome characterised by episodic diffuse abdominal pain and tenderness, mild pyrexia and joint pain. Symptoms are usually mild and resolve within 24–72 hours. Rarely pericardial or meningeal inflammation may occur. Amyloidosis is a long-term complication.

FMF is associated with mutations in the *MEFV* (Mediterranean fever) gene most frequently found in Arab, Armenian and Jewish populations. *MEFV* encodes the protein pyrin, which is expressed in neutrophils and is thought to regulate interleukin-1B (a proinflammatory cytokine) release.

Symptoms often present in childhood and may be misdiagnosed as appendicitis. Treatment of an acute episode is symptomatic. Colchicine can be used to reduce the frequency and severity of attacks and to prevent development of amyloidosis.

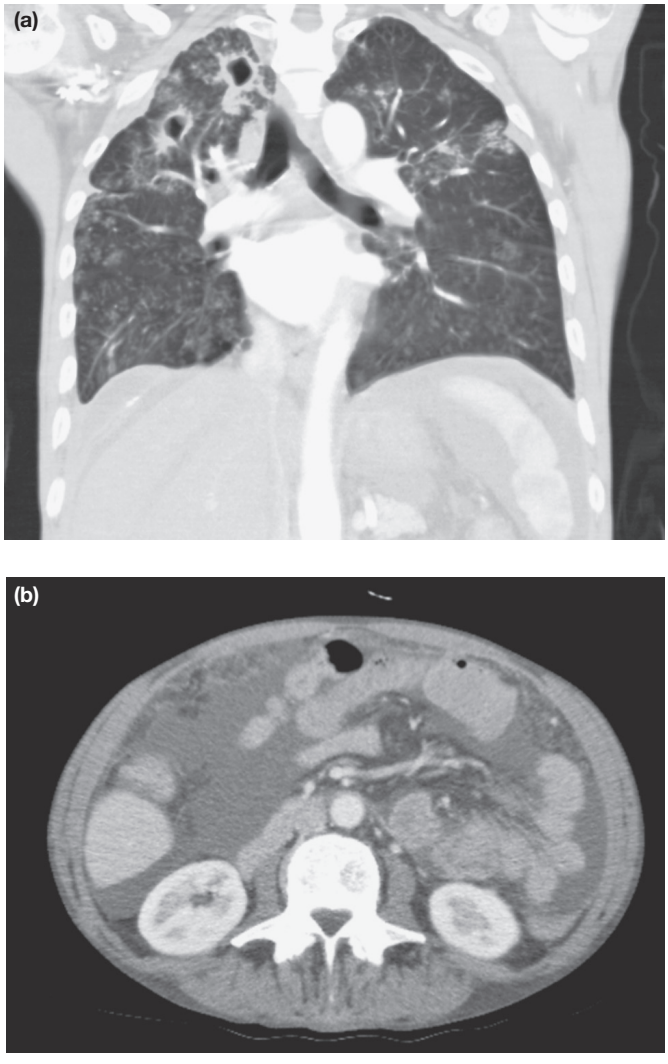

Figure 65.8 (a) Plain chest radiograph from a 55-year-old man showing miliary tuberculosis (TB); **(b, c)** representative computed tomography images from the same patient showing gross ascites, nodular stranding in the omentum and mesentery, as well as nodular enhancement of the peritoneum – TB peritonitis (courtesy of Dr S Burke, Homerton University Foundation Trust, London, UK).

TUMOURS OF THE PERITONEUM

Primary peritoneal malignancy

Primary tumours of the peritoneum are rare. They arise in the mesothelium of the peritoneum. Mesothelioma of the peritoneum is less frequent than in the pleural cavity but is equally lethal. Asbestos is a recognised cause. It has a predilection for the pelvic peritoneum. Cytoreductive surgery with heated intraperitoneal chemotherapy (HIPEC) or systemic cisplatin-based chemotherapy are the mainstays of treatment.

Secondary peritoneal malignancy

Peritoneal carcinomatosis

Peritoneal carcinomatosis is common and refers to malignant nodules on the surface of the peritoneum. It normally arises in conjunction with ovarian malignancy or malignancy in an organ of the mesenteric domain. It can be localised or diffuse. Any peritoneal surface can be involved. Sometimes the omentum is diffusely involved, forming a mass termed an omental cake.

The symptoms and signs are mainly related to the primary pathology. If the tumour burden is considerable, a mass may be palpable and the accompanying ascites substantial. Radiological cross-sectional imaging with CT or magnetic resonance imaging (MRI) is usually diagnostic; however, histological or cytological confirmation is essential to distinguish it from peritoneal TB. The visceral origin of peritoneal carcinomatosis is important as this can guide chemotherapy and cytoreductive or extirpative surgery.

The visceral origin of peritoneal carcinomatosis is important because if curative resection of the primary tumour is deemed feasible and the peritoneal disease considered resectable, resection with peritonectomy and HIPEC should be considered. HIPEC is a highly concentrated, heated (41–42°C) chemotherapy delivered directly into the abdomen for 90 minutes after cytoreductive surgery. HIPEC is particularly valuable in treatment of pseudomyxoma peritonei and has become the standard of care in carefully selected patients assessed in specialist centres (Sugerbaker) (see ***Chapter 76***).

Paul H Sugerbaker, b. 1941, Director of Surgical Oncology, Washington Cancer Institute, Washington, DC, USA.

In the majority of patients with peritoneal carcinomatosis treatment is palliative. Subacute intestinal obstruction may require intestinal bypass or a defunctioning stoma (see ***Chapter 78***). Malignant ascites may be drained externally or via a peritoneovenous shunt (LeVeen).

PERITONEAL INCLUSION CYSTS

Introduction

These are benign cysts lined by peritoneal mesothelium. They can arise at any location of the peritoneum, in continuity with the surface of either parietal or visceral peritoneum. They can gradually expand and rarely rupture. Most are asymptomatic and are identified incidentally on cross-sectional imaging for other indications. There is a loose association with ovarian malignancy and thus MRI evaluation of the ovaries is advisable in the premenopausal context. If symptomatic an inclusion cyst may be drained under imaging control, deroofed or excised. Recurrent rates are high.

Abdominal fluid collections

Abdominal collections are subdivided into intraperitoneal and retroperitoneal collections. Retroperitoneal collections are further subdivided into those limited to the retroperitoneal space (e.g. in pancreatitis) and collections arising in relation to retroperitoneal organs such the kidney. The latter are collections of the retroperitoneum. Collections of the retroperitoneal space and retroperitoneum are considered in the final section of the chapter.

Intraperitoneal collections

Ascites

Peritoneal fluid is constantly secreted and absorbed. Accumulation of peritoneal fluid, termed ascites, occurs when there is excess production or reduced absorption. Production of large volumes of a protein-rich fluid occurs in peritonitis and carcinomatosis peritonei. Reduced absorption occurs when capillary pressure is increased as a result of generalised water retention, cardiac failure, constrictive pericarditis or vena cava obstruction. Capillary pressure is also raised selectively in the portal venous system in the Budd–Chiari syndrome, hepatic cirrhosis or extrahepatic portal venous obstruction. Plasma colloid osmotic pressure may be lowered in patients with reduced nutritional intake, diminished intestinal absorption, abnormal protein losses or defective protein synthesis, such as occurs in cirrhosis. Peritoneal lymphatic drainage may be impaired, resulting in the accumulation of protein-rich fluid.

Hepatic cirrhosis is the most common cause of ascites due to portal venous hypertension secondary to fibrosis of the intrahepatic venous bed. In the Budd–Chiari syndrome (see ***Chapter 69***), thrombosis of hepatic veins leads to obstruction of venous outflow from the liver and hence from the mesenteric domain in general. Alternative routes of venous drainage may open up. One such route involves the vestigial umbilical vein at the base of the falciform ligament. Venous drainage via this route may reach the systemic venous drainage at the umbilicus. This is termed a portosystemic shunt and has a characteristic clinical appearance (involving veins) at the umbilicus (caput medusae).

Congestive heart failure increases pressure in the vena cava and resistance to the venous outflow from the liver. In this setting, ascitic fluid is light yellow and has a low specific gravity and low protein concentration (<25 g/L). In constrictive pericarditis there is a diminished capacity of the right heart. This leads to simultaneous peritoneal and pleural effusions due to engorgement of the venae cavae (Pick's disease).

Ascites occurring in peritoneal metastases is due to excessive exudation of fluid and lymphatic blockage. The fluid is dark yellow and frequently blood stained. The specific gravity and protein content (>25 g/L) are high. Rarely, ascites and pleural effusion are associated with solid fibromas of the ovary (Meigs' syndrome). These effusions disappear when the tumour is excised.

Summary box 65.7

Causes of ascites

Transudates (protein <25 g/L)

- Low plasma protein concentrations
  - Malnutrition
  - Nephrotic syndrome
  - Protein-losing enteropathy
- High central venous pressure
  - Congestive cardiac failure
- Portal hypertension
  - Portal vein thrombosis
  - Cirrhosis

Exudates (protein >25 g/L)

- Peritoneal malignancy
- Tuberculous peritonitis
- Budd–Chiari syndrome (hepatic vein occlusion or thrombosis)
- Pancreatic ascites
- Chylous ascites
- Meigs' syndrome

Ascites normally becomes clinically recognisable when greater than 1.5 litres of fluid is apparent (although greater volumes may be required in obese patients). The abdomen is distended evenly with fullness of the flanks, which are dull to percussion. Usually, shifting dullness is present but, when there is a very large accumulation of fluid, this sign is absent. In such cases, flicking the abdominal wall produces a characteristic

fluid thrill on the other side of the abdomen. This is not a reliable clinical sign. In women, ascites must be differentiated from an enormous ovarian cyst.

Investigations

The aims are identification of ascites and determination of the underlying cause. Liver function tests (LFTs), cardiac function, ultrasonography and/or CT scanning (***Figure 65.9***) may help diagnose aetiology, e.g. carcinomatosis or liver disease.

Ascitic aspiration or tap under imaging guidance helps minimise the risk of visceral injury. It can be both diagnostic and therapeutic. After the bladder has been emptied, puncture of the peritoneum is carried out under local anaesthetic using a moderately sized trocar and cannula. A peritoneal drain may be inserted at the time.

In cases where the effusion is caused by cardiac failure, fluid must be evacuated slowly. Fluid is sent for microscopy/cytology, culture, including mycobacteria (see ***Tuberculus peritonitis*** above), and analysis of protein content and amylase. Unless other measures are taken the fluid soon accumulates and repeated tappings remove valuable protein.

Management

Management aims to address any reversible primary pathology (following which the ascites resolves) or symptom-based management of the ascites itself. If portal venous pressure is raised, it may be possible to lower it by treatment of the primary condition or by transjugular intrahepatic portosystemic shunt or transjugular intrahepatic portosystemic stent shunting (commonly abbreviated as TIPS or TIPSS).

Dietary sodium restriction to 200 mg/day may be helpful, but diuretics are usually required (combination of spironolactone and furosemide). For patients failing to respond to such measures, therapeutic needle paracentesis can be performed. Serial large volume paracentesis (4–6 L/day and up to 8 litres in one session) can be performed safely with colloid replacement and can be performed in patients with cirrhosis and deranged clotting. Guidelines recommend albumin replacement after paracentesis to reduce complications. It may also be possible to leave an indwelling external drain for smaller volume home paracentesis.

Chylous ascites

In some patients, the ascitic fluid appears milky because of an excess of chylomicrons (triglycerides). Most of these cases are associated with malignancy (usually lymphoma). Other causes include cirrhosis, TB, filariasis, nephrotic syndrome, abdominal trauma (including surgery), constrictive pericarditis, sarcoidosis and congenital lymphatic abnormality. The prognosis is poor unless the underlying condition can be cured. In addition to other measures used to treat ascites, patients should be placed on a fat-free diet with medium-chain triglyceride supplements.

INTRAPERITONEAL ABSCESS FORMATION

An intraperitoneal abscess is a collection of pus in the peritoneal cavity (***Figure 65.10***). It normally arises secondary to another pathology. Inflammation of any viscus, if unresolved, will lead to hypersecretion of peritoneal fluid. The nature of the fluid progresses to frank pus unless adsorbed or drained. Hence, abscess formation commonly accompanies inflammation of an abdominal viscus and is usually labelled either according to location (subphrenic, intrapelvic) or with reference to nearby organs (periappendiceal, paracolic, subhepatic).

Intraperitoneal abscess formation is associated with a spectrum of symptoms and signs. At one end, patients may be asymptomatic or may feel somewhat unwell, anorectic, fatigued, with failure to maintain or gain weight. At the opposite end, patients may have significant abdominal symptoms and signs (nausea, vomiting, abdominal pain, diarrhoea) and be extremely unwell. A swinging pyrexia is strongly suggestive of intraperitoneal abscess formation.

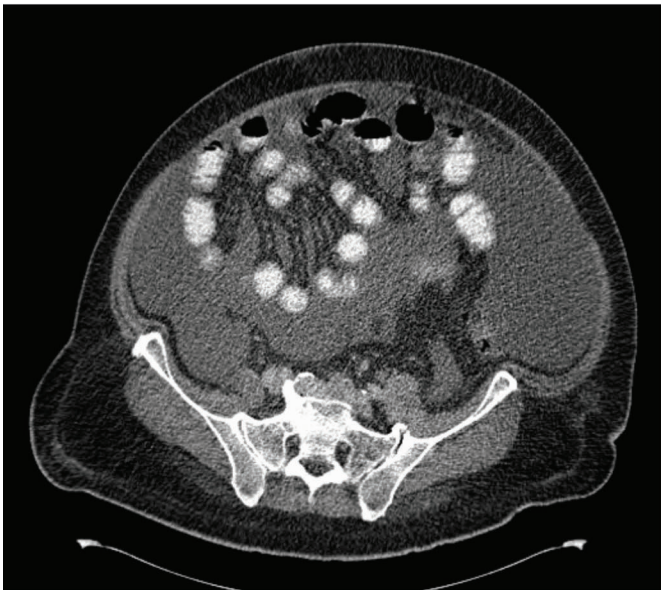

Figure 65.9 Computed tomography axial scan of the abdomen showing gross ascites.

Summary box 65.8

Clinical features of an abdominal/pelvic abscess

Symptoms

- Malaise, lethargy – failure to recover from surgery as expected
- Anorexia and weight loss
- Sweats +/– rigors
- Abdominal/pelvic pain
- Symptoms from local irritation, e.g. shoulder tip/hiccoughs (subphrenic), diarrhoea and mucus (pelvic), nausea and vomiting (any upper abdominal)

Signs

- Increased temperature and pulse +/– swinging pyrexia
- Localised abdominal tenderness +/– mass (including on pelvic examination)

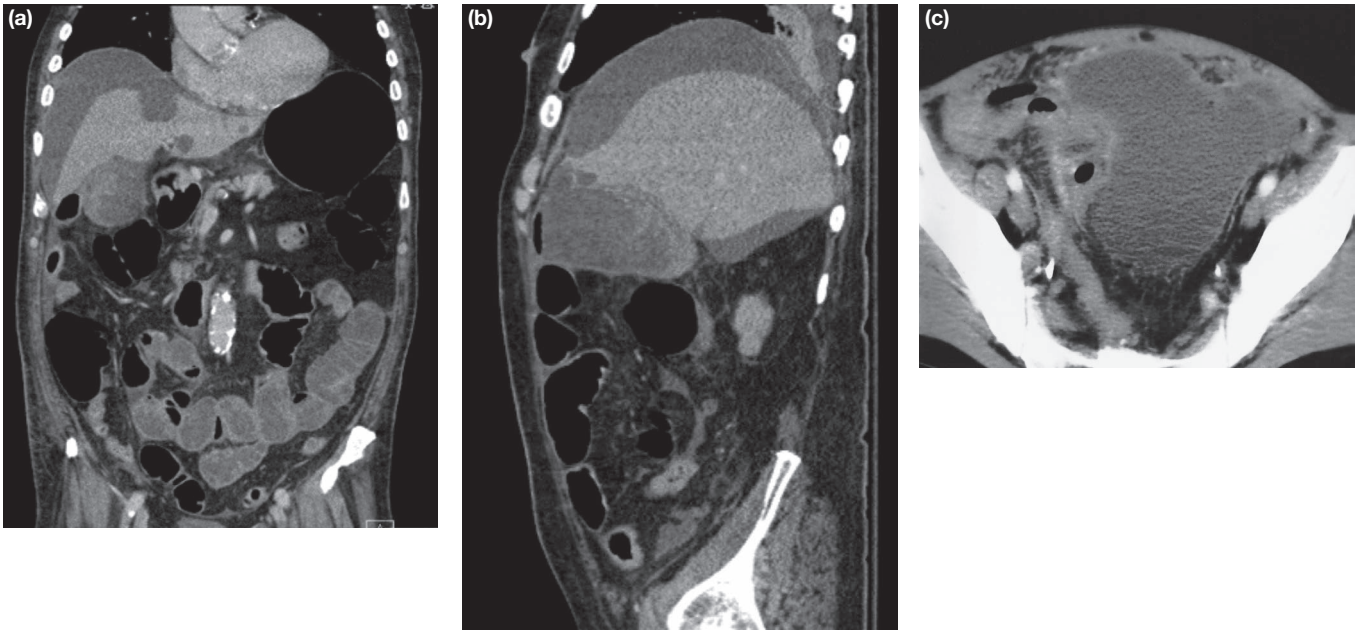

Figure 65.10 Intraperitoneal abscesses. **(a)** and **(b)** Subphrenic and subhepatic abscesses seen on computed tomography (CT) scanning. **(c)** Pelvic abscess seen on CT scanning.

Investigation

The modern diagnosis of an abscess is radiological using CT (***Figure 65.10***). CT imaging can also guide treatment by drain placement or aspiration. Ultrasound is a useful (though non-specific) modality for use in select populations (e.g. paediatric or pregnant patients). Serial imaging is used to monitor treatment efficacy or disease progression. Radiolabelled white cell scanning may occasionally prove helpful if an abscess is suspected but has not been identified by the above means.

Treatment

Abscesses less than 5 cm in diameter normally resolve with intravenous antibiotic treatment. As antibiotics take effect, the magnitude of the swinging pyrexia can decrease with each successive spike in temperature. Serial monitoring of C-reactive protein levels is useful to non-invasively monitor response to treatment.

Abscesses greater than 5 cm require either percutaneous aspiration/drainage or surgical intervention. If percutaneous radiological approaches fail, then operative washout is indicated. This can be conducted laparoscopically (laparoscopic lavage) or via an open approach. The technical challenges involved are such that this should only be undertaken by an experienced surgeon. The bowel may be matted and difficult to separate in order to access the abscess. All regions of the peritoneal cavity should be accessed, with a view to drainage of any residual collections. The entirety of the small intestine and adjoining mesentery should be exposed to ensure that there are no residual interloop abscesses. If a phlegmon is apparent, then only in the setting of life-threatening circumstances should the components of this be separated.

Special considerations: Prevention of abscess formation after appendicitis

During appendectomy, it is important to aspirate the pelvic, paracolic and subhepatic spaces prior to closure of the abdominal wall. This simple measure can reduce the incidence of postoperative abscess, which is common after appendectomy, occurring in up to 30% of patients following appendectomy for a perforated appendix. It can lead to frustration for patients if not forewarned of the possibility.

Special considerations: Abscess formation following intestinal surgery and anastomosis

The development of an abscess following intestinal resection and anastomosis signifies infection of a haematoma or an anastomotic leak. Locules of gas or free contrast (Gastrografin) on CT support anastomotic leak. Pelvic abscess formation is not uncommon following excision of the rectum and formation of a pelvic anastomosis.

Special considerations: Subphrenic abscess

This refers to the presence of pus immediately beneath the diaphragm. Patients may complain of shoulder tip pain. The diaphragm also develops at the same level as the C5 dermatome. If the parietal peritoneum under the diaphragm is irritated, pain is referred to the shoulder tip. This also explains why patients frequently complain of shoulder tip pain following laparoscopic or robotic surgery. In the era preceding that of cross-sectional imaging via CT, the adage 'pus somewhere, pus nowhere, pus under the diaphragm' was useful.

Special considerations: Pelvic abscess

The pelvis is the most common site of abscess formation because the vermiform appendix is often pelvic in position and the Fallopian tubes are also frequent sites of infection. A pelvic abscess can also occur as a sequel to diffuse peritonitis and is common after anastomotic leakage following colorectal surgery.

Clinical features

The most characteristic symptoms are pelvic pain, diarrhoea and passage of mucus in the stools. The patient may complain of lower back pain or a pressure sensation in the pelvis. This symptom can be quite severe in intensity. The abscess may discharge into the anal canal as the pelvic collection points through an anastomotic leak (the point of least resistance). Rectal or vaginal examination can be extremely uncomfortable for the patient.

Investigation and management

If any uncertainty exists, the presence of pus should be confirmed by ultrasonography or CT scanning. Pelvic abscesses can be drained transanally or transgluteally. The past vogue for transintestinal drainage is no longer practised because of the high incidence of complications such as fistulae. Laparotomy may sometimes be indicated.

PERITONEAL (MESOTHELIAL) SAC AND HERNIA FORMATION

The processus vaginalis refers to a peritoneal tube that advances into the inguinal ligament in tandem with migration of the testes. The lumen of the processus vaginalis is in continuity with the peritoneal cavity. Given this, it provides a conduit for herniation of abdominal contents. Even a residual indentation at the ostium of the processus vaginalis represents a mechanical defect at which repeated episodes of raised intraperitoneal pressure can lead to gradual extension of the parietal peritoneum into the inguinal canal.

The mesothelial sac is a near constant feature of incisional and parastomal hernias. In these instances, the peritoneum gradually advances over subcutaneous fat, or the serosal surface of the intestine, bringing that region of anatomy directly in continuity with the peritoneal cavity. Not surprisingly, incisional or parastomal hernias gradually increase in size with time. In addition, they are frequently complicated by parastomal herniation of intestinal contents and intestinal compromise.

THE MESENTERY

GENERAL CONSIDERATIONS

The arterial supply and venous and lymphatic drainage of each digestive organ are located in the mesentery. Thus diseases of individual organs can have significant effects on the adjoining mesentery and its components. The pancreas and the effects of pancreatitis are a good example. The pancreas is positioned on the mesentery (▶ ***65.5***). It arches over the SMA and superior mesenteric vein (both of which are intramesenteric). The neck of the pancreas is anterior to the region of the mesentery that contains the portal vein. The body and tail of the pancreas are in the dorsal mesogastrium (i.e. the posterior wall of the upper region sack) and the tip of the tail of the pancreas is located at the hilum of the spleen (see ***Development of the mesentery and peritoneum***). Given these anatomical relations, acute inflammation of the pancreas can affect any of these structures. Complications of acute pancreatitis thus include thrombosis in the portal and splenic vein, gastric outlet obstruction and arterial haemorrhage (see ***Chapter 72***).

The mesentery is remarkably well preserved in most diseases. Although rarely encountered in clinical practice, mesenteric necrosis is mostly seen in advanced necrotising pancreatitis. Primary defects (i.e. non-surgical causes) of the mesentery are rare. These are always accompanied by failure of normal development of the adjoining organ. For example, intestinal atresia arises when a section of the adjoining mesentery fails to develop.

The mesentery comprises adipose, connective tissue, neurological, lymphatic and vascular components. Abnormalities can arise in any of these and lead to either solid (tumour deposits, lymphatic metastases) or cystic lesions. The supportive capacity of the mesentery is reflected in the finding of splenunculi, heterotopic pancreas, ossification, teratomas and even ectopic pregnancies in different regions of the mesentery.

MESENTERIC HAEMATOMA

A mesenteric haematoma can follow abdominal compression in trauma (e.g. seat-belt syndrome) or during abdominal surgery, when the mesentery must be manipulated. The mesenteric stroma is mainly adipose and thus easily damaged. It bleeds readily if disrupted. A haematoma may form and quickly enlarge to compress mesenteric veins. Mesenteric haematoma can sometimes occur during surgery for Crohn's disease.

MESENTERIC ADENITIS

This is inflammation of the lymph nodes of the mesentery (***Figure 65.11***). It mostly occurs in the ileocaecal region because of the volume of lymphatic tissue. It is often the site of viral or infective lymphadenopathy (*Yersinia* spp., *Campylobacter* spp., *Mycobacterium tuberculosis*) and may follow an upper respiratory tract infection with either a viral or bacterial pathogen. Mesenteric adenitis caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is not uncommon. Swelling of ileocaecal lymph nodes results in capsular stretch and somatic pain in the right iliac fossa. The patient is frequently pyretic (often the temperature is markedly elevated) and may have enlarged cervical lymph nodes.

During childhood, acute, non-specific mesenteric adenitis is a common condition. The typical history is one of short attacks of central abdominal pain lasting from 10 to 30 minutes, commonly associated with vomiting. The patient seldom looks ill. In more than half of the cases the temperature is

elevated. Abdominal tenderness is poorly localised and, when present, shifting tenderness is a valuable sign for differentiating the condition from appendicitis. The neck, axillae and groins should be palpated for enlarged lymph nodes.

Investigation

There is often a leukocytosis of 10 000–12 000/μL (10–12 × 10^9/L) or more on the first day of the attack, but this falls on the second day. Ultrasonography may be helpful in differentiating this from appendicitis. Sometimes a CT or exploratory laparoscopy is required.

Treatment

This is normally supportive. Viral mesenteric adenitis normally resolves spontaneously but can recur. The symptoms in bacterial mesenteric adenitis include cramping pain, vomiting and diarrhoea. They can be severe and require hospitalisation.

MESENTERIC ADENITIS AND THE MESENTERY IN CROHN'S DISEASE

Ileocaecal mesenteric adenitis occurs in ileocolic Crohn's disease and the mesentery is thickened, shortened and oedematous with a tendency to bleed readily when handled. The vascular pedicles within the mesentery may not be apparent, thus great care is needed when dividing the mesentery as normal techniques may not be suitable.

In Crohn's disease, the mesentery can extend over adjoining intestine as 'fat wrapping' or 'creeping fat' (***Figure 65.12***). These appear to be specific to Crohn's disease. The mesentery changes from normal to abnormal at the mesenteric transition zone. Conventional surgery for Crohn's disease involves amputation of the intestine at its intersection with adjoining mesentery. The mesentery is thus retained. Increasingly, surgeons are removing the mesentery adjoining the diseased intestine (see ***Chapter 75***).

TUBERCULOSIS OF THE MESENTERIC LYMPH NODES

Tuberculous mesenteric lymphadenitis is considerably less common than acute non-specific lymphadenitis. Tubercle bacilli, usually, but not necessarily, bovine, are ingested and enter the mesenteric lymph nodes by way of Peyer's patches. Sometimes only one lymph node is infected; usually there are several, and occasionally massive involvement occurs. The presentation may be with abdominal pain (a rare differential for appendicitis) or with general constitutional symptoms (pyrexia, weight loss, etc.). Calcified lymph nodes may be demonstrated on a plain radiograph of the abdomen, where they must be distinguished from other calcified lesions, e.g. renal or ureteric stones.

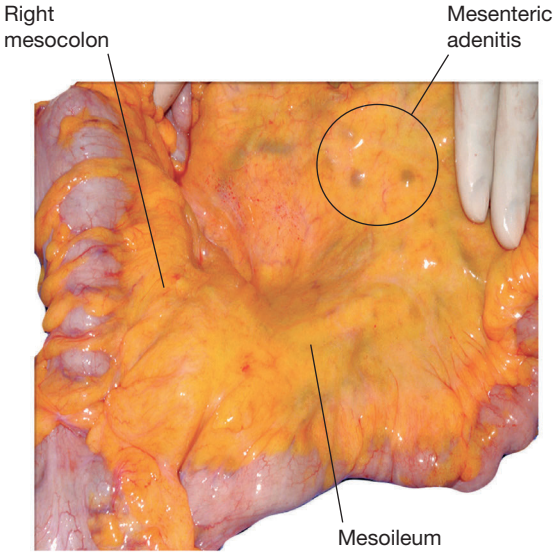

Figure 65.11 Mesenteric adenitis. (Reproduced with permission from Coffey JC, Lavery I, Sehgal R (eds). *Mesenteric principles of gastrointestinal surgery: basic and applied principles*. Boca Raton: CRC Press, 2017: 69–84.)

VASCULAR ABNORMALITIES OF THE MESENTERY

Acute mesenteric ischaemia

The arterial inflow to the mesenteric domain is limited to three major vessels: the coeliac trunk and the superior and inferior mesenteric arteries (***65.5***). Additional arterial inflow in the pelvis comes via the middle rectal arteries. The limited number of arterial inputs to the mesenteric domain mean that narrowing or occlusion at the origin of any one vessel can have significant clinical effects. Acute mesenteric ischaemia mostly follows embolisation to the origin of either the coeliac or superior mesenteric arterial trunk. Unless quickly reversed, it can lead to ischaemia and necrosis of most of the intestine. At first, the severity of abdominal pain does not match clinical findings on examination. If ischaemia and necrosis occur, the patient develops peritonism as a result of irritation of the parietal peritoneum by the necrotic intestine.

The inferior mesenteric artery (IMA) is usually divided at open repair of an abdominal aortic aneurysm; however, anastomoses between peripheral branches of the SMA and IMA, referred to as the marginal artery of Drummond, usually prevent critical ischaemia of the sigmoid and descending colon. If ischaemia is limited to the mucosa, the patient may experience cramping suprapubic pain and diarrhoea that normally settles. If ischaemia is transmural the colon may become necrotic and require resection.

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.
Sir David Drummond, 1852–1932, born Dublin, Ireland, pathologist and physician at the Royal Victoria Infirmary, Newcastle (1878–1920), President of the British Medical Association (1921–1922) and vice chancellor of the University of Durham (1920–1922).

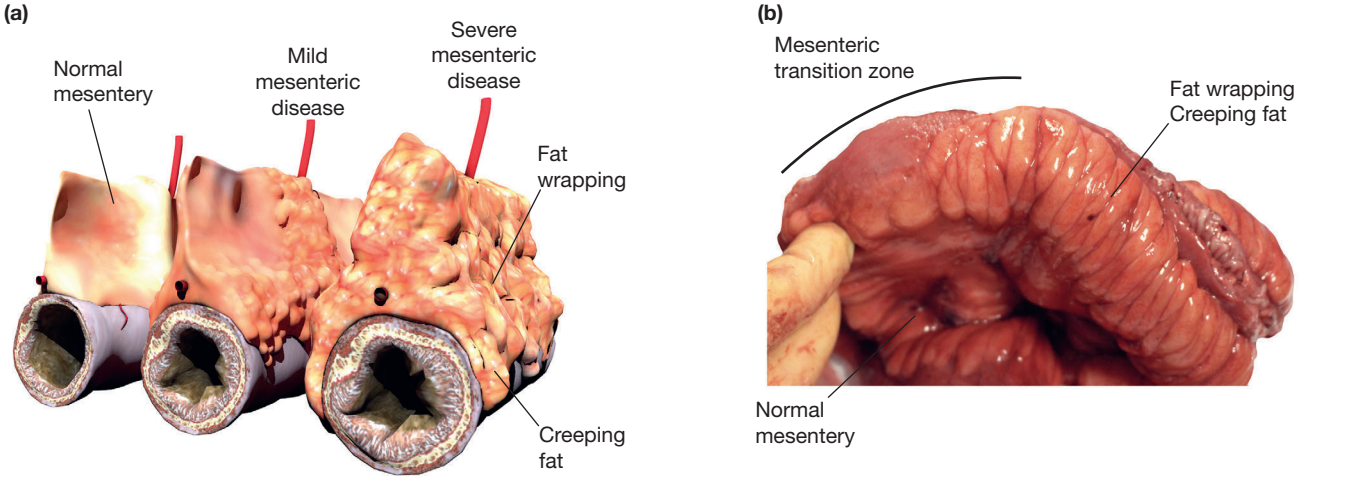

Figure 65.12 The mesentery in Crohn's disease. **(a)** Levels of mesenteric disease manifestations. **(b)** The mesenteric transition zone and creeping fat. Chronic mesenteric ischaemia

Chronic mesenteric ischaemia is due to atherosclerotic narrowing at the origin of any of the three arterial trunks. Patients describe postprandial abdominal pain that can be severe, resulting in a fear of eating with progressive weight loss. The diagnosis requires CT angiography. Radiological stent placement may be successful, but surgical endarterectomy of bypass repair may be required.

Venous ischaemia

The venous drainage of the mesenteric domain is limited to the junction between the hepatic veins and the inferior vena cava. Narrowing or blockage of the lumen at this junction occurs in Budd–Chiari syndrome. It has major clinical implications. Most venous drainage of the mesenteric domain returns to the liver via the portal vein. Portal venous thrombosis impedes venous drainage of all abdominal digestive organs unless an alternative drainage route opens (i.e. a portosystemic shunt) or is created (see ***Chapter 69***) (***65.5***).

ROTATIONAL DISORDERS

Malrotation

Malrotation refers to a failure of formation of the mid-region switch (described in ***Development of the mesentery and peritoneum***) (***Figure 65.13***) and is the most common abdominal surgical emergency in the neonatal period. Early during development, the right and left side of the mid-region fold of the mesentery are aligned from the central to peripheral zones. Later, the sides switch position at the periphery but not at the central zone. Adjoining intestine similarly changes position to take up the normal conformation. In malrotation, the switch does not occur, and the sides of the mid-region fold remain aligned. This explains why the duodenum, jejunum and ileum are aligned in the right flank of the abdomen. Malrotation in itself is not pathogenic. However, the small intestine and adjoining mesentery are abnormally mobile and can undergo torsion around the superior mesentery artery, which can be life-threatening.

History

The neonate with a volvulus due to malrotation is patently distressed, vomiting and has a distended abdomen.

Investigation

Urgent CT is mandated and clarifies the position of the duodenojejunal junction. Normally the duodenojejunal flexure is positioned at or to the left of the midline. In volvulus due to malrotation, the duodenojejunal junction is on the right of the midline (i.e. the mid-region switch has not occurred).

Treatment

The mainstay of treatment is Ladd's procedure, in which the volvulus is first reversed and then the intestine is secured to the posterior abdominal wall. Although this does not correct the underlying mesenteric abnormality, it does reduce the mobility of the intestine and mesentery and reduces the likelihood of further volvulus. It is possible however to address the underlying mesenteric abnormality by recapitulating the mid-region switch. This returns the intestine and mesentery to a normal conformation. They can then be fixed to the posterior abdominal wall.

Volvulus of the intestine and adjoining mesentery

Volvulus can only be understood if considered in mesenteric terms. Where a section of intestine is curved, the adjoining mesentery is buckle-shaped or folded. If the intestine progresses from a curve to a coil, the adjoining mesentery acquires a

William Edwards Ladd, 1880–1967, Surgeon in Chief, Boston Children's Hospital, Boston, MA, USA.

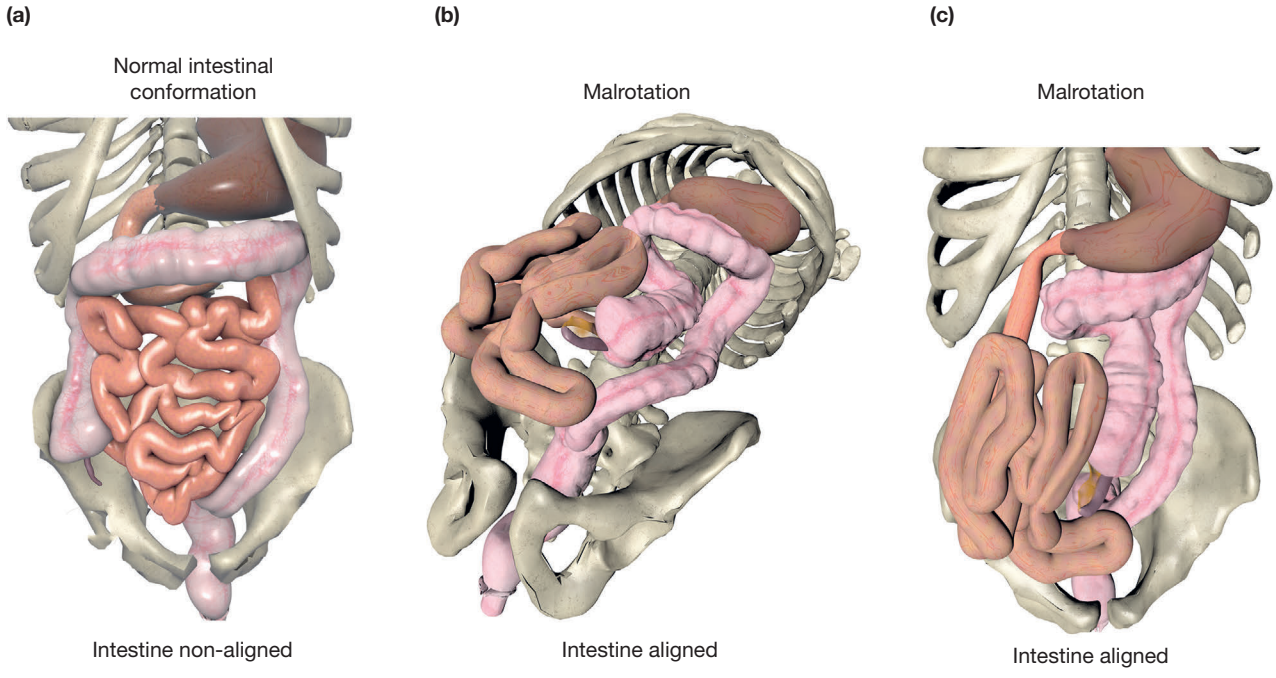

Figure 65.13 Malrotation. (Reproduced with permission from Coffey JC, Lavery I, Sehgal R (eds). *Mesenteric principles of gastrointestinal surgery: basic and applied principles*. Boca Raton: CRC Press, 2017: 85–108.)

spiral shape. The resultant coil/spiral complex of the intestine and mesentery is termed a volvulus. Its formation is normally prevented by adhesion of the mesentery to the posterior abdominal wall during development. Wherever mesenteric adhesion is inadequate, there is a risk of volvulus formation. Sigmoid volvulus is the commonest type, followed by ileocaecal. However, the anatomy of the mesentery is such that volvulus can theoretically arise at any level from the oesophagogastric to anorectal junction.

History

In ileocaecal volvulus the patient often describes a longstanding history of intermittent, colicky abdominal pain associated with distension and vomiting. In between episodes (when the volvulus has detorted) the patient is entirely asymptomatic and repeated CT and endoscopic examinations are normal. The clinical picture is similar to that of irritable bowel syndrome.

Sigmoid volvulus occurs mainly in the elderly as the intestine and mesentery continue to lengthen throughout life.

Investigation

A plain film of the abdomen is frequently diagnostic. CT is recommended when planning operative intervention.

Treatment

Sigmoid volvulus can be quickly reversed with endoscopic decompression, but recurrence is common. Most patients will ultimately require surgery to resect the intestine and adjoining mesentery. These patients often have multiple comorbidities and present challenging anaesthetic and ethical dilemmas (see ***Chapter 77***).

Mesenteric stretch during colonoscopy

Development of pain doing colonoscopy is frequently attributed to distension of the colon and stretch of the colon wall. In reality, substantial volumes of gas would be required to insufflate the colon to the degree at which the colon stretches. Pain during colonoscopy is common and arises mainly because of stretch of the adjoining mesentery. Looping of the intestine is a frequent event during colonoscopy. The loop corresponds to a coil, which means that the mesentery adjoining the loop must form a spiral. It thus resembles the anatomical arrangement seen in volvulus. Attempts to advance the endoscope beyond a coil will place both the intestine and mesentery under stretch. Stretch of the mesentery leads to severe central colicky abdominal pain, often accompanied by bradycardia. An understanding of the anatomical basis of loop formation enables the endoscopist to take appropriate preventative or corrective measures.

Mesenteric sclerosis and panniculitis

Mesenteric sclerosis

This is also termed sclerosing encapsulating peritonitis or abdominal cocoon syndrome (***Figure 65.14***). It occurs mostly in patients on long-term peritoneal dialysis. It is a disease of the mesothelial component of visceral peritoneum (i.e. peritoneum overlying organs of the mesenteric domain). The mesothelium undergoes hypertrophy and the peritoneum becomes thickened. Underlying organs become encapsulated by a peritoneal 'cocoon'. Mesenteric sclerosis may follow intraperitoneal sepsis, when fibrin plaques accumulate along the

intestine and mesentery leading to a reactionary mesothelial hypertrophy.

History and investigation

The clinical picture is highly variable, as is the natural history of the condition among individuals. Mesenteric sclerosis can lead to obstruction of the intestine. The diagnosis is normally made based on CT and intraoperative appearances and post-operative surgical histology.

Treatment

Treatment is supportive and surgery is reserved for emergency cases only as surgical intervention may lead to further peritoneal sclerosis.

Mesenteric panniculitis

This is inflammation of the mesodermal mesentery (i.e. the mesenteric stroma). It is always present in Crohn's disease (see ***Mesenteric adenitis and the mesentery in Crohn's disease***). Often it is an incidental finding on cross-sectional imaging of the abdomen by CT ('misty mesentery'; ***Figure 65.14***). Although there are concerns over malignant potential, this is not supported by the general literature. It can arise secondary to inflammation in any digestive organ. It is associated with connective tissue disorders (including Weber–Christian disease). As with mesenteric sclerosis, treatment is normally medical and surgery is rarely required. Serial CT scanning is indicated to ensure resolution.

Sclerosing mesenteritis

Sclerotic (mesothelial) and inflammatory (mesodermal) abnormalities of the mesentery may coexist. Although this can arise *de novo*, it is normally a secondary manifestation of another pathology (i.e. immunoglobulin G4 [IgG4] disease, which is a systemic fibroinflammatory disease).

Adhesions

Pathology

Adhesions are best classified with reference to their appearance. They are subdivided into peritoneal, areolar and dense adhesions.

Peritoneal (sclerotic) adhesions

These are mesothelial adhesions between two mesothelial surfaces (***Figure 65.15a***). They reflect mesothelial proliferation, resemble peritoneum and are generally soft and non-vascular. They are similar in appearance (though not in consistency) to the peritoneal cocoon that occurs in mesenteric sclerosis. These can be band-like. They may occur following laparoscopic surgery, where they form a band linking a viscus to the inner surface of a port site. Band adhesions can lead to focal abdominal pain, internal herniation (through the window created with surrounding related structures) or intestinal torsion around the band.

Areolar adhesions

These flimsy connective tissue adhesions are identical to the connective tissue that fills the retroperitoneal space between the mesentery and posterior abdominal wall (***Figure 65.15b***). Given this appearance they have been called 'angel hairs'. They are generated in a process similar to that involved when the mesentery adheres to the posterior abdominal wall.

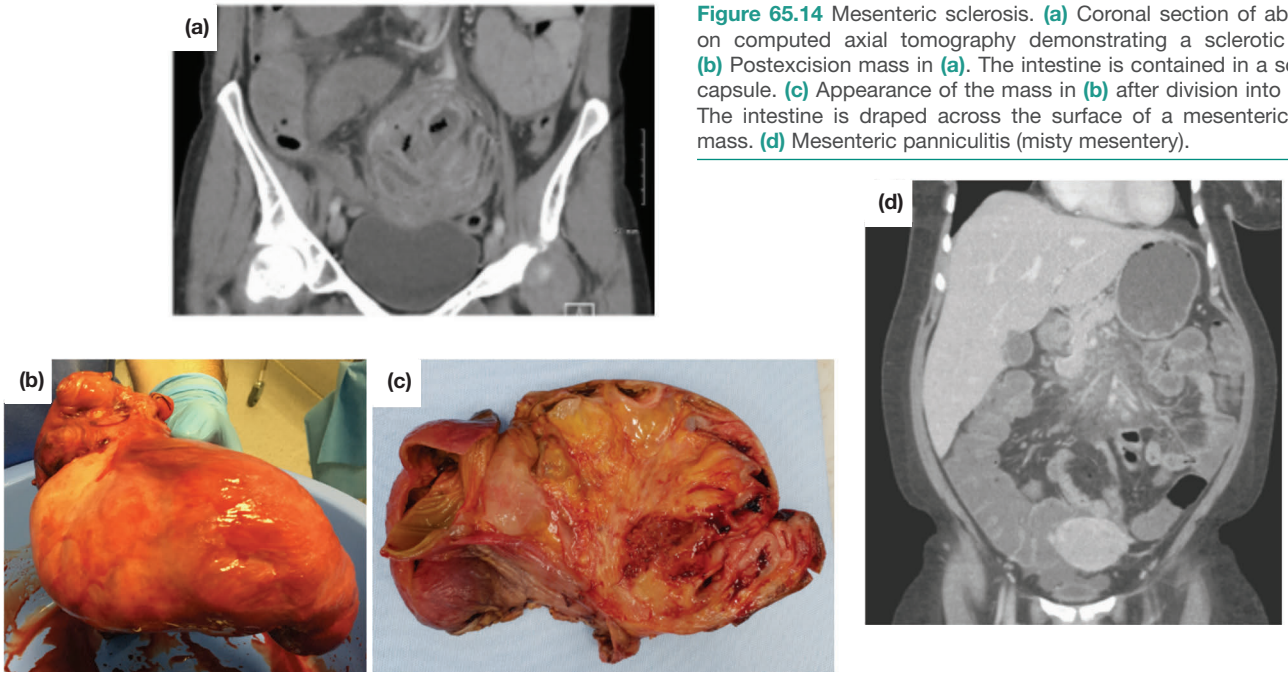

Figure 65.14 Mesenteric sclerosis. **(a)** Coronal section of abdomen on computed axial tomography demonstrating a sclerotic mass. **(b)** Postexcision mass in **(a)**. The intestine is contained in a sclerotic capsule. **(c)** Appearance of the mass in **(b)** after division into halves. The intestine is draped across the surface of a mesenteric tissue mass. **(d)** Mesenteric panniculitis (misty mesentery).

Frederick Parkes Weber, 1863–1962, physician, Mount Vernon Hospital, London, UK.
Henry Asbury Christian, 1876–1951, pathologist, Boston, MA, USA.

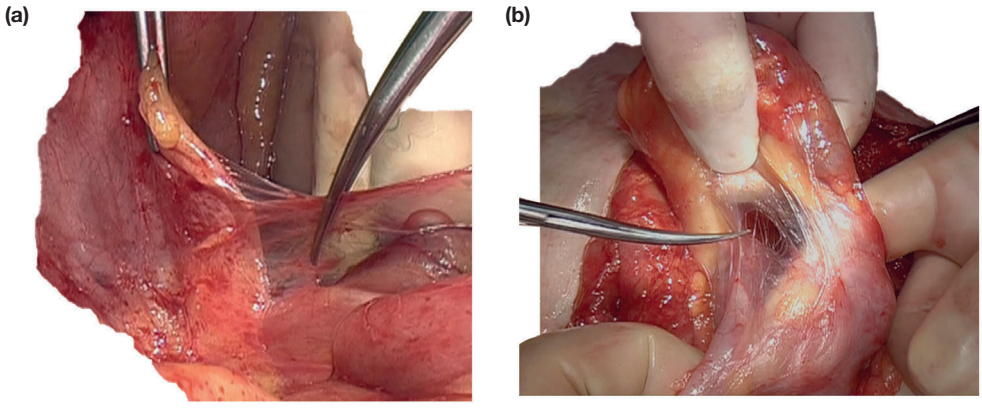

Figure 65.15 Adhesions. **(a)** Peritoneal (sclerotic) adhesions. **(b)** Areolar adhesions. (Reproduced with permission from Coffey JC, Lavery I, Sehgal R (eds). *Mesenteric principles of gastrointestinal surgery: basic and applied principles*. Boca Raton: CRC Press, 2017: 333–42.)

The capacity to adhere is shared by all organs of the mesenteric domain. This explains the anatomical relations between the liver, colon, spleen and mesentery on one side and the abdominal wall on the other. The capacity is retained to varying degrees among individuals and explains adhesion formation in the adult setting. Adhesion occurs following abdominal surgery when the intestine and mesentery adhere to the inside surface of the anterior abdominal wall. The resultant anatomical arrangement is similar to that observed during development, except the anterior abdominal wall is involved.

Postoperative adhesion formation occurs to varying degrees. At one end of the spectrum, it may be entirely absent. At the other end, mesenteric, intestinal and other components of the mesenteric domain may adhere over broad areas to the anterior abdominal wall. This normally commences in the midline and extends laterally towards the flanks, displacing the overlying peritoneum. The conformation of the peritoneal cavity changes markedly. In the most extremes cases, the peritoneal cavity may be obliterated or limited to small pockets at the flanks. This generates considerable technical challenges during reoperative surgery.

Dense adhesions

These differ markedly in appearance from peritoneal or areolar adhesions. They can bridge the abdominal wall and intestine, or intestine and mesentery, and lead to fusion of the bridged structures. Surgical division can be challenging. Sometimes it is not possible to separate conjoined organs without disrupting the integrity of one of them. Such dense adhesions arise mostly following severe intraperitoneal contamination (e.g. after perforation) at sites of gross fibrin deposition and are highly variable in terms of vascularity.

Complications of adhesions

The most common adhesion-related problem is small bowel obstruction (SBO). Adhesions are the most frequent cause of SBO in resource-rich countries and are responsible for 60–70% of SBOs (see ***Chapter 74***). Adhesions are also implicated as a major cause of secondary infertility (see ***Chapter 87***). The relationship of adhesions to chronic abdominal and pelvic pain is contentious. Unguided division of adhesions has not been shown to reduce chronic abdominal pain although conscious pain mapping (laparoscopy under local anaesthesia) to direct lysis may improve success rates.

A substantial industry has developed around the prevention of adhesions. To date, no agent or mechanism has been identified that reliably reduces adhesion formation.

Mesenteric cysts

Cysts may occur in any region of the mesentery (***Figure 65.16***). They are most often observed in mesentery adjoining the small intestine (60%) or the colon (40%) and can be classified as follows:

- chylolymphatic;
- enterogenous;
- traumatic;
- hydatid.

Chylolymphatic cysts

Although mesenteric cysts are rare, this is the most common variety, probably arising in congenitally misplaced lymphatic tissue that has no efferent communication with the lymphatic system (most frequently in the mesentery of the ileum). The thin wall of the cyst, which is composed of connective tissue

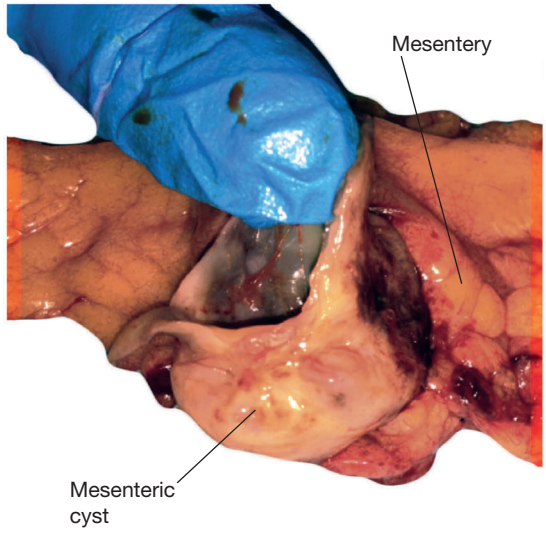

Figure 65.16 Mesenteric cyst. (Reproduced with permission from Coffey JC, Lavery I, Sehgal R (eds). *Mesenteric principles of gastrointestinal surgery: basic and applied principles.* Boca Raton: CRC Press, 2017: 85–108.)

lined by flat endothelium, is filled with clear lymph or, less frequently, with chyle, varying in consistency from watered milk to cream. Occasionally, the cyst attains a large size. More often unilocular than multilocular, a chylolymphatic cyst is almost invariably solitary, although there is an extremely rare variety in which myriads of cysts are found in various regions of the mesentery. A chylolymphatic cyst has a blood supply that is independent from that of the adjacent intestine and, thus, enucleation is possible without the need for resection of the gut.

Enterogenous cysts

These are believed to be derived either from a diverticulum of the mesenteric border of the intestine that has become sequestrated from the intestinal canal during embryonic life or from a duplication of the intestine (see ***Chapter 18***). An enterogenous cyst has a thicker wall than a chylolymphatic cyst and is lined by mucous membrane, which is sometimes ciliated. The content is mucinous and either colourless or yellowish brown as a result of past haemorrhage. The muscle in the wall of an enteric duplication cyst and the bowel with which it is in contact have a common blood supply; consequently, removal of the cyst always entails resection of the related portion of intestine.

Tumours of the mesentery

Primary tumours of the mesentery include carcinoid, lymphoma, sarcoma and desmoid tumours. The mesentery is affected in local lymphatic spread of carcinoma arising from abdominal viscera (***Figure 65.17***). If indicated, a benign tumour of the mesentery may be excised with resection of the adjacent intestine. A malignant tumour of the mesentery requires biopsy confirmation and specific, usually non-surgical, treatment, e.g. chemotherapy for lymphoma.

Diffuse fibromatosis

Fibromatosis is rare, characterised by an abnormal proliferation of myofibroblasts. Although non-metastasising, and said to be benign, it can nevertheless prove widely invasive, compressing and infiltrating surrounding tissues such as the bowel and mesentery with complications thereof. There is an association with familial adenomatous polyposis (FAP).

Summary box 65.9

Mesenteric cysts: clinical features

- Cysts occur most commonly in adults with a mean age of 45 years
- Twice as common in women as in men
- Rare: incidence around 1 per 140 000
- Approximately a third of cases occur in children younger than 15 years
- The mean age of children affected is 5 years
- The most common presentation is of a painless fluctuant abdominal swelling near the umbilicus
- Other presentations are with recurrent attacks of abdominal pain with or without vomiting (pain resulting from recurring temporary impaction of a food bolus in a segment of bowel narrowed by the cyst or possibly from torsion of the mesentery) and acute abdominal catastrophe due to:
  - torsion of that portion of the mesentery containing the cyst
  - rupture of the cyst, often as a result of a comparatively trivial accident
  - haemorrhage into the cyst
  - infection

Summary box 65.10

Mesenteric tumours

Benign

- Lipoma
- Fibroma
- Fibromyxoma
- Desmoid

Malignant

- Lymphoma
- Secondary carcinoma
- Neuroendocrine tumours
- Lymphatic metastases
- Tumour deposits (lymphovascular and perineural)
- Peritoneal carcinomatosis

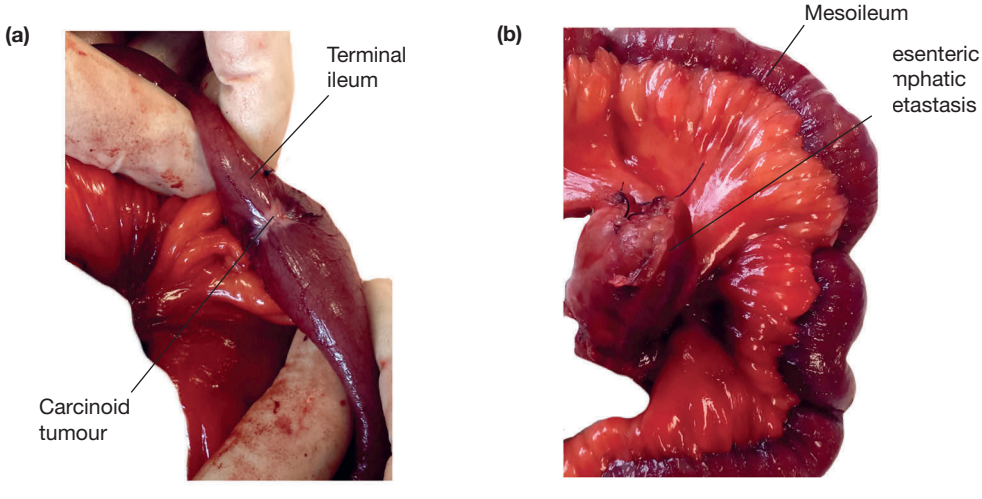

Figure 65.17 Terminal ileal carcinoid **(a)** and lymphatic metastasis **(b)**. (Reproduced with permission from Coffey JC, Lavery I, Sehgal R (eds). *Mesenteric principles of gastrointestinal surgery: basic and applied principles*. Boca Raton: CRC Press, 2017: 85–108.)

Figure 65.18 The mesoappendix. (Reproduced with permission from Coffey JC, Lavery I, Sehgal R (eds). *Mesenteric principles of gastrointestinal surgery: basic and applied principles*. Boca Raton: CRC Press, 2017: 11–40.)

THE GREATER OMENTUM

The **greater omentum** corresponds to the anterior wall of the upper region of the mesentery. Rutherford Morison called the greater omentum 'the abdominal policeman'. The greater omentum attempts, often successfully, to limit intraperitoneal infective and other noxious processes. For instance, an acutely inflamed appendix is often found wrapped in omentum, and this saves many patients from developing diffuse peritonitis. The omentum often plugs the neck of a hernial sac and prevents a coil of intestine from entering and becoming strangulated. The omentum can also be a cause of obstruction (acting as a large adhesion). The omentum is usually involved in tuberculous peritonitis and carcinomatosis of the peritoneum.

The **mesoappendix** arises from the posterior aspect of the ileocaecal region of the mesentery (***Figure 65.18***). As a result, it often occupies a retrocaecal position, as does the adjoining appendix. The position of the mesoappendix is thus a determinant of the symptoms and signs associated with acute appendicitis (see ***Chapter 76***).

A **Meckel's diverticulum** (see ***Chapter 74***) resembles the appendix in that it comprises an intestinal diverticulum at the periphery of a flange of mesentery. The latter arises from a nearby small intestinal region of mesentery.

The bloodless fold of Treves, a flange of mesentery at the antimesenteric side of the ileum just proximal to the ileocaecal valve, is a mesenteric remnant that arises after differentiation of the intestine at that level.

THE RETROPERITONEAL SPACE AND RETROPERITONEUM

The non-mesenteric domain is posterior to the mesenteric domain. The space between both is termed the retroperitoneal space (***Figure 65.19***) (***65.4***). It is a conceptual space as it contains areolar connective tissue. Regions of the connective tissue were separately named Toldt's, Waldeyer's, Denonvilliers', Gerota's and Fredet's fascia, as if they are separate entities. These are merely different zones of the same connective tissue layer that is interposed between the mesenteric domain in front and the non-mesenteric domain behind.

The space continues into the thorax and thereafter into the neck. This explains why, on occasion, a patient with an intestinal perforation during colonoscopy develops surgical emphysema and crepitus at the neck level. In these cases, perforation occurs into the retroperitoneal space (***Figure 65.20***). Gas tracks along the space into the thorax and thereafter into the neck, where it accesses subcutaneous tissue to generate surgical emphysema and crepitus. The volume of gas insufflated can be considerable given that the peritoneal cavity will not have been entered and the endoscopist may not recognise the perforation. The space may be obliterated following radiation treatment, in Crohn's disease or in longstanding diverticular inflammation. This presents considerable challenges for the surgeon who needs access to the plane whenever conducting visceral surgery.

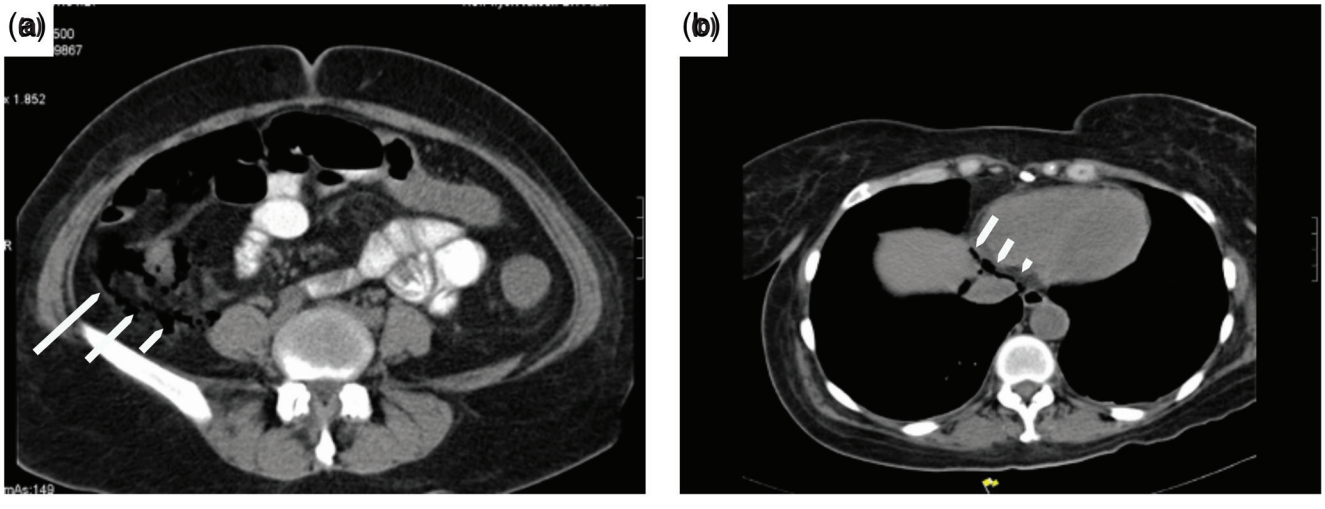

Figure 65.20 Perforation into the retroperitoneal space. Axial computed tomography section of the abdomen demonstrating gas (arrows) in the retroperitoneal space **(a)** and mediastinum **(b)**.

RETROPERITONEAL SPACE COLLECTIONS

These are fluid collections in the retroperitoneal space and these differ from intraperitoneal collections because of their location (***Figure 65.21***). They are a common finding in moderate to severe acute pancreatitis. Fluid accumulates as a result of pancreatic inflammation, dissecting the left mesocolon off the underlying fascia and posterior abdominal wall. With continued expansion retroperitoneal space collections track subperitoneally around the flanks. A rapidly expanding retroperitoneal collection, such as occurs with a ruptured aortic aneurysm, may rupture intraperitoneally.

THE RETROPERITONEUM

The retroperitoneum is the region of the non-mesenteric domain deep to the retroperitoneal space. It contains the kidneys, adrenal glands, major vessels, ureters and gonadal vessels and is surrounded by adipose tissue.

Swellings in the retroperitoneum include abscess, haematoma, cysts and malignancy from retroperitoneal organs (kidney, ureter, adrenal). The term retroperitoneal tumour refers to primary tumours arising in connective tissues in this region.

Retroperitoneal fibrosis

This is a relatively rare diagnosis characterised by development of a flat grey/white plaque of tissue that usually develops in

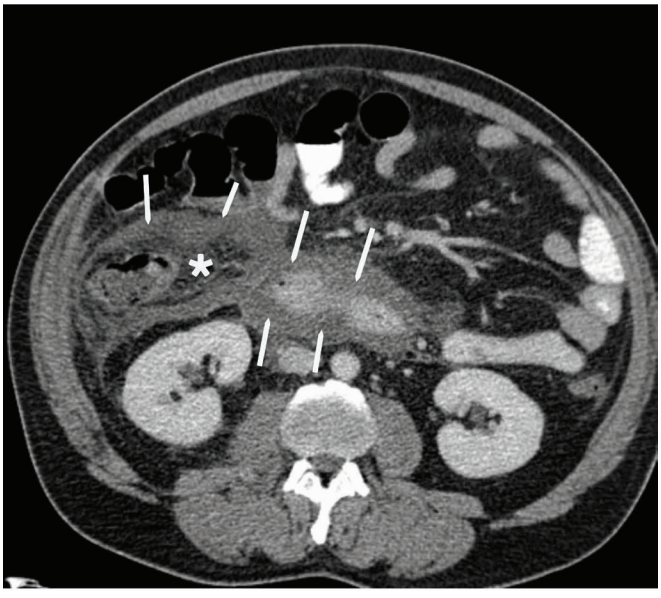

Figure 65.21 Computed tomography scan demonstrating retroperitoneal space collection in acute pancreatitis. The collection (arrows) has dissected the right mesocolon (asterisk) and duodenum, off the underlying retroperitoneum. Fluid is apparent in the retroperitoneal space.

the low lumbar region and later spreads laterally and upwards to encase the common iliac vessels, ureters and aorta. Histological appearances vary from active inflammation with a high cellular content interspersed with bundles of collagen through to one of relative acellularity and mature fibrosis/calcification. Its aetiology is obscure in most cases (idiopathic; synonym Ormond's disease), being allied to other fibromatoses (others being Dupuytren's contracture and Peyronie's disease).

Summary box 65.11

Causes of retroperitoneal fibrosis

Benign

- Idiopathic (Ormond's disease)
- Chronic inflammation
- Extravasation of urine
- Retroperitoneal irritation by leakage of blood or intestinal content
- Aortic aneurysm (inflammatory type)
- Trauma
- Drugs (chemotherapeutic agents and previously methysergide)

Malignant

- Lymphoma
- Carcinoid tumours
- Secondary deposits (especially from carcinoma of stomach, colon, breast and prostate)

Retroperitoneal (psoas) abscess

The psoas abscess is an abscess of the retroperitoneum (***Figure 6.22***). At the start of the twentieth century, psoas abscess was mainly caused by TB of the spine (Pott's disease). With the decline of *M. tuberculosis* as a major pathogen in resource-rich countries, a psoas abscess was mostly found secondary to direct spread of infection from the inflamed digestive or urinary tract with or without perforation. In more recent years it is most commonly seen in advanced Crohn's disease. Rarely, it arises due to haematogenous spread from an occult source in immunocompromised patients and in association with intravenous drug misuse.

History

Clinical presentation is with back pain, lassitude and fever. A swelling may point to the groin as it tracks distally along the iliopsoas muscle, under the inguinal ligament. Pain may be elicited by passive extension of the hip or a fixed flexion of the hip evident on inspection.

Investigation and treatment

Radiological investigation is by CT scanning and treatment is usually by percutaneous CT-guided drainage and appropriate antibiotic therapy. Surgical intervention is required if these are unsuccessful.

Retroperitoneal lipoma

The patient may seek advice on account of a swelling or because of indefinite abdominal pain. The swelling sometimes reaches an immense size. Diagnosis is usually by CT scan. A retroperitoneal lipoma sometimes undergoes myxomatous degeneration, a complication that does not occur in a lipoma

Figure 65.22 Representative sagittal computed tomography reconstruction of a right-sided psoas abscess (arrow) (courtesy of Dr K Patel, Homerton University Foundation Trust, London, UK).

John Kelso Ormond, 1886–1978, urologist, Ann Arbor, MI, USA.
Baron Guillaume Dupuytren, 1777–1835, Surgeon in Chief, Hôtel Dieu, Paris, France.

Percival Pott, 1714–1788, surgeon, St Bartholomew's Hospital, London, UK.

in any other part of the body. A lesion that rapidly increases in size is often malignant (liposarcoma).

Retroperitoneal sarcoma

Retroperitoneal sarcomas are rare tumours accounting for only 1–2% of all solid malignancies (10–20% of all sarcomas are retroperitoneal). The peak incidence is in the fifth decade of life, although they can occur at almost any age. The most frequently encountered cell types are:

- liposarcoma;
- leiomyosarcoma;
- malignant fibrous histiocytoma.

History and examination

Patients with sarcomas present late because these tumours arise in the large potential spaces of the retroperitoneum and can grow to a considerable size without producing symptoms. Moreover, when symptoms do occur, they are non-specific, such as abdominal pain and fullness, and are easily dismissed as being caused by other less serious processes. Retroperitoneal sarcomas are therefore often very large at the time of presentation.

Investigation

Detailed multiplanar imaging (CT and MRI) with reconstructions is required not only for tumour detection, staging and surgical planning but also for guiding percutaneous or surgical biopsy of these tumours.

Treatment

The definitive treatment of primary retroperitoneal sarcomas is surgical resection. Chemotherapy and radiotherapy without surgical debulking have rarely been beneficial, when used alone or in combination. A multidisciplinary treatment approach with imaging review will be required when assessing operability (based on adjacency or involvement of vital structures) and approach. Up to 75% of retroperitoneal sarcoma resections involve resection of at least one adjoining intra-abdominal visceral organ (commonly large or small bowel or kidney). The most common types of vascular involvement precluding resection are involvement of the proximal superior mesenteric vessels or involvement of bilateral renal vessels.

Prognosis

Survival rates are in general poor, even after complete resection, being of the order of 35–50% (excluding low-grade liposarcomas, which may frequently be cured by resection).

ACKNOWLEDGEMENTS

The author would like to acknowledge the artistic support of Dara Walsh, who generated all digital images and videos. He would also like to acknowledge Mr Kevin Byrnes for his work on the development of the mesentery and abdominal digestive system.

PART 11 | Abdominal

CHAPTER
66 The oesophagus

Learning objectives

To understand:

- The anatomy and physiology of the oesophagus and their relationship to disease
- The clinical features, investigations and treatment of benign and malignant disease with particular reference to common adult disorders

APPLIED SURGICAL ANATOMY AND PHYSIOLOGY

The oesophagus is a muscular tube connecting the pharynx to the stomach. It starts at the level of the cricoid cartilage (C6 vertebra) and ends at the oesophagogastric junction (OGJ) (opposite T11 thoracic vertebra). In the neck, it descends behind the trachea and anteriorly to the vertebral column following its curvature into the thorax. At the lower part of the thoracic cavity, it transverses the diaphragmatic hiatus, clasped by the crura of the diaphragm and into the stomach. There are slight curvatures of the oesophagus; in the neck, it leans slightly more towards the left side, while in the mid-chest it curves slightly towards the right and in the lower part of the thorax edges to the left again. Thus, in the neck exposure of the cervical oesophagus is generally easier from the left side. The recurrent laryngeal nerves lie in the tracheo-oesophageal grooves. On the right side, the recurrent laryngeal nerve at the lower neck is often at a small distance from the tracheo-oesophageal groove, while on the left side the nerve is apposed closely to the oesophagus and trachea. This is an important anatomical detail when exposing the oesophagus and when cervical lymphadenectomy is performed. In perforation from Boerhaave's syndrome, the perforation tends to affect the lower oesophagus on the left side, as this part of the oesophagus is less well supported anatomically.

There are multiple relative constrictions along the oesophagus. First is the upper oesophageal sphincter (UOS); second is where the arch of the aorta/left main bronchus crosses the oesophagus; and third is the lower oesophageal sphincter (LOS). Foreign bodies such as food boluses tend to lodge at these sites.

The UOS is a structural sphincter formed by a band of striated muscles of the inferior pharyngeal constrictor and cricopharyngeus. The LOS is much less well defined. It is a complex interplay of the intrinsic muscle tone of the oesophageal wall, as well as the diaphragmatic crura. It is also variably exposed to the negative intrathoracic and positive intra-abdominal pressure. Thus, on oesophageal manometry, it is identified as a high-pressure zone; the diaphragmatic contribution is more obvious in the presence of a hiatus hernia, where two components of the high-pressure zone can be identified. Disorders of the coordination in UOS and pharyngeal function can result in dysphagia or aspiration symptoms. A common example is in elderly patients following a cerebrovascular accident or in those with neurological diseases. Dysfunction of the UOS is also related to the pathogenesis of the pharyngeal pouch/upper oesophageal diverticulum (Zenker's). Weakness of the LOS or inappropriate relaxation can result in oesophagogastric reflux disease (GORD), or tightness (incomplete relaxation) can lead to dysphagia, such as in achalasia.

For clinical purposes, the oesophagus is divided into the cervical, the thoracic and the abdominal oesophagus (***Figure 66.1***). These divisions are relevant for cancer staging purposes. The 'cardia' is the portion of the stomach that lies immediately below the OGJ, but there is no clear definition of its extent. Tumours around this region are often referred to as cancer of the cardia; however, it may be better to refer to 'cancer at the oesophagogastric junction'.

Anatomically the OGJ is defined as the point where the tubular oesophagus becomes the saccular stomach; histologically it is the junction between the squamous mucosa and the columnar mucosa, but these levels will be different in Barrett's oesophagus. The physiological LOS does not correspond to the anatomical OGJ; the LOS is a high-pressure zone defined physiologically but not anatomically. In practice, the most relevant definitions relate to findings on endoscopy. Endoscopically the OGJ is defined as the top of the gastric folds (the oesophagus is tubular and does not have folds while the stomach has rugae). In Japan, it is also commonly recognised as

Hermann Boerhaave, 1668–1738, Professor of Medicine and Botany, the University of Leiden, The Netherlands.
Friedrich Albert Zenker, 1825–1898, Professor of Pathology, Dresden, Germany.
Norman Rupert Barrett, 1903–1979, surgeon, St Thomas' Hospital, London, UK.

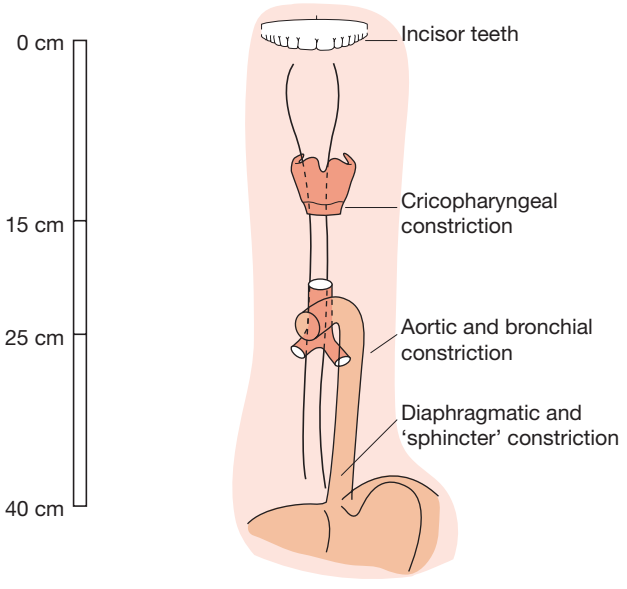

Figure 66.1 Anatomy of the oesophagus, divisions of the oesophagus and measurements endoscopically from the incisors. The three relatively 'narrow' parts of the oesophagus are at the level of the cricopharyngeus muscle (upper oesophageal sphincter), where the left main bronchus and aorta cross the oesophagus and the oesophagogastric junction (lower oesophageal sphincter).

the distal end of the oesophagus where palisading vessels are found (***Figure 66.2***). Which definition used is not so important; rather, it requires experience from the endoscopist to define this point accurately. In a real-life situation, the junction is somewhat dynamic with the patient's breathing excursions; an excessive amount of air insufflation may 'flatten' the gastric folds, making it difficult to define their 'top'. The presence of a hiatus hernia adds to the difficulty. The location of the junction is important in defining hiatus hernia, assessing the presence of Barrett's oesophagus, defining cancers around the OGJ and tumour staging.

Histologically the oesophageal wall has layers: mucosa, submucosa, muscularis propria and adventitia. The mucosa consists of a non-keratinised stratified squamous epithelium, the lamina propria and the muscularis mucosae. The oesophageal wall lacks a serosa; it is the muscularis mucosae and submucosa that give it strength for suture holding. The muscularis propria has an inner circular muscle and external longitudinal muscle layer (***Figure 66.3***). The muscle of the upper third of the oesophagus is made up of striated muscle, the middle third with a mixture of striated and smooth muscle and the lower third with smooth muscle. Connective tissue disease, such as scleroderma, mainly affects smooth muscle, hence the lower oesophagus.

The blood supply of the upper oesophagus is derived from the superior and inferior thyroid arteries. The middle oesophagus receives its supply from direct branches of the aorta and bronchial and intercostal vessels. The distal oesophagus has the arterial supply from the left gastric, left inferior phrenic and splenic vessels. The blood supply is usually excellent, and a long length of the oesophagus can be mobilised without compromising perfusion. An anastomotic leak from oesophageal anastomosis after oesophagectomy is rarely attributed to poor blood supply of the oesophagus; rather, it is the conduit that lacks perfusion. Venous return to the systemic circulation forms a network of vessels within the oesophageal wall. They drain to the inferior thyroid, azygos, hemiazygos and gastric veins. The communications of oesophageal veins and left gastric veins form part of the portal–systemic anastomosis. Cirrhosis leads to their dilatation (varices).

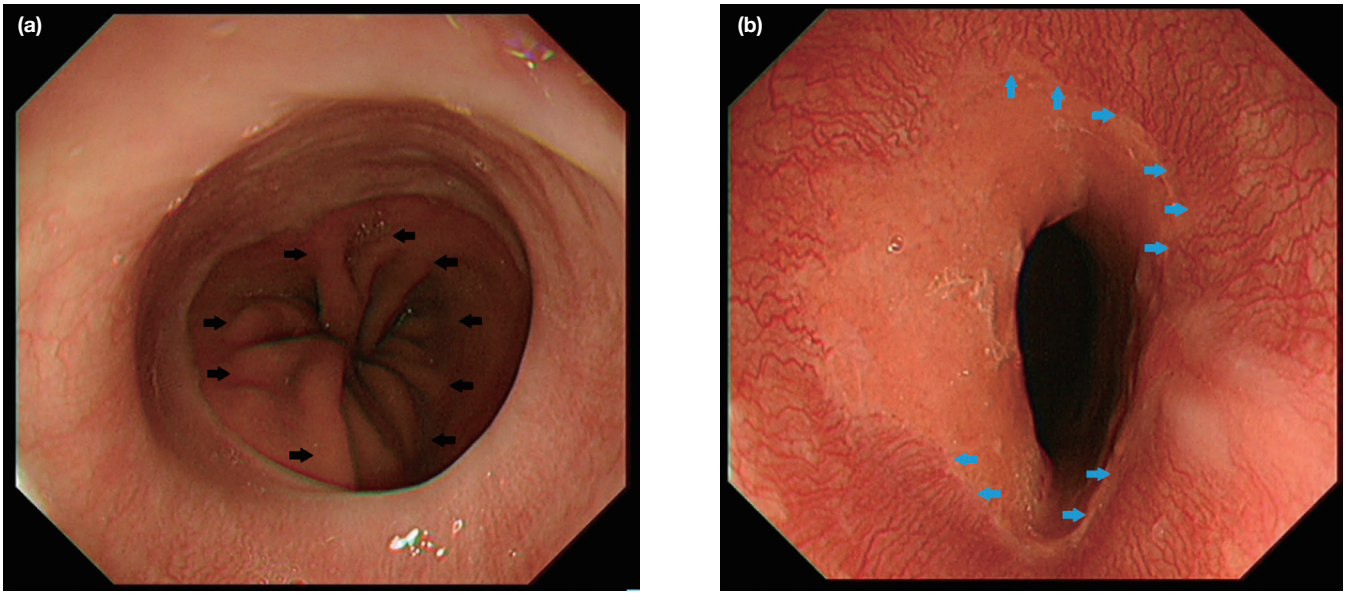

Figure 66.2 (a) Endoscopic image showing the 'top of the gastric folds' (black arrows), indicating that this is the oesophagogastric junction. **(b)** The distal end of the 'palisading vessels' also indicates the oesophagogastric junction (blue arrows pointing at the end of the palisading vessels).

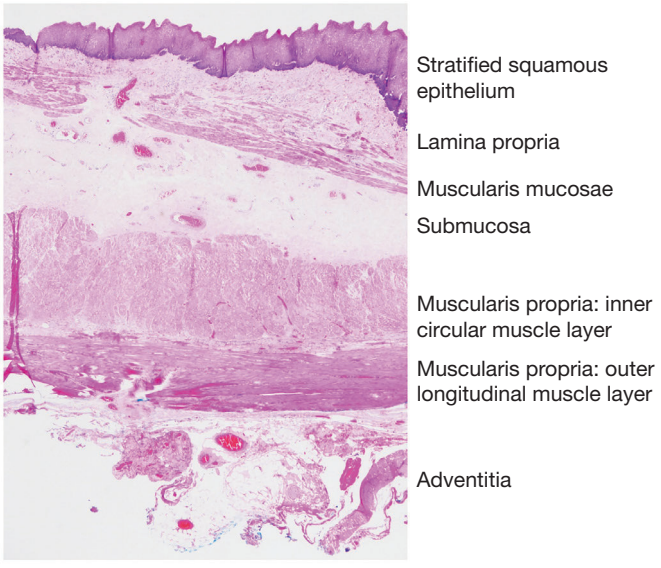

Figure 66.3 Histological layers of the oesophagus (courtesy of Dr Anthony Lo, Department of Pathology, Queen Mary Hospital, Hong Kong SAR, China).

The lymphatic drainage of the oesophagus is important, especially for cancer spread. There is a rich plexus of lymphatics in the submucosa, and direct drainage to the thoracic duct is also demonstrated. Submucosal spread of cancer along the oesophagus proximally and distally is common, and a longer resection margin reduces the chance of local recurrence. In the neck, the cervical oesophagus drains to the deep cervical and paratracheal nodes. In the thoracic oesophagus, lymphatic spread from a tumour can travel widely; potentially, it can spread to the neck, mediastinum and the nodes around the coeliac axis. Although upper third tumours tend to spread upwards and lower oesophageal cancer distally, this can be unpredictable and skip lesions can occur. Of particular importance is lymph node spread along the bilateral recurrent laryngeal nerves. This should be treated as a continuum of lymph node chains along both nerves, and thus they traverse from the chest into the neck. This widespread lymph node spread is the rationale behind the concept of three-field lymphadenectomy, whereby lymph nodes in the cervical region, mediastinum and around the coeliac axis are treated as regional nodes and dissection is recommended in curative surgery. The data mostly come from studies on squamous cell cancers in Japan. The lack of sufficient data for adenocarcinomas (mostly in the lower oesophagus) makes the benefit of such extended lymphadenectomy less certain.

The thoracic duct is the largest lymphatic vessel in the body. It is formed from the abdominal confluence of the left and right lumbar lymph trunks, as well as the left and right intestinal lymph trunks between T12 and L2. The confluence of lymph trunks is saccular and is referred to as cisterna chyli. Through the diaphragmatic hiatus, the thoracic duct is formed as it ascends along the aorta, next to the azygos vein and oesophagus. It then crosses to the left side at T4–T6, going upwards behind the aortic arch and left subclavian artery. In the left neck, it drains into the junction between the left jugular vein and left subclavian vein. Around 75% of the lymph from the entire body (aside from the right upper limb, right breast, right lung and right side of the head and neck) passes through the thoracic duct. The cells of the immune system circulate through the lymphatic system. Also, large molecular products of digestion, such as fats, first need to be absorbed into the lymphatic system, and then reach the systemic circulation through the venous system.

During oesophagectomy, the thoracic duct and its tributaries may be damaged, postoperatively presenting as chylothorax. The thoracic duct may also be injured during cervical lymphadenectomy, leading to a chylous leak from the neck wound after surgery. Prolonged chylous drainage cannot be tolerated because there is loss not only of fluid and electrolytes but also important proteins as well as lymphocytes, which cannot be replaced. The path of drainage of lymph explains the finding of Virchow's node (Troisier's sign), when a metastatic node is found in the left supraclavicular fossa, both from intra-abdominal malignancies as well as from oesophageal cancer.

INVESTIGATIONS OF OESOPHAGEAL DISEASES

Radiography

As a posterior mediastinal structure, the oesophagus is normally obscured on plain radiographs by other structures such as the spine, major vessels, airway and heart. However, this simple imaging test often gives clues of major pathologies, such as a dilated oesophagus with a fluid level in advanced achalasia (***Figure 66.4***) or pneumomediastinum and pleural effusion in oesophageal perforation (***Figure 66.5***). Radio-opaque foreign bodies can also be seen. A barium contrast swallow can demonstrate narrowing, anatomical distortion or abnormal oesophageal motility. It is however inaccurate in the diagnosis of GORD and should not be used for this purpose. Computed tomography (CT) scanning is important in the staging of a malignant neoplasm, delineating the anatomical relationship with other mediastinal structures, or detecting surgical site infection and extraluminal gas densities (***Figure 66.6***). When used in conjunction with oral contrast, CT is sensitive in identifying perforation and leakage.

Endoscopy

Endoscopy is an essential tool with both diagnostic and therapeutic roles. A standard diagnostic upper endoscopy includes the examination of the pharynx, hypopharynx, laryngeal inlet, oesophagus, stomach and part of the duodenum. The risk of the procedure, depending on complexity, is generally low. Extra care should be taken when performing endoscopy for patients with achalasia or obstruction as the oesophagus can be fluid-filled and regurgitation may lead to aspiration. For patients

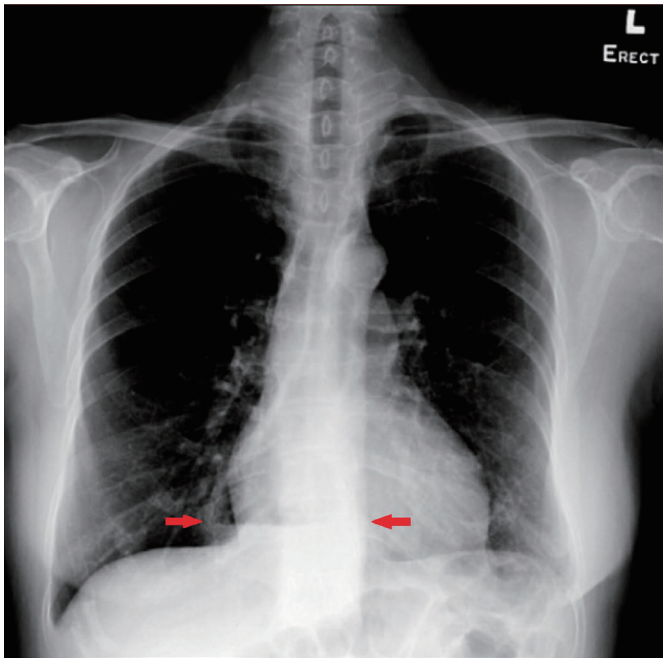

Figure 66.4 A fluid level (arrows) is apparent in a dilated oesophagus in a patient with achalasia.

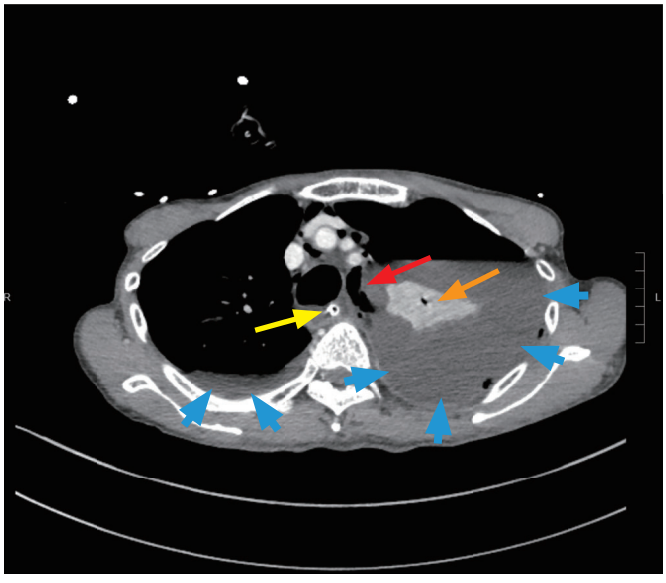

Figure 66.6 Computed tomography scan showing perforation of the oesophagus secondary to Boerhaave's syndrome. There is pneumomediastinum (red arrow), bilateral pleural effusion (blue arrows) and atelectasis of the left lung (orange arrow). A nasogastric tube is in the oesophagus (yellow arrow).

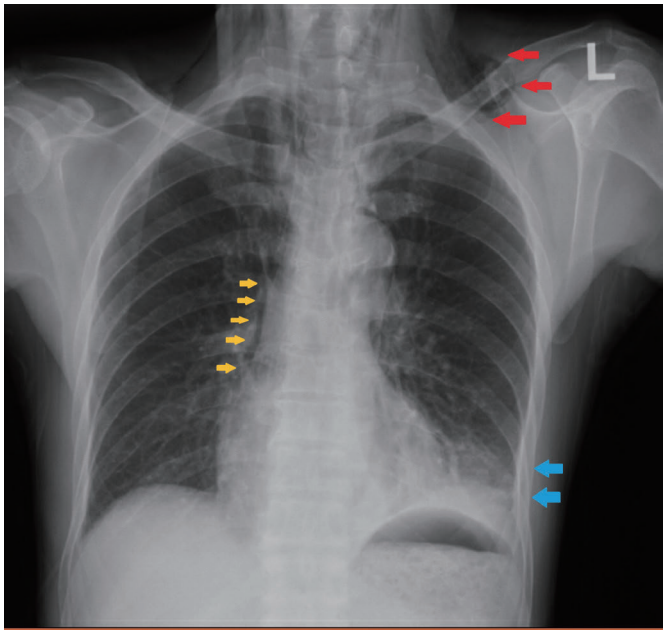

Figure 66.5 Chest radiography showing pleural effusion (blue arrows), subcutaneous emphysema (red arrows) and pneumomediastinum (yellow arrows).

with suspected oesophageal perforation or when the procedure is expected to be prolonged, carbon dioxide should be used for insufflation since it is absorbed more quickly than air. Rigid oesophagoscopy is rarely used nowadays except for unusual circumstances, such as retrieving large or sharp foreign objects. Flexible endoscopy with the use of an overtube is an alternative.

In patients with significant trismus or obstruction, an ultra-thin endoscope could be used, via either the oral or nasal route, to facilitate the diagnostic or therapeutic procedure. Increasingly ultra-thin endoscopy can be used in an outpatient clinic setting.

Image-enhanced endoscopy improves the diagnostic yield and sensitivity of assessment. It should be performed with a high-definition upper gastrointestinal endoscope, equipped with digital image enhancement such as narrow-band imaging (NBI) and magnification. It can be further supplemented by chromoendoscopy, using Lugol's iodine (0.5–1%) to look for any suspicious unstained areas and pink colour sign in squamous neoplasia. Similarly, acetic acid (1–3%) is used to look for any loss of aceto-whitening of the mucosal surface of Barrett's mucosa and neoplasia (***Figure 66.7***). Endocytoscopy is a novel ultra-high-magnification endoscopic technique enabling high-quality *in vivo* assessment of lesions with continuous zoom magnification up to 500 times. However, standardised staining methods and endocytoscopic classification are still lacking. With the aid of machine learning and deep learning by artificial intelligence, it is foreseeable that this technique of pattern recognition will greatly improve the sensitivity and specificity of early neoplasia detection and diagnosis.

Endosonography

Endoscopic ultrasonography (EUS) relies on a high-frequency (5–30 MHz) transducer to provide highly detailed images of the layers of the oesophageal wall and mediastinal structures close to the oesophagus. There are two types of EUS: radial echoendoscope, which has a rotating transducer that creates

Jean Guillaume Auguste Lugol, 1786–1851, physician, Hôpital Saint Louis, Paris, France, suggested that his iodine solution could be used to treat tuberculosis.

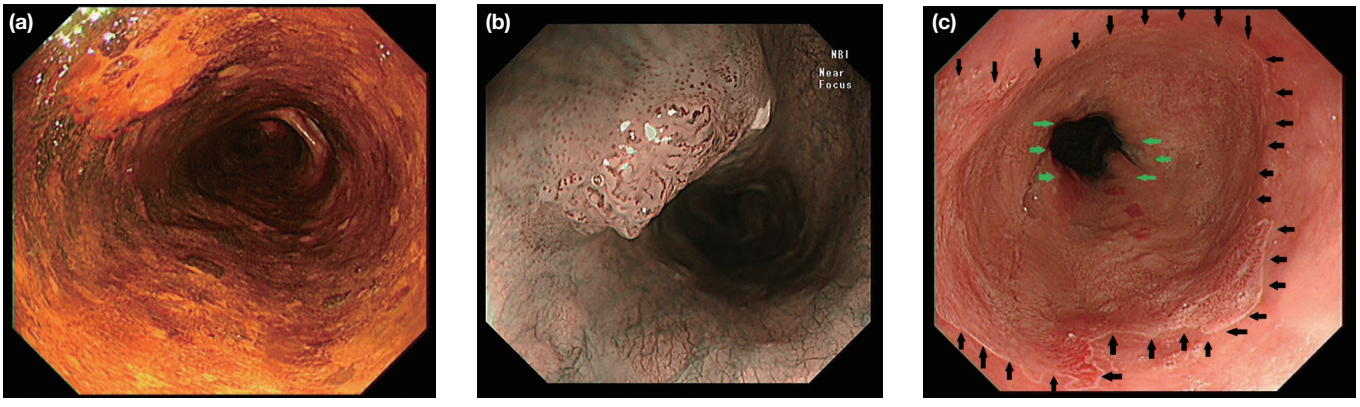

Figure 66.7 Endoscopic pictures of the oesophagus. **(a)** High-grade dysplasia of the oesophagus stained by Lugol's iodine solution. The unstained area is the abnormal area. **(b)** Early squamous cell cancer examined using narrow-band imaging. a circular image with the endoscope in the centre, and linear echoendoscope, which produces a sectoral image in the line of the endoscope. Mini-ultrasound probes that are around 2.0–2.9 mm in diameter can be inserted through the biopsy channel of an ordinary endoscope to give a simple radial diagnostic assessment within a narrowed lumen. This is useful for obstructive tumour.

The different layers of the oesophageal wall are characterised by its alternating echogenicity (***Figure 66.8***). Different structures can be identified adjacent to the oesophagus and used as landmarks, such as the aorta, the azygos vein and the spine. EUS can also provide a Doppler signal to differentiate index lesions from genuine vascular structures or abnormality before attempting biopsy. Biopsy of submucosal oesophageal lesions or mediastinal masses such as lymph nodes can be performed with linear echoendoscopes for histological diagnosis and staging.

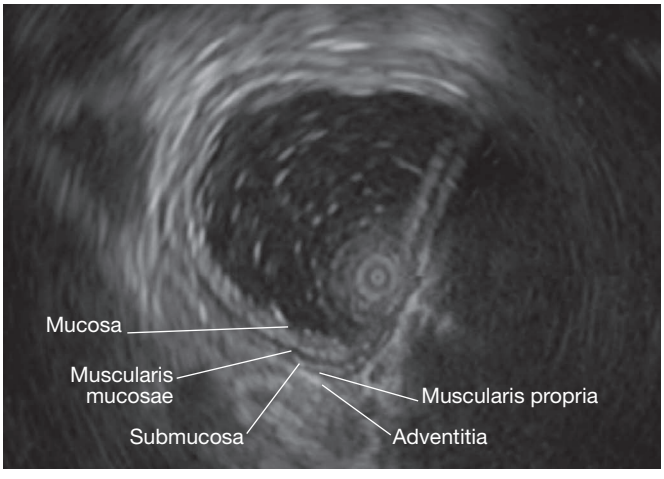

Figure 66.8 Endosonographic picture of an oesophagus. Five layers of the oesophageal wall can be seen.

Oesophageal manometry

Manometry is used to diagnose oesophageal motility disorders and to assess the oesophageal body and LOS function before surgery, such as antireflux operations. Conventional manometry was developed in the 1950s with water-perfused catheters. Recordings were made by passing a multilumen catheter (usually with only eight channels) down the oesophagus and into the stomach. The catheter is withdrawn progressively up the oesophagus and recordings are taken at intervals of 0.5–1.0 cm to measure the length and pressure of the LOS and assess motility in the body of the oesophagus during swallowing water boluses. With the introduction of the colour contour plot by Ray Clouse in 1995, conventional manometry is gradually being replaced by high-resolution manometry (HRM) with solid-state pressure catheters. A typical HRM catheter has 36 circumferential sensors along its length, each spaced 1 cm apart. HRM defines important anatomical landmarks and abnormality of the UOS, LOS and hiatus hernia. It also measures the contractility of the oesophageal body (***Figure 66.9***). Various parameters are measured in response to a standardised protocol of drinking a small volume of water. Other optional evaluations include solid test swallows and/or pharmacological provocation tests. Oesophageal peristalsis that is triggered by the swallow centre in the brain is called primary peristalsis. A hierarchical analysis is established under the Chicago classification to diagnose various oesophageal motility disorders.

Endoluminal functional lumen imaging planimetry

Endoluminal functional lumen imaging planimetry (FLIP) is a volume-controlled distension balloon device. It utilises impedance planimetry to measure the cross-sectional areas along the length of the balloon, and one pressure sensor measures the intra-balloon pressure. When placed inside the oesophagus

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the Doppler principle in 1842.
Ray E Clouse, 1951–2007, gastroenterologist, Washington University, St Louis, MO, USA.

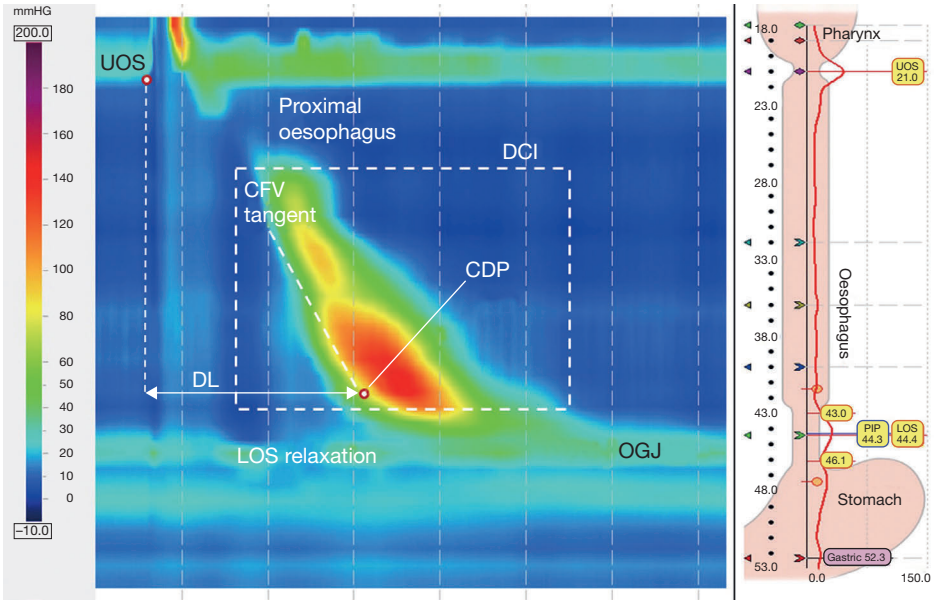

Figure 66.9 High-resolution manometry picture of a typical swallow. The break at the upper oesophageal sphincter (UOS) signifies the beginning of a swallow. The oesophageal body contractility is represented by the distal contractile integral (DCI), calculated by multiplying the pressure (mmHg) and time (seconds) along the whole length (cm) of the oesophageal body. There is a reflex relaxation of the lower oesophageal sphincter (LOS) upon each swallow. The time between the start of a swallow to the contractile deceleration point (CDP) is the distal latency (DL). CFV, contractile front velocity; OGJ, oesophagogastric junction; PIP, pressure inversion point.

spanning across the LOS, it gives a real-time assessment of LOS distensibility (cross-sectional area divided by intra-bag pressure) and oesophageal contractility in response to balloon distension. The device is mostly still investigational but is expected to gain wider clinical use. It can be used to guide the intraoperative end point for completeness of myotomy for achalasia (change in diameter and distensibility of the LOS) or in screening oesophageal function to assess the need for formal HRM (***Figure 66.10***).

Ambulatory reflux and combined pH–impedance monitoring

Ambulatory reflux monitoring is considered one of the most important confirmatory tests for GORD. There are two types of monitoring devices: catheter based and wireless capsule (***Figure 66.11***). Both measure the pH value at 5–6 cm above the upper border of the LOS, as defined by manometry. For the catheter-based device, data are captured conventionally for 24 hours. The wireless capsule device is anchored onto the mucosa of the oesophagus by a pin and can transmit pH data for up to 96 hours. Various parameters are measured, such as the number of reflux episodes (when pH drops below 4) and oesophageal acid exposure time (the percentage of time exposed to pH < 4) (***Figure 66.12***). An oesophageal exposure time of more than 4% can be considered abnormal, and one more than 6% is considered diagnostic. A composite score (Johnson–DeMeester) consists of six parameters that can be calculated. The patient needs to record their symptoms throughout the study period, so that symptom correlation with pH data can be calculated.

The catheter-based pH monitoring device also incorporates measurement of impedance. Impedance is inversely proportional to the electrical conductivity of the luminal contents and the cross-sectional area. Liquid refluxate has high conductivity and therefore low impedance. On the other hand, air has low conductivity and high impedance. With the change in the temporal–spatial patterns in different impedance sensors spreading across different levels of the monitoring catheter, any bolus transit can be assessed in its direction (antegrade or retrograde) as well as by its nature (air or liquid). Thus, acid reflux, aerophagia, belching and liquid passage can be distinguished (***Figure 66.13***).

GASTRO-OESOPHAGEAL REFLUX DISEASE

Aetiology

GORD is defined by the 'Montreal definition' as a condition that develops when the reflux of stomach contents causes troublesome symptoms and/or complications. The aetiology of GORD can be explained by the interaction between the reflux barrier and the pressure difference between the thoracic and abdominal cavity. The reflux barrier consists of the crural diaphragm and the LOS. Physiological relaxation of the LOS in response to stretching of the gastric fundus, particularly after a meal to allow venting of swallowed air, is termed transient

Lawrence F Johnson, contemporary, gastroenterologist, Birmingham, AL, USA.
Tom R DeMeester, contemporary, surgeon, Los Angeles, CA, USA.

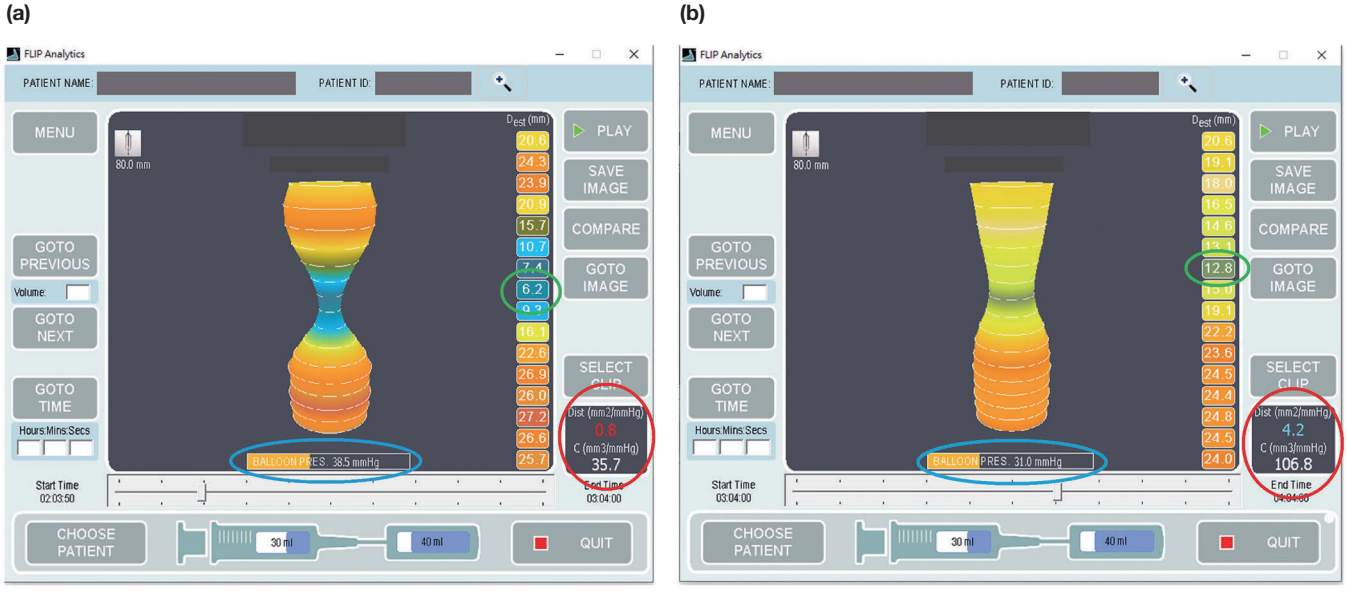

Figure 66.10 Endoluminal functional lumen imaging planimetry reading before **(a)** and after **(b)** peroral endoscopic myotomy (POEM) in a patient with achalasia. The column of numbers on the right-hand side of each panel shows the diameter of each 0.5-cm segment along the catheter (the narrowest segment is indicated by the green circle). This is used to calculate the cross-sectional area. The distensibility index (DI) (red circle) is calculated by dividing the cross-sectional area (mm^3) by the intra-balloon pressure (mmHg) (blue circle). The DI improves from 0.8 mm^3/mmHg to 4.2 mm^3/mmHg after POEM, indicating that the lower oesophageal sphincter has become more 'compliant'.

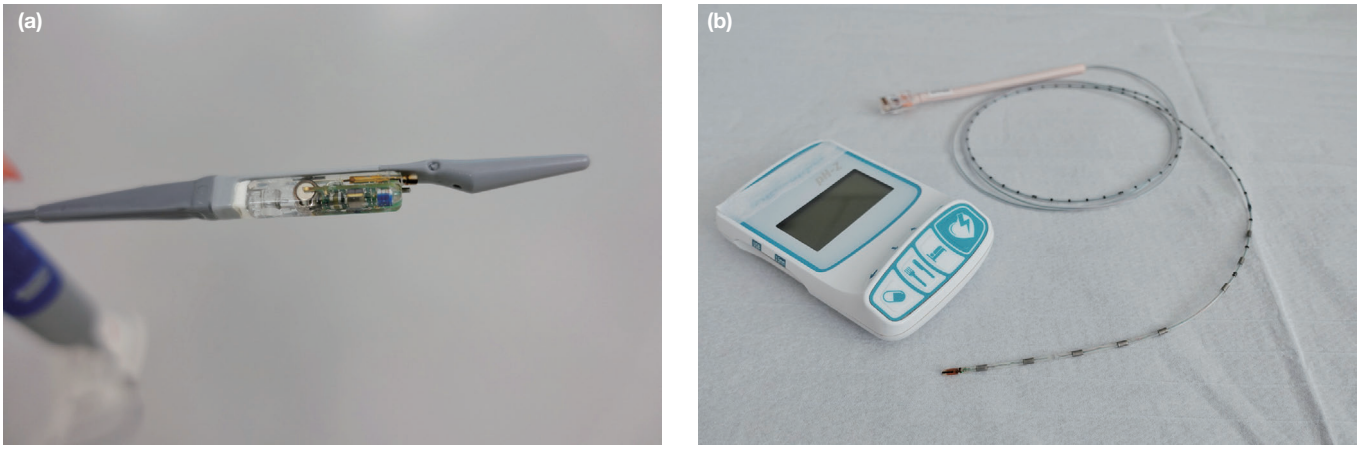

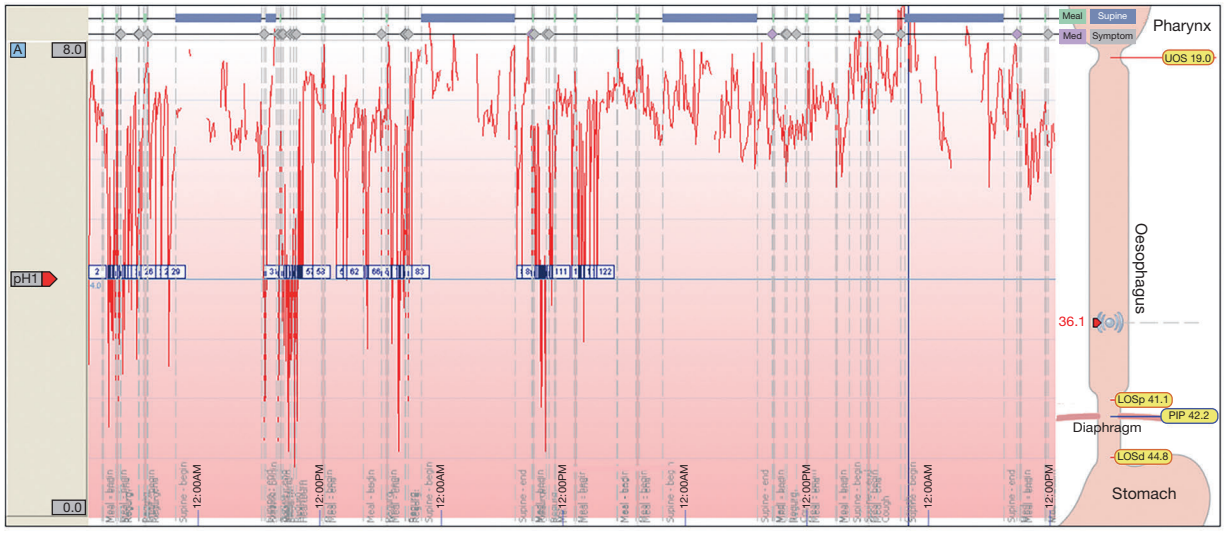

Figure 66.11 (a) Wireless capsule used to measure pH data in pH monitoring, with the capsule in the delivery catheter before deployment. **(b)** Catheter used to measure pH as well as impedance. The catheter is placed through the nostril. The most distal sensor is placed 5 cm above the upper border of the lower oesophageal sphincter measured on high-resolution manometry.

LOS relaxations (TLOSRs). An increased number of TLOSRs and a more compliant LOS would increase reflux. Delay in acid refluxate clearance from the oesophagus, as a result of defective oesophageal motility, also contributes to oesophageal exposure.

Hiatus hernia is associated with GORD; it is formed when the weakened phreno-oesophageal ligament and widened crural opening allow the proximal stomach to herniate through the diaphragmatic hiatus. Ageing, connective tissue disease and elevated intra-abdominal pressure (e.g. central obesity, pregnancy, tight garments, chronic straining) will further aggravate the hernia. An acid pocket is an area of unbuffered gastric acid that accumulates in the proximal stomach after meals and serves as a reservoir for acid reflux. Together with a hiatus hernia, it can exacerbate the severity and symptoms of GORD.

The overall global incidence of GORD is increasing and has a predominant regional distribution in the Americas and Europe; up to 33% of the population is affected, compared with <10% in Asia. The increase in GORD incidence is attributed to the global increase in obesity and declining rates of *Helicobacter pylori* infection. This increasing prevalence of GORD coincides with the increased mortality rates from oesophageal adenocarcinoma. Central obesity, independent of body mass index, is a risk factor for developing Barrett's oesophagus and adenocarcinoma, while *H. pylori* may have a preventive role.

Interpretation / Findings

	DeMeester Score	Acid exposure time	No. of total reflux/post-prandial/supine	SI, SSI, SAP
Day1 off PPI	40.2	2 h 42 min	57/46/1	77.8, 12.3, 100.0
Day2 off PPI	16.9	1 h 17 min	54/48/0	85.7, 11.1, 100.0
Day3 on PPI	4.3	15 min	10/9/0	0
Day4 on PPI	0.3	0	0	0

Overall

- DeMeester Score = 15.9

Figure 66.12 A wireless pH monitoring trace over 4 days. A reflux episode is defined when the pH drops to less than pH 4 (below the horizontal blue line). This patient had stopped taking a proton pump inhibitor (PPI) 2 weeks before the study. He was then given a daily dose of PPI starting on day 3 of the examination. The DeMeester scores were abnormal (>14.7) on days 1 and 2 but returned to the normal range after acid suppression by the PPI. The symptom association probability (SAP) was 100% on days 1 and 2, meaning that every time there was acid reflux the patient experienced symptoms. SI, symptom index; SSI, symptom sensitivity index. LOSd, lower oesophageal sphincter, distal; LOSp, lower oesophageal sphincter, proximal; PIP, pressure inversion point; UOS, upper oesophageal sphincter.

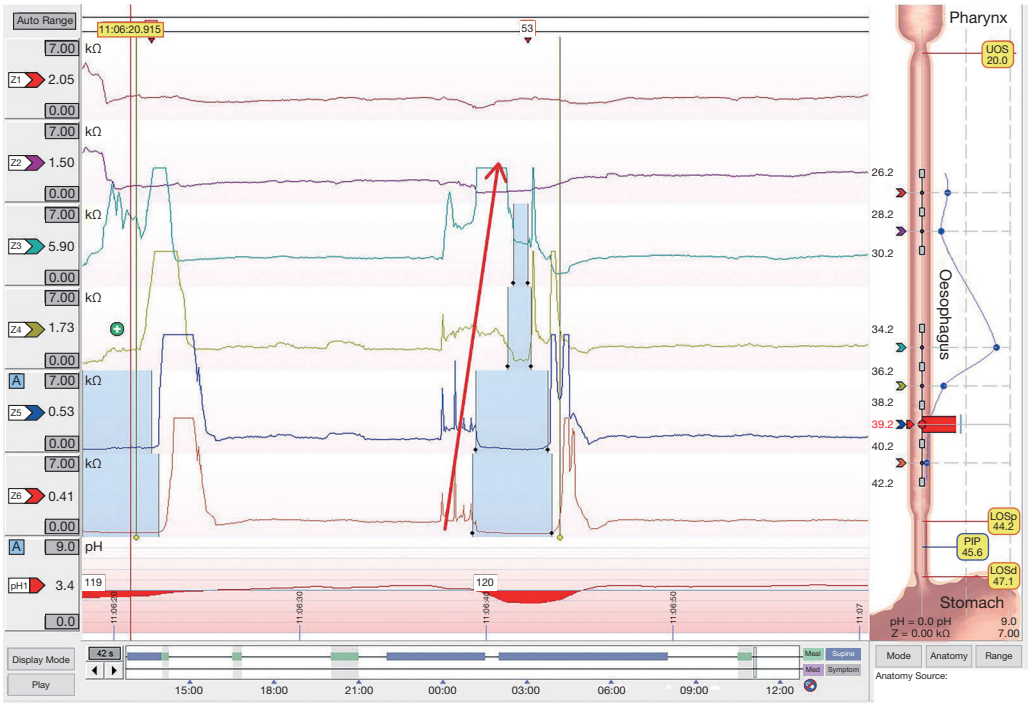

Figure 66.13 pH impedance data tracing. A drop in impedance signifies liquid within the oesophageal lumen while a belch (with air) results in a rise in impedance. In this figure, the x-axis represents time. There is a sequential drop of impedance from the distal sensor (Z6) to the more proximal sensor (Z3) (indicated by the red arrow and the shaded boxes), signifying a liquid reflux episode. At the same time, the pH sensor detected pH < 4 (lowest row), indicating that the reflux episode is an acid reflux. LOSd, lower oesophageal sphincter, distal; LOSp, lower oesophageal sphincter, proximal; PIP, pressure inversion point; UOS, upper oesophageal sphincter.

The postulated mechanism is that decreased acid production as a result of *H. pylori*-related corpus gastritis or gastric atrophy would lead to decreased oesophageal acid exposure.

Clinical features

Symptoms of GORD can be classified into oesophageal or extraoesophageal. Typical oesophageal complaints include heartburn, which is defined as a burning sensation behind the sternum, and regurgitation, which is the perception of the flow of refluxed gastric content into the mouth or hypopharynx. Patients may also complain of epigastric pain, which can be a manifestation of erosive oesophagitis. Symptoms cannot accurately predict the severity of the mucosal injury. Dysphagia can be related to large hiatus hernia, stricture or even oesophageal carcinoma. Bleeding from erosive oesophagitis, Cameron ulcers (gastric ulcers at the level of the diaphragmatic constriction within large hiatus hernias) or tumours can present as coffee-ground vomiting or frank haematemesis. Extraoesophageal symptoms may include chronic cough, laryngitis, asthma and dental erosions (especially on the lingual and palatal tooth surfaces). The causative relationship of extraoesophageal manifestations can sometimes be vague. These problems are usually multifactorial but can be aggravated by GORD. Other conditions with proposed association with GORD include sinusitis, pulmonary fibrosis, pharyngitis and recurrent otitis media.

Symptoms are often provoked by food, particularly after a full meal with increased intragastric pressure or food that delays gastric emptying (e.g. oily, spicy food). The refluxate can cause an unpleasant taste, often described as 'acidic' or 'bitter'. Intensive exercise may sometimes induce GORD in healthy subjects owing to an increase in intra-abdominal pressure. Some patients may complain of nocturnal symptoms especially when lying supine, probably related to the gravitational effect. This may significantly affect patients' sleep. Mild symptoms occurring two or more days a week or moderate/severe symptoms affecting more than one day a week are considered troublesome.

Diagnosis

In most cases, the diagnosis is assumed rather than proven, and treatment is empirical. Proton pump inhibitors (PPIs) are very effective drugs in managing erosive oesophagitis and acid-related symptoms. They are often used empirically as a diagnostic trial. However, there is a significant placebo effect. A positive treatment response with 2 weeks of a PPI can be observed in 69% of GORD patients and 51% of those without GORD (as defined by pH monitoring and endoscopic oesophagitis). This may create a problem of overdiagnosis of GORD and overuse of PPIs.

Endoscopic examination provides anatomical assessment, screening for complications of GORD and potential alternative diagnoses such as eosinophilic oesophagitis (EOO), oesophageal motility disorder or oesophageal cancer (***Figure 66.14***). In practice, many patients will have received PPIs before referral to endoscopy and such information must be available before the procedure because PPIs can heal oesophagitis quickly (***Figure 66.15***). It is worth remembering that the correlation between symptoms and endoscopic appearances is poor.

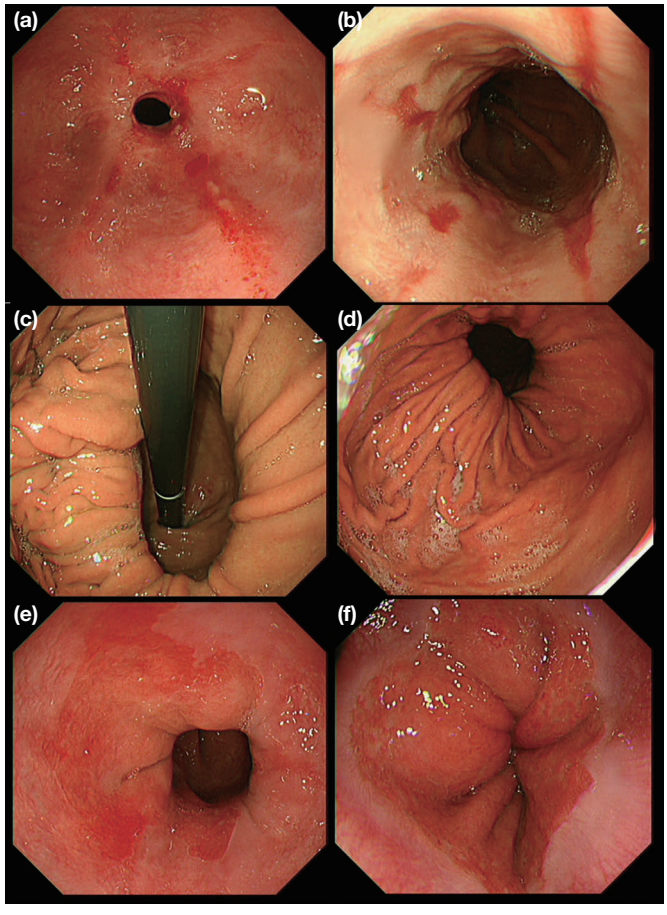

Figure 66.14 Endoscopic appearance of an oesophageal stricture with esophagitis **(a)**; Los Angeles classification grade C oesophagitis **(b)**; retrograde view of a hiatus hernia **(c)**; end view of a hiatus hernia **(d)**; Barrett's oesophagus **(e)**; normal oesophagogastric junction **(f)**.

In patients with atypical or persistent symptoms despite PPI therapy, oesophageal manometry and ambulatory pH recording (with or without impedance measurement) are justified to establish the diagnosis and guide management. In patients considered for surgery, it is also prudent to have objective proof of significant reflux before embarking on a potentially irreversible invasive procedure.

HRM is useful in (i) detecting major oesophageal motility disorder, e.g. achalasia, which can sometimes mimic GORD; (ii) defining the location of the LOS for accurate pH monitoring placement; (iii) assessing the function and morphology of the LOS, including the size of a hiatus hernia; and (iv) assessing oesophageal body motility to tailor intervention, especially the various antireflux procedures.

PPIs are usually stopped for 2 weeks before oesophageal pH recording. For patients with a strong pretest probability of

Alan J Cameron, contemporary, gastroenterologist, Mayo Clinic, Rochester, MN, USA.

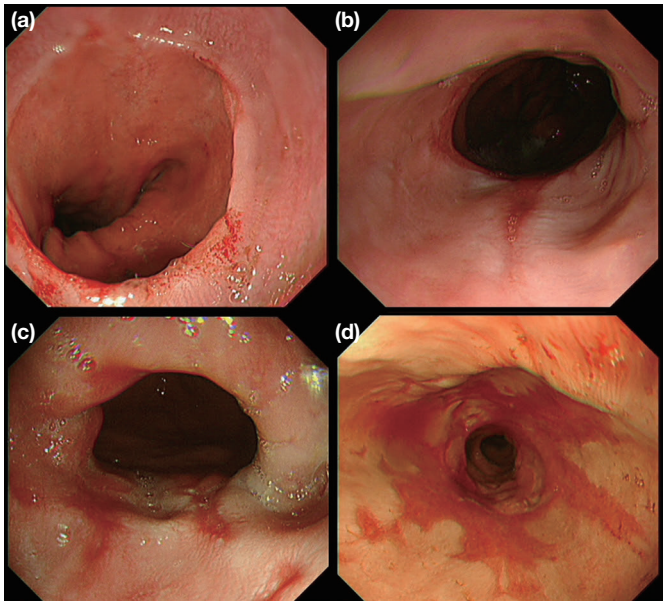

Figure 66.15 Grading of oesophagitis according to the Los Angeles classification. Grade A, one (or more) mucosal breaks no longer than 5 mm that do not extend between the tops of the two mucosal folds **(a)**. Grade B, one (or more) mucosal breaks longer than 5 mm that do not extend between the tops of two mucosal folds **(b)**. Grade C, mucosal breaks that are continuous between the tops of two or more mucosal folds but that involve less than 75% of the circumference **(c)**. Grade D, mucosal break that involves at least 75% of the oesophageal circumference **(d)**.

GORD but refractory to PPI treatment, an 'on-PPI' assessment can be performed to test for breakthrough acid exposure despite PPI therapy. Wireless pH monitoring increases the duration of recording to 96 hours and could potentially increase the test sensitivity and diagnostic yield.

A barium contrast study gives an objective and dynamic assessment of the oesophagogastric anatomy. This may be important in the context of surgery for rolling or mixed hiatus hernias. It is also useful in assessing surgical complications after antireflux surgery, such as a disrupted wrap, slipped fundoplication or wrap herniation. However, it is not mandatory for ordinary and uncomplicated GORD patients.

Management of uncomplicated GORD

Lifestyle modification

Patients are recommended to have a healthy diet, avoid overeating and avoid dietary items (e.g. carbonated drinks, alcohol, tea or coffee) or activities that in the patient's experience would provoke the symptoms. Patients with nocturnal symptoms should have early dinner and avoid recumbence after meals. Elevation of the head of the bed may also help. Smoking cessation reduces severe reflux symptoms in normal-weight individuals on medical treatment. Weight management is recommended for overweight patients.

Medical management

Most patients with GORD self-medicate with over-the-counter medicines such as simple antacids, antacid–alginate preparations and H_2-receptor antagonists. Consultation is more likely when symptoms are severe, prolonged and unresponsive to simple measures and treatments. Pharmacological treatments mainly target acid reduction or neutralisation. With the development of PPIs in the 1980s, they have quickly become the first-line treatment for symptomatic GORD. Given an adequate dose for 8 weeks, most patients have a rapid improvement in symptoms (within a few days), and more than 90% can expect full mucosal healing of oesophagitis (if present) at the end of this time. A policy of 'step-down' medical treatment is advocated after the initial 8 weeks of treatment to a dose that keeps the patient free of symptoms, and this might even mean the cessation of PPI.

Most patients do not make sustained major lifestyle changes and because PPIs are so effective many remain on long-term treatment. Those patients who have an inadequate treatment response may benefit from changing to another PPI, an increased dosage of the same PPI, a twice-a-day regimen or the addition of an H_2-receptor antagonist. PPI is also important in patients with reflux-induced strictures, resulting in significant prolongation of the intervals between endoscopic dilatations. There have been numerous reports on the association between chronic PPI use and a myriad of side effects. Most could not demonstrate a causal relationship except some enteric infections and fundic gland polyps. However, patients are still advised to use the lowest effective dose for symptom control.

Prokinetic agents, e.g. metoclopramide and domperidone, are not particularly useful and have potential safety issues. Other TLOSR inhibitors were also disappointing. Antacid–alginate preparations target the acid pockets and form a polysaccharide barrier at the proximal stomach. A more recent development are the potassium-competitive acid blockers (P-CABs). Compared with PPIs, P-CABs have a more rapid, competitive, reversible inhibition of proton pumps. However, they are available in only limited regions. With pH monitoring, it is possible to identify patients with different phenotypes, especially distinguishing those having pathological versus physiological reflux, and positive versus negative symptom correlations. For patients with discordant reflux activity and symptom association, as in oesophageal hypersensitivity or functional disorder, antireflux therapy is likely to fail. Other treatment options include perception modulators, e.g. tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs), or alternative therapies, e.g. hypnosis and behavioural therapy.

Summary box 66.1

Gastro-oesophageal reflux disease

- GORD is common but symptomatology may be confused with other disorders, such as achalasia; both may present with regurgitation
- Sliding hiatus hernia predisposes to GORD
- Heartburn and regurgitation are typical GORD symptoms
- Beware of extraoesophageal manifestations of GORD
- A PPI is the most effective medical treatment, but regurgitation is not well controlled by PPIs

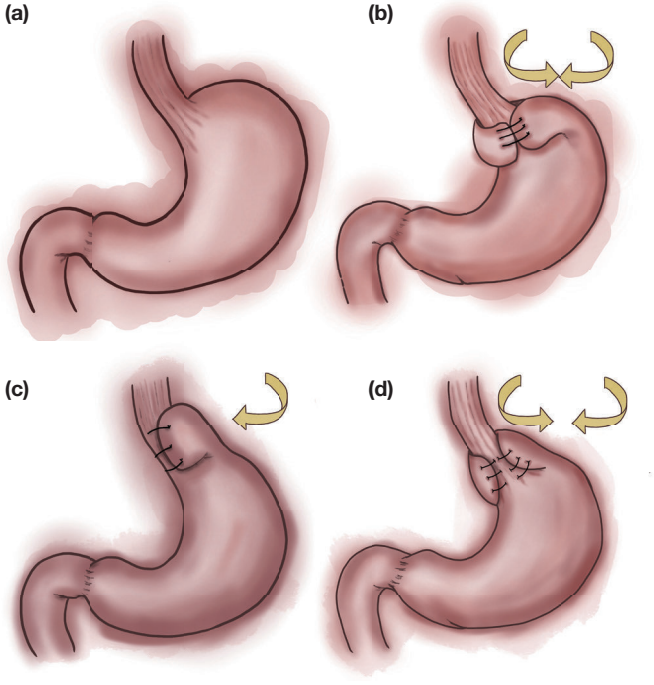

Figure 66.16 Examples of various types of fundoplication. **(a)** Normal anatomy. **(b)** Nissen 360° fundoplication. **(c)** Dor anterior fundoplication. **(d)** Toupet posterior fundoplication.

Surgical management

While most patients' symptoms are satisfactorily controlled with PPIs and other medications, surgery remains an important option. The indications for surgery include (i) incomplete symptom control with medical management, (ii) intolerance of, or unwillingness to comply with, long-term medical therapy, (iii) regurgitation despite medication (less well amenable to PPI), (iv) presence of a large hiatus hernia, (v) complications arising from GORD, and (vi) extraoesophageal symptoms. The predictors of good surgical outcome include typical GORD symptoms, PPI responders, presence of hiatus hernia and presence of GORD complications, e.g. reflux oesophagitis (grade B or above) and non-dysplastic Barrett's oesophagus. Factors leading to poor surgical outcomes are normal preoperative pH monitoring when performed off PPI, functional heartburn, EOO, connective tissue diseases and extreme obesity.

Careful preoperative counselling is essential. Risks of antireflux surgery include a small mortality rate (0.1–0.5%), failed operation (5–10%) and side effects such as dysphagia, gas bloat or abdominal discomfort (10%). When performed well in appropriately selected patients, 80–90% of patients should be satisfied with the result of the operation.

Which operation?

Antireflux operations have three essential components: (i) restoration of an intra-abdominal segment of the oesophagus, (ii) crural repair, and (iii) some form of reinforcement of the LOS by the upper stomach (fundoplication) or by a prosthesis placed around the intra-abdominal oesophagus.

The major types of antireflux operations were all developed in the 1950s. For many years, the relative merits of thoracic and abdominal approaches were hotly debated. With the introduction of laparoscopy, laparoscopic fundoplication with hiatal reconstruction is the standard approach. The mechanism of fundoplication is to create a 'floppy' valve around the OGJ and to restore the angle of His. It has the effect of increasing LOS basal pressure, lessening TLOSR and reducing the capacity of the gastric fundus, thereby enhancing gastric emptying. The different types of fundoplication have been compared extensively in clinical trials but the superiority of one over the others could not be shown.

Complete fundoplication (Nissen) is associated with a higher incidence of short-term dysphagia but is most durable in reflux control. Partial fundoplication, whether performed posteriorly (Toupet) or anteriorly (Dor, Watson), has fewer short-term side effects, although this is at the expense of a slightly higher long-term failure rate (***Figure 66.16***).

The most common side effect of fundoplication is short-term dysphagia, related presumably to tissue oedema and inflammation. It usually resolves within 3 months of surgery. Some patients may experience 'gas-bloat syndrome', especially after a complete fundoplication. Typically, the patient would complain of gaseous distension of the abdomen and failure to belch or vomit, together with an increase in flatulence.

In the last decade, a magnetic prosthesis has become available to reinforce the LOS after hiatal reconstruction (***Figure 66.17***). This has a similar efficacy to fundoplication in the mid- to long term and has fewer gas-bloat side effects. The magnetic ring prosthesis consists of titanium-coated magnetic beads, connected by titanium wire. The physics of the magnets allows a lower attraction force when the beads are separated. This property of 'relaxation' is a more physiological sphincter to allow food passage and is less likely to create oesophageal outflow obstruction. This device is contraindicated in patients with major motility disorders, ineffective oesophageal motility or connective tissue disease.

Summary box 66.2

Laparoscopic fundoplication

- HRM and pH monitoring are recommended investigations before consideration of surgical treatment
- pH monitoring confirms GORD and HRM assesses oesophageal body function and LOS characteristics
- Surgery should be tailored to oesophageal motility

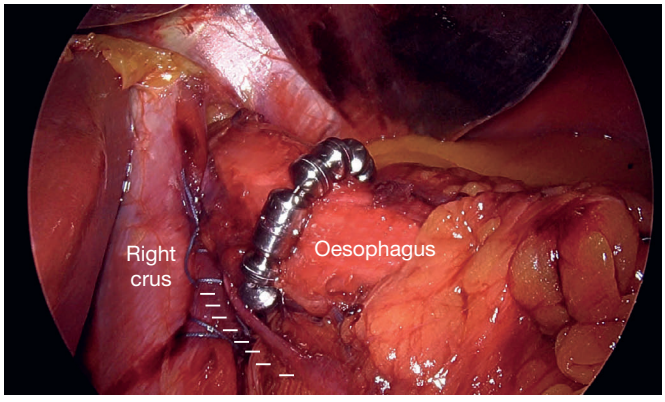

Figure 66.17 Magnetic sphincter augmentation. Intraoperative photograph following hiatus hernia repair. The magnetic sphincter is implanted around the lower oesophagus, in between the posterior vagus nerve (white arrows) and the oesophageal wall.

Complications of antireflux surgery and revisional surgery

Structurally, a wrap can be too tight or too loose. It can also be partially or completely disrupted, herniated or slipped. Structural laxity can give rise to recurrent or persistent GORD. Too long or too tight a fundoplication can give rise to dysphagia and gas-bloat syndrome. Endoscopy, contrast radiography and functional testing can assess the anatomy responsible and guide further management.

Management strategies include a PPI for recurrent acid reflux, endoscopic dilatation of stenosis and surgical revision as a last resort. A tight complete fundoplication can be remedied by conversion to a partial fundoplication. For patients with anatomical failure and refractory symptoms, revisional surgery carries a lower chance of success; in some patients, local revision is technically impossible, as often there will be adhesion formation and altered anatomy. Transient dysphagia is common after both fundoplication and magnetic sphincter augmentation. For the latter, there may be more prolonged dysphagia requiring dilatation or, rarely, migration and erosion (0.15%). Removal of the device is required in 2.7% of patients; the majority can be accomplished endoscopically or laparoscopically.

Endoscopic treatment

Several endoscopic treatments have been tested that attempt to augment a failing LOS. Transoral incisionless fundoplication mimics classic fundoplication by recreating the dynamics of the angle of His using an endoscopic stapling device. Meta-analysis demonstrates improvement in clinical response compared with PPIs; however, oesophageal acid exposure time and reflux episodes are not significantly improved and PPI usage increases with time. Radiofrequency ablation (RFA) is another strategy to remodel the LOS by reducing compliance. Again, it partially improves quality of life but does not normalise pH exposure time and almost 50% of patients still require PPI at follow-up. Antireflux mucosectomy makes use of the endoscopic mucosal resection (EMR) technique to remove subcardiac mucosa while preserving a 1-cm gap at the lesser and greater curves. The contraction and scarring presumably improve the reflux barrier. Small case series have shown improvement in both quality of life and acid reflux. A significant proportion of patients require balloon dilatation for stenosis. These procedures have been applied to patients with only small hiatus hernias or none at all, so only a small proportion of patients are suitable. Recently argon plasma coagulation has been used to accomplish the same subcardiac mucosal injury instead of EMR. Technically this is much less demanding than EMR.

Complex gastro-oesophageal reflux disease

Peptic strictures and dilatation

Reflux-induced strictures are relatively rare in the era of PPIs as most patients will be treated empirically before long-term complications occur. These strictures generally respond well to dilatation and long-term treatment with a PPI. Antireflux surgery is an alternative to long-term PPI treatment, just as in uncomplicated GORD. Most patients do not require anything other than a standard operation.

Hiatus hernia and paraoesophageal ('rolling') hernia

Hiatus hernia is a condition in which the abdominal contents migrate through the hiatal opening of the diaphragm into the mediastinum. There are four types of hiatus hernia (***Figure 66.18***): (i) the sliding hernia (type I), accounting for most hiatus hernias (85–95%), where the OGJ is herniated upwards; (ii) the true paraoesophageal/rolling hernia (type II), where there is asymmetrical herniation of the stomach next to the oesophagus and the OGJ remains in its normal intra-abdominal position (this is relatively uncommon); (iii) the more common mixed sliding and paraoesophageal hernia (type III); and (iv) when abdominal viscera other than the stomach migrate into the hernia sac, it is classified as type IV. Hiatus hernia is closely related to advanced age and obesity.

A sliding hiatus hernia predisposes to GORD and is usually diagnosed in the presence of reflux symptoms. For asymptomatic patients, it can be an incidental finding on plain chest radiographs or CT as an intrathoracic gas bubble or fluid level (***Figure 66.19***). A paraoesophageal hernia, especially when large, presents more with obstructive symptoms. The term 'giant paraoesophageal hernia' is present when more than half of the stomach has herniated into the thoracic cavity (***Figure 66.20***). This may present as a surgical emergency if gastric volvulus occurs. It is more common for the stomach to rotate along its longitudinal axis, termed organoaxial volvulus. When the stomach rotates around the transverse axis, it is called mesentericoaxial volvulus.

Gastric volvulus can produce symptoms such as dysphagia and chest pain. In severe cases, it can cause obstruction, strangulation, ischaemia, perforation and compression on the lungs, leading to impaired lung function. Emergency presentation and operation with any of these complications carries a high morbidity rate on account of a combination of late diagnosis, advanced patient age, comorbidities and the complexity of surgery involved. Therefore, all symptomatic paraoesophageal

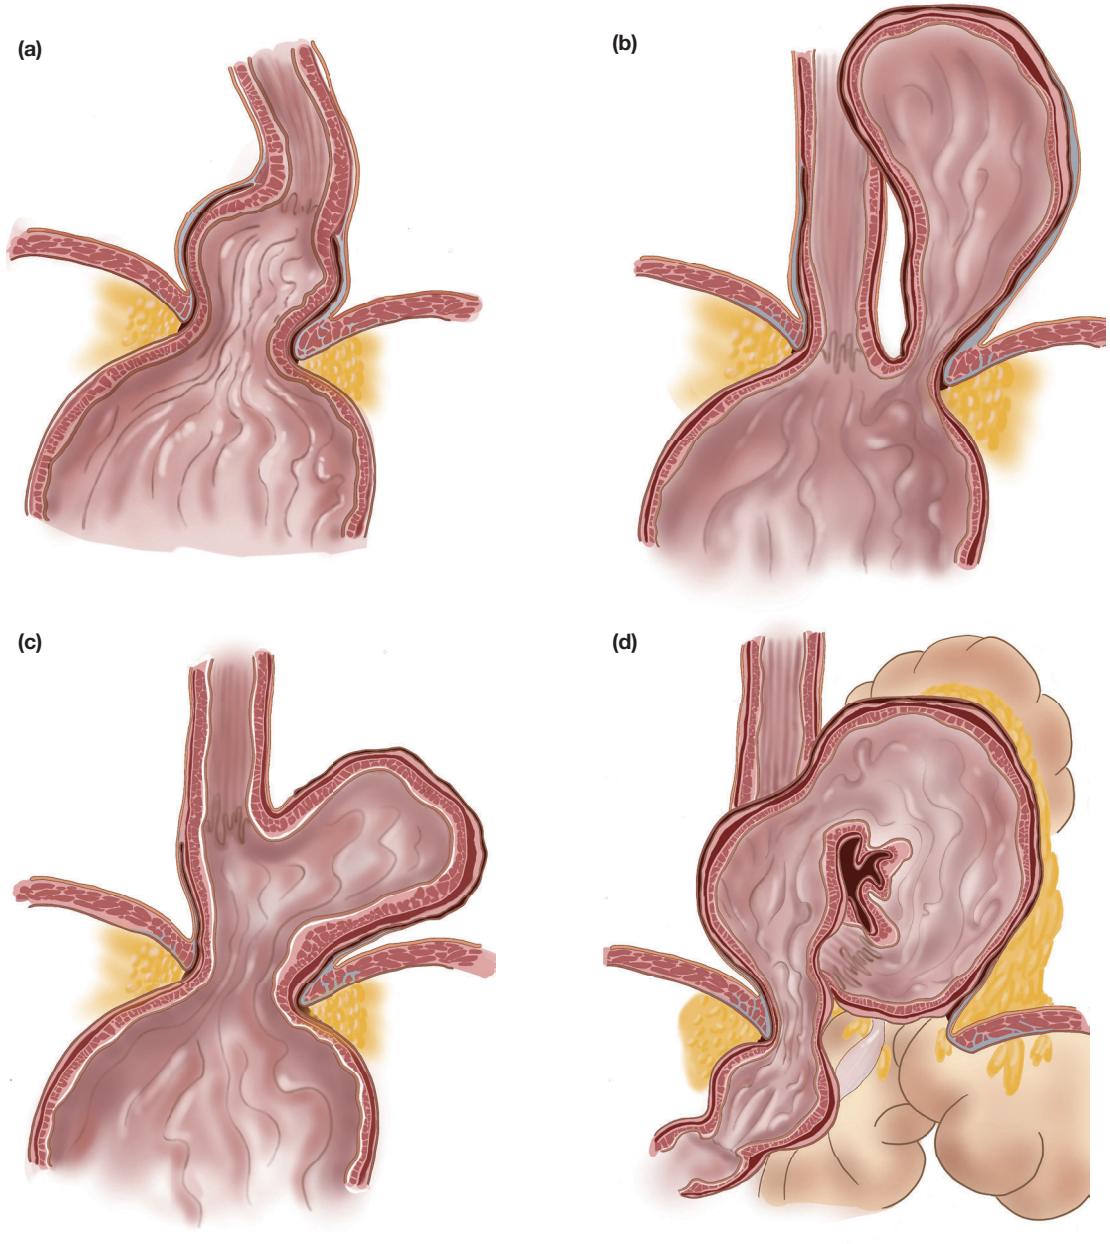

Figure 66.18 Types of hiatus hernias. **(a)** Type I, sliding hiatus hernia. **(b)** Type II, true rolling/paraoesophageal hiatus hernia. **(c)** Type III, mixed paraoesophageal hernia. **(d)** Type IV, giant hiatus hernia with herniation of another abdominal organ, e.g. colon.

hiatus hernias should be repaired. The decision to repair an asymptomatic paraoesophageal hernia needs to balance risk with the patient's age and comorbidities, as the annual risk of developing acute symptoms requiring emergency surgery is probably less than 2%.

Patients who present acutely should first be resuscitated, followed by nasogastric tube decompression. Immediate surgery is needed if there is suspicion of ischaemia, perforation or unresolved obstruction. The surgical principle is similar to that of sliding hiatus hernia repair but more technically demanding. The steps include reduction of any herniated organ, extensive mediastinal dissection to restore the intra-abdominal length of the oesophagus, excision of the hernia sac to prevent a recurrence, repair of the crura in a tension-free manner and some form of fixation of the stomach in the abdomen.

Summary box 66.3

Hiatus hernia

- Type I sliding hernia predisposes to GORD
- Types II/III/IV paraoesophageal hernia present mainly with obstructive symptoms
- Volvulus and strangulation require emergency surgical treatment

BARRETT'S OESOPHAGUS

Diagnosis and definitions

Barrett's oesophagus is a known complication of GORD. First described in 1950 as peptic ulceration in a tubular organ lined by columnar epithelium, it was interpreted as an intrathoracic tubular stomach with a congenitally short oesophagus. Later it was correctly identified as 'oesophagus lined with a gastric mucous membrane'. Currently, the commonly agreed definition of Barrett's oesophagus is the proximal migration of columnar epithelium (salmon-coloured mucosa) in the lower oesophagus extending more than 1 cm above the OGJ. The additional criterion of the biopsy-proven presence of mucus-secreting goblet cells or intestinal metaplasia is controversial.

Endoscopically, the OGJ is defined as the proximal end of the longitudinal gastric folds under minimal air insufflation. It should not be confused with the diaphragmatic hiatal pinch or the squamocolumnar junction. The Prague C&M Classification for Barrett's length is based on validated, explicit, consensus-driven criteria, including assessment of the circumferential (C) and maximal (M) extent of the endoscopically visualised Barrett's segment (***Figure 66.21***). The length of Barrett's oesophagus is a risk factor for developing neoplasia.

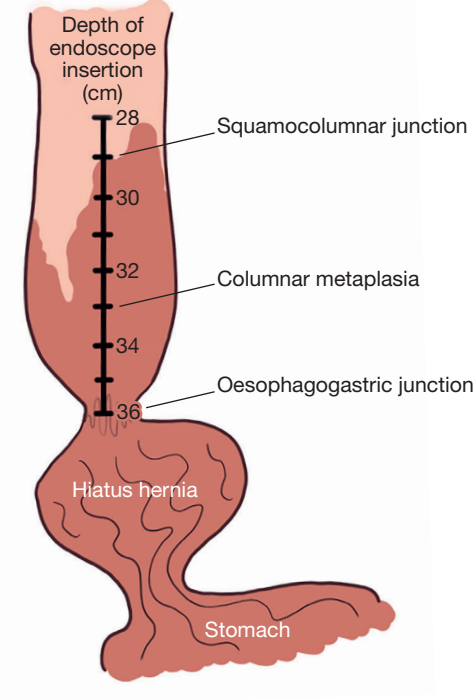

Figure 66.21 Prague C&M criteria to report endoscopic Barrett's oesophagus. The location of the oesophagogastric junction is defined by the top of the gastric folds (36 cm). Prague criteria of Barrett's oesophagus are expressed in C (circumferential), in this case 33–36 cm (3 cm), and M (maximum extent), in this case 28–36 cm (8 cm). This patient therefore has Prague C3 M8 Barrett's oesophagus.

Screening and surveillance

The risk factors for Barrett's oesophagus and related neoplasm include chronic (>5 years) GORD symptoms, advanced age (>50 years), smoking, central obesity and male gender. For non-dysplastic Barrett's, the risk of progression to cancer is around 0.2–0.5% per year. This increases to around 0.7% per year for low-grade dysplasia. For high-grade dysplasia, the risk of cancer progression can be as high as 7%. Therefore, screening and surveillance protocols should be tailored to individuals according to the potential benefit of cancer prevention and the risk and cost-effectiveness of such intervention (***Figure 66.22***). Screening or surveillance aims to identify premalignant lesions and to treat them early.

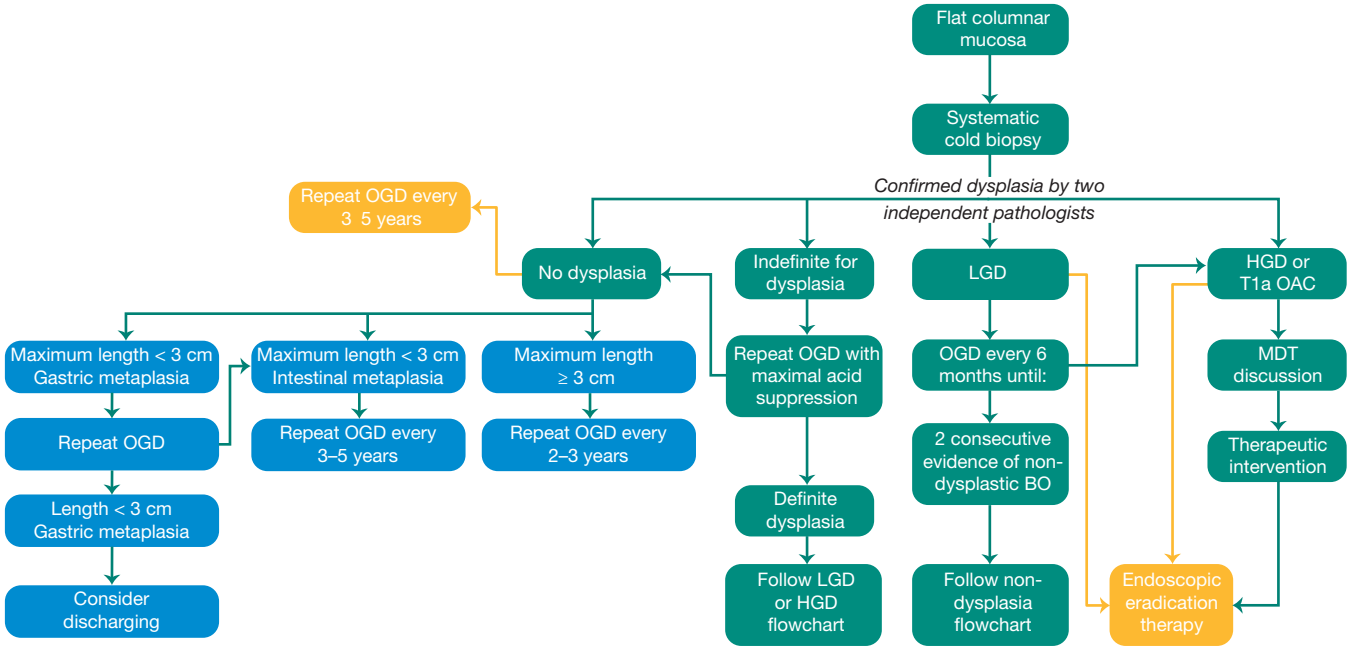

Figure 66.22 Algorithm for managing Barrett's oesophagus, including dysplasia. Summary of guidelines from the American College of Gastroenterology (orange) and the British Society of Gastroenterology (blue). BO, Barrett's oesophagus; HGD, high-grade dysplasia; LGD, low-grade dysplasia; MDT, multidisciplinary team; OAC, oesophageal adenocarcinoma; OGD, oesophagogastroduodenoscopy.

The vast majority of patients with Barrett's oesophagus in the community are asymptomatic; a general population screening programme is considered not to be cost-effective. High-definition white light endoscopy including NBI is used to assess the mucosal and vascular patterns of the Barrett's segment. Additional chromoendoscopy using different agents, e.g. methylene blue, acetic acid or indigo carmine, could aid diagnosis. The histological specimen obtained should be examined by an experienced gastrointestinal pathologist. The sensitivity of the assessment can be improved by increasing the number of biopsies and, when in doubt, endoscopy and biopsy should be repeated. The Seattle biopsy protocol, which includes four-quadrant random biopsies every 2 cm in addition to targeted biopsies on macroscopically visible lesions, is recommended at the time of diagnosis and subsequent surveillance.

Treatment

When Barrett's oesophagus is discovered, the treatment is that of the underlying GORD. Pharmacological therapy generally is the same as treatment of symptomatic GORD patients. Antireflux surgery is indicated if it is associated with GORD symptoms. A randomised trial suggested that aspirin, as a chemoprevention agent, in combination with a high-dose PPI, may improve outcomes in patients with Barrett's oesophagus measured by progression to cancer and mortality.

In patients with dysplastic Barrett's oesophagus without suspicion of invasive cancer, the epithelium can be ablated or resected. Indication for such procedures in non-dysplastic Barrett's oesophagus is controversial. Ablative therapy aims to completely eradicate all intestinal metaplasia. When the mucosa regenerates after ablation in a non-acidic environment (when a high-dose PPI is prescribed), a 'neosquamous' lining is formed. Ablative approaches that are supported by evidence include photodynamic therapy, RFA and cryotherapy. Among these methods, RFA is most popular because there is evidence of its effectiveness, cost and side-effect profile. EMR by the cap method or multiband technique can be done to remove the whole segment of the mucosa. When this is applied to circumferential Barrett's oesophagus, the stricture rate is high when healing occurs. The procedure can be performed in stages, allowing mucosal healing to occur first in one half of the oesophagus before a second stage to remove the other half, thus lessening the chance of stenosis. In contrast, the incidence of stricture formation is low following RFA, because the depth of ablation extends to the muscularis mucosae only.

Endoscopic ablation should only be applied to flat lesions without nodularity, ulceration or irregular contour. Such features are suggestive of invasive neoplasm that should be investigated and treated by EMR or endoscopic submucosal dissection (ESD). ESD, though more technically demanding, provides en bloc resection of the index lesion with better margins for histological diagnosis. EMR is easier and large areas can be resected in a piecemeal manner. If histological examination of the resected tissue demonstrates the absence of invasive cancer, or T1a tumour, only the 'biopsies' can be regarded as curative. When T1b lesions are found on histology, or when the resection margins (lateral or deep) are involved, additional therapy including oesophagectomy should be considered. Regardless of treatment performed, the patient should enter a surveillance programme to detect recurrent or persistent Barrett's oesophagus or neoplasia.

Summary box 66.4

Barrett's oesophagus

- Endoscopic examination and biopsies are crucial in the diagnosis of Barrett's oesophagus
- Dysplasia should be confirmed by at least two experienced pathologists
- Surveillance or ablation are options for low-grade dysplasia
- In patients with high-grade dysplastic Barrett's oesophagus, ablative, endoscopic resection and oesophagectomy should be considered

MOTILITY DISORDERS AND DIVERTICULA

Oesophageal motility disorders

Oesophageal motility disorders are a spectrum of diseases that involve the diminished, overaction or desynchronised neuromuscular function of the oesophageal body or sphincters. The most common presenting symptom is dysphagia. Chest pain, with or without swallowing difficulty, is another frequent complaint. Patients often undergo extensive investigations before the oesophagus is considered the responsible organ. It is important to have a proper diagnostic work-up before treatment is considered.

Manometric classification

Oesophageal motility disorders are classified on HRM under the Chicago classification. A hierarchy diagnostic algorithm is utilised (***Figure 66.23***). Broadly speaking, these disorders can be classified as disorders of OGJ outflow and disorders of peristalsis. Disorders of OGJ outflow are characterised by an elevated integrated relaxation pressure (IRP), which is the relaxation pressure across the OGJ in response to a swallow. Diagnoses include the three types of achalasia and OGJ outflow obstruction (OGJOO). Disorders of peristalsis include absent contractility, distal oesophageal spasm, hypercontractile oesophagus and ineffective oesophageal motility. All motility disorders have to be associated with symptoms or other supporting tests to make them clinically relevant. Various metrics have been developed in HRM; the details are beyond the scope of this chapter and the reader is encouraged to consult the relevant publications.

Achalasia

Pathology and aetiology

The term achalasia originated from the Greek word 'khalasis', meaning 'failure to relax'. It is uncommon, with a prevalence of 1.8–12.6 per 100 000 persons per year. The aetiology remains uncertain but is postulated to be due to loss of the inhibitory ganglion cells in the myenteric (Auerbach's) plexus, possibly related to a virus-induced autoimmune effect. Histology of muscle specimens generally shows a reduction in the number of ganglion cells with a variable degree of chronic inflammation. During a normal swallow, the food bolus will trigger primary peristalsis in the oesophagus by sequential activation of excitatory lower motor neurones. At the same time, relaxation of the LOS allows oesophageal emptying. The mismatch in excitatory and inhibitory activity results in the failure of LOS relaxation and absent peristalsis. With time, the oesophagus dilates and contractions disappear, so that the oesophagus empties mainly by the hydrostatic pressure of its contents. This is nearly always incomplete, leaving residual food and fluid. The air–fluid level in the stomach evidenced on radiography taken in the erect position in normal individuals is frequently absent, as no bolus with its accompanying air passes through the LOS. The oesophagus becomes progressively more tortuous and dilated (megaoesophagus); persistent retention oesophagitis due to fermentation of food residues may predispose to the increased incidence of carcinoma of the oesophagus. In South America, chronic infection with the parasite *Trypanosoma cruzi* causes Chagas' disease and the destruction of the myenteric plexus has marked clinical similarities to achalasia. A rare genetic syndrome (Allgrove syndrome) is associated with familial adrenal insufficiency, alacrimia and achalasia.

Clinical features

The disease is most commonly diagnosed between 30 and 60 years of age. It typically presents with dysphagia (to both solid and liquid), regurgitation and heartburn (often mistaken for GORD), although chest pain/odynophagia is also common in the early stages. Patients often present late and, having had relatively mild symptoms, remain untreated for many years. Patients may or may not have experienced weight loss. Frequently, patients will adjust their diet according to symptoms and can maintain their body weight after an initial drop. An 'Eckardt score' was developed to assess the severity of symptoms and monitor treatment outcome (***Table 66.1***). Aspiration-related respiratory symptoms and pneumonia can also occur when there is significant stasis of food residue in the dilated oesophagus. The retained food substance can cause fermentation and therefore halitosis. Patients may report regurgitating food that they have ingested before.

Diagnosis

A high index of suspicion is needed in the diagnosis of achalasia as symptoms can be mild and chronic and can be easily misdiagnosed as GORD. Endoscopy typically shows frothy saliva pooling in the oesophagus and the presence of food residue. The oesophagus may be dilated and can be tortuous. The OGJ appears tight and spastic but can usually allow an endoscope to

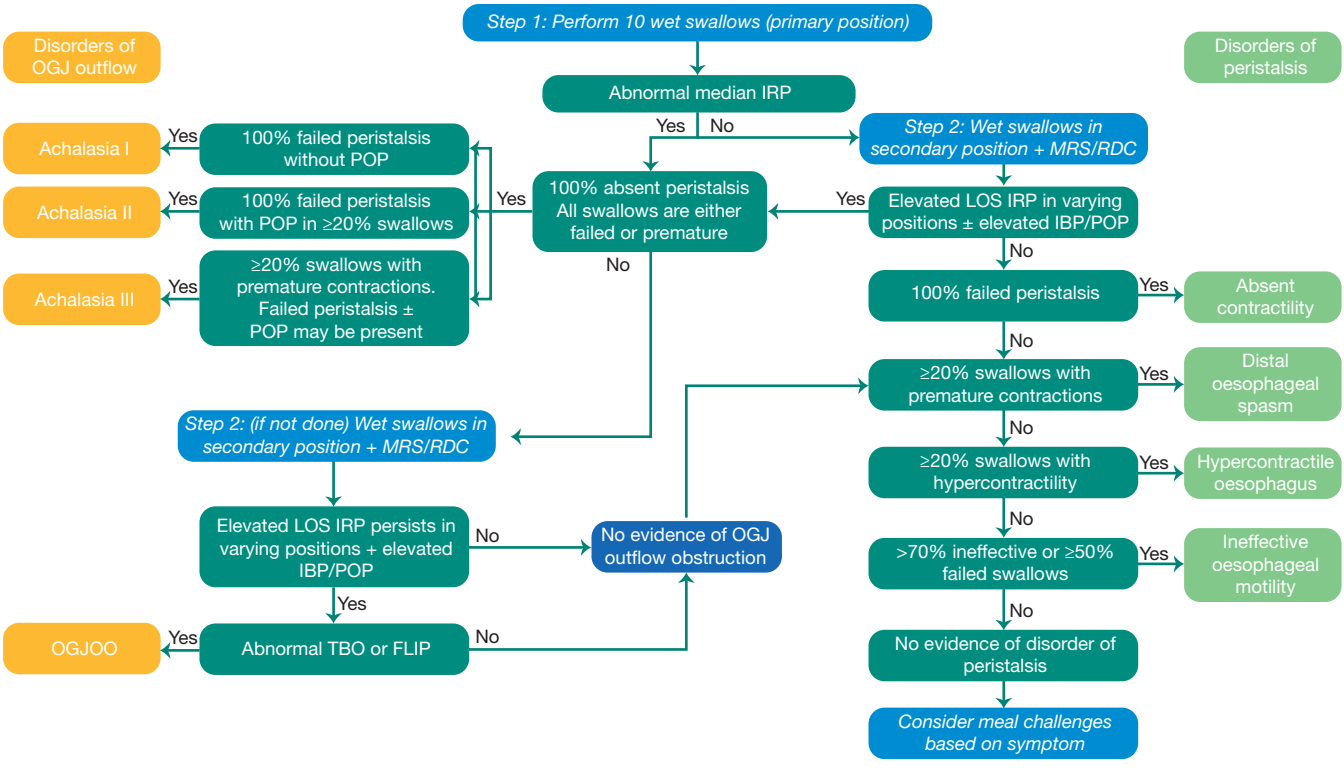

Figure 66.23 Hierarchy diagnostic algorithm of oesophageal motility disorders according to the Chicago classification 4.0. The broad categories of 'disorders of oesophagogastric junction (OGJ) outflow' and 'disorders of oesophageal peristalsis' are differentiated by the integrated relaxation pressure (IRP). FLIP, functional lumen imaging planimetry; IBP, intrabolus pressurisation; LOS, lower oesophageal sphincter; MRS, multiple rapid swallow; OGJOO, oesophagogastric outflow obstruction; POP, pan-oesophageal pressurisation; RDC, rapid drink challenge; TBO, timed barium oesophagram.

Table 66.1 Clinical scoring system for achalasia (Eckardt score).

Score	Symptom			
	Weight loss (kg)	Dysphagia	Retrosternal pain	Regurgitation
0	None	None	None	None
1	<5	Occasionally	Occasionally	Occasionally
2	5–10	Daily	Daily	Daily
3	>10	Each meal	Each meal	Each meal

pass with gentle pressure. A normal endoscopy however does not exclude achalasia, as 30–40% of endoscopies are reported as normal before a final diagnosis of achalasia is made. It is an important investigation to exclude 'pseudo-achalasia', often referring to cancer of the gastric cardia mimicking achalasia (***Figure 66.24***).

Barium contrast study typically shows a hold-up of contrast in the distal oesophagus, abnormal contractions in the oesophageal body and a tapering stricture in the distal oesophagus, described as a 'bird's beak' or 'rat's tail' (***Figure 66.25***). Progressive dilatation leads to a 'sigmoidal'-shaped oesophagus. A timed barium oesophagogram is used to quantify the height of the retained contrast at a specific time after ingestion to determine the severity of the disease. All these investigations are suggestive of achalasia but definitive diagnosis relies on HRM.

Treatment

The treatment goal of achalasia is for symptom palliation since there is no therapy to reverse the neuronal degeneration. Therapies target the LOS, aiming to reduce its contractility by pharmacological means or by destroying the muscle fibres using endoscopic or surgical methods.

Medical therapy

Pharmacological therapy has a limited role. Calcium channel blockers, nitrates or 5′-phosphodiesterase inhibitors are used to reduce the LOS pressure. Most have limited efficacy in symptom improvement. There are also significant side effects, such as headache, oedema and hypotension, after repeated doses. Medical therapy should be reserved for selected patients who are poor candidates for endoscopic or surgical treatments.

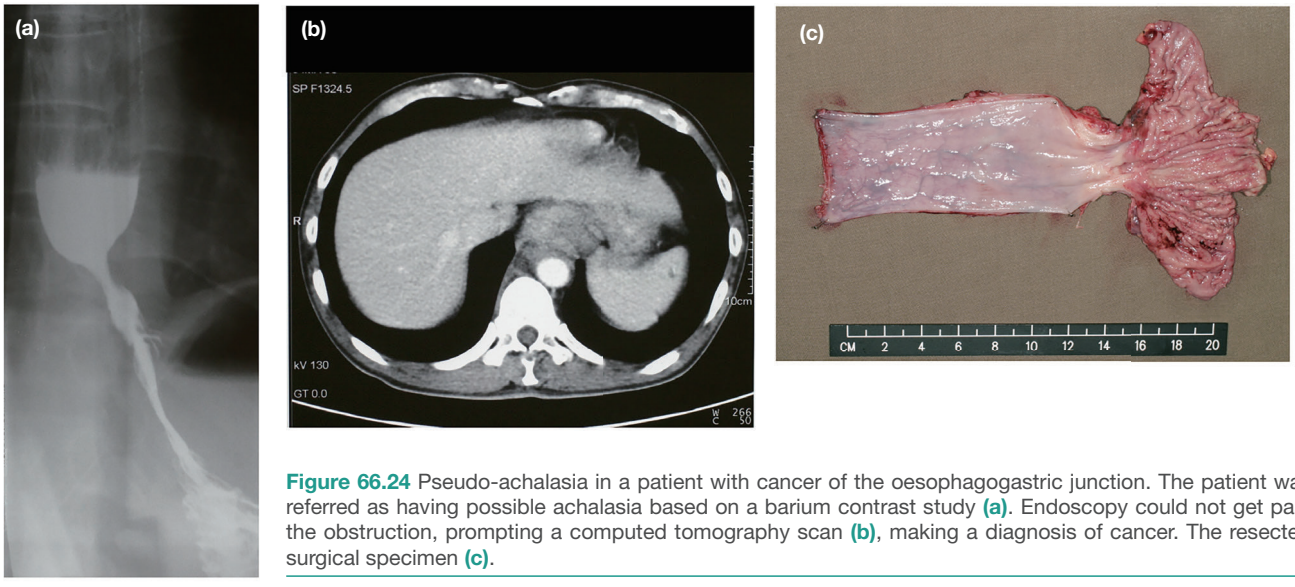

Figure 66.24 Pseudo-achalasia in a patient with cancer of the oesophagogastric junction. The patient was referred as having possible achalasia based on a barium contrast study **(a)**. Endoscopy could not get past the obstruction, prompting a computed tomography scan **(b)**, making a diagnosis of cancer. The resected surgical specimen **(c)**.

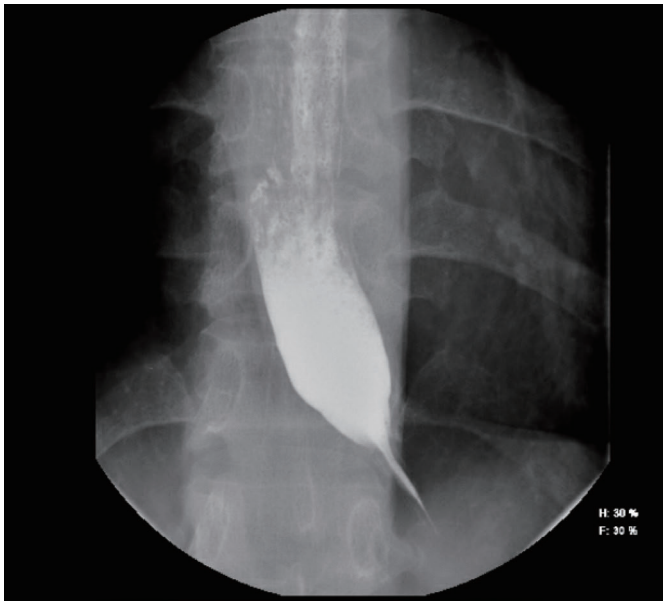

Figure 66.25 Barium contrast study showing the typical 'rat's tail' appearance of achalasia.

Botulinum toxin

Botulinum toxin is a potent presynaptic inhibitor of acetylcholine release from nerve endings. When injected endoscopically into the LOS, it interferes with the LOS cholinergic excitatory neural activity and paralyses the sphincter muscle. The reported symptom relief decreased from 70% in 3 months to around 40% in a year. The injection usually has to be repeated after a few months. Because the effect is temporary, it is sometimes used when the diagnosis of achalasia is in doubt. Repeated injection may result in scarring, making subsequent treatments more difficult. It should not be offered as first-line treatment in patients who are suitable for myotomy or pneumatic dilatation and its indication is usually restricted to elderly patients with comorbidities.

Pneumatic dilatation

This involves stretching the LOS with a non-compliant balloon to disrupt the sphincter muscle and render it less competent. Plastic (polyethene) balloons with a precisely controlled external diameter are used. If the pressure in the balloon is too high, the balloon is designed to split along its length rather than expanding further. Balloons of 30–40 mm in diameter are available and are inserted over a guidewire. There is no standardised dilatation protocol. Generally, it is preferred to have serial dilatations in a graded manner, from 30 mm to 35 mm and 40 mm.

Serial pneumatic dilatation has similar efficacy to surgical myotomy in selected patients. Features that predict optimal response are: patients older than 45 years, female, those with an undilated oesophagus, those who have responded to first dilatation and those with type II achalasia. Perforation is uncommon; the reported incidence averaged about 1.9% (0–16%). With a 30-mm balloon, the chance of perforation should be less than 0.5%. The risk of perforation increases with bigger balloons, which should be used cautiously for progressive dilatation over weeks. It is important to have an experienced endoscopist performing the procedure and surgical back-up in case of perforation.

Heller's myotomy

This involves cutting the muscle of the lower oesophagus and gastric cardia (***Figure 66.26***).Typically, anterior myotomy is

Ernst Heller, 1877–1964, surgeon, St George's Krankenhaus, Leipzig, Germany.

performed for at least 6 cm proximally at the oesophageal side and 2–3 cm distally into the gastric cardia. Transabdominal or transthoracic approaches have been advocated. Currently, the standard procedure is a laparoscopic approach. The major complication is GORD, which can occur in up to 40% of patients. The addition of a partial fundoplication (anterior Dor or posterior Toupet) has been shown to be effective in reducing the incidence of GORD. A complete 360° fundoplication (Nissen) is considered contraindicated because the increase in outflow resistance against an aperistaltic oesophageal body will probably result in postoperative dysphagia. Laparoscopic myotomy is superior to single pneumatic dilatation in efficacy and durability. The surgical outcome is better in types I and II achalasia than in type III. For the latter, a longer extended proximal myotomy is often needed for adequate treatment.

Peroral endoscopic myotomy

Peroral endoscopic myotomy (POEM) involves opening the mucosa at a short distance proximal to the intended myotomy site. Entrance is gained into the submucosal plane, which is extended distally to about 2–3 cm into the gastric cardia. The circular +/– longitudinal muscles are then cut using ESD instruments. Typically, the myotomy extends a minimum of 6 cm in the oesophagus proximally and 2 cm into the gastric cardia distally (***Figure 66.27***). The mucosal opening is then closed with endoclips. In type III achalasia, there is a spastic component at the distal oesophagus that responds less well to pneumatic dilatation and Heller's myotomy. POEM has the advantage in that it can extend the length of the myotomy proximally, tailored to preoperative HRM and barium swallow parameters. POEM can also be utilised to treat other types of 'spastic' oesophageal motility disorders such as distal oesophageal spasm and hypercontractile oesophagus. Randomised controlled trials have demonstrated similar efficacy of POEM to pneumatic dilatation and Heller's myotomy in relieving dysphagia. Without any antireflux procedure, the incidence of GORD is expectedly higher in POEM compared with Heller's myotomy with partial fundoplication. The incidence of oesophagitis at 3 months after POEM can be as high as 57%, which may subject patients to lifelong acid suppression therapy or subsequent antireflux operation.

Oesophagectomy

Oesophagectomy is reserved only for the treatment of patients with 'end-stage' achalasia with a sigmoidal or megaoesophagus that is not responding to other methods (***Figure 66.28***). Depending on the chronicity of the disease, the symptoms of achalasia may be tolerated. However, a grossly dilated oesophagus predisposes to regurgitation and aspiration pneumonia. Balancing the risk of an oesophagectomy with the patient's quality of life and risk of aspiration complication, surgery can be a reasonable option for surgically fit patients.

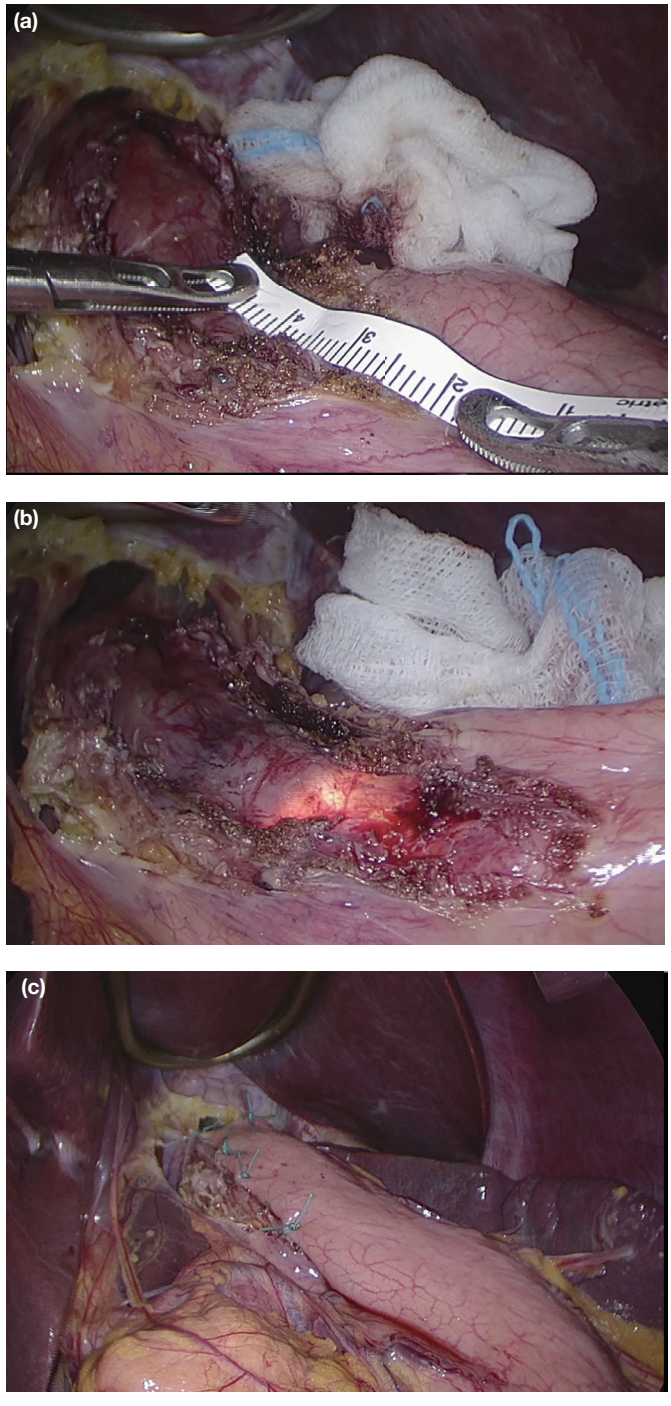

Figure 66.26 Laparoscopic myotomy and Dor hemi-fundoplication. **(a)** The lower oesophageal myotomy extending onto the stomach for at least 2 cm. **(b)** Completion of the myotomy; the light of the endoscope can be seen shining through the thin mucosa. **(c)** Completion of the Dor anterior fundoplication.

Follow-up

Treatment success is usually defined by symptom relief. The Eckardt score is quantified and compared with the preoperative score. Patients should be counselled on a post-treatment diet as the oesophageal body motility remains defective. Ideally, HRM, barium contrast study, endoscopy and 24-hour pH monitoring should be performed postoperatively to objectively assess LOS function, bolus retention, response to treatment, presence of oesophagitis and acid reflux. This depends on the availability of resources and patients' preference.

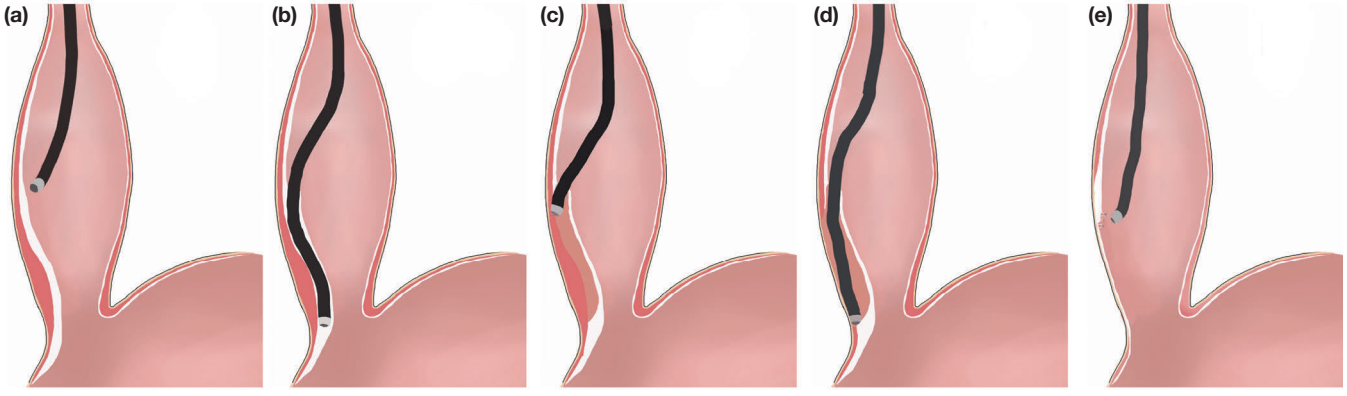

Figure 66.27 The procedure of peroral endoscopic myotomy (POEM). **(a)** Creation of a mucosal opening. **(b)** A tunnel is created between the mucosa and the muscle layer down to the stomach. **(c)** Myotomy starts a short distance below the mucosal opening. **(d)** Myotomy is carried out into the proximal stomach. **(e)** The mucosal opening is closed by endoclips.

Summary box 66.5

Achalasia

- Achalasia is the most common oesophageal motility disorder
- A normal endoscopy does not exclude the diagnosis of achalasia
- Beware of pseudo-achalasia
- HRM is the gold standard for the diagnosis of oesophageal motility disorder
- Laparoscopic myotomy, pneumatic balloon dilatation and POEM are effective treatments of achalasia
- Type III achalasia may be better treated with long myotomy by POEM

Other oesophageal motility disorders

Hypercontractile motility disorders

Distal oesophageal spasm is a condition in which there are incoordinate, premature and rapidly propagated contractions of the oesophagus, causing dysphagia and/or chest pain. The condition may be dramatic, with marked hypertrophy of the circular muscle and a corkscrew oesophagus on the barium oesophagogram (***Figure 66.29***). These abnormal contractions are more common in the distal two-thirds of the oesophageal body. Hypercontractile (jackhammer) oesophagus is characterised by high-amplitude contractions and should be differentiated from contractility disorder secondary to outflow obstruction. Patients may present with dysphagia or pain.

There is no well-proven treatment strategy for hypercontractile motility disorders. Patients should avoid any identifiable triggering factors (e.g. dietary or GORD related). Similar to achalasia, medical therapy such as calcium channel blockers, nitrates, 5′-phosphodiesterase inhibitors and pain modulators have been used with limited efficacy. Botulinum toxin injection in the oesophageal body may be useful. Long-segment surgical myotomy has been attempted with good results. POEM with extended myotomy is also advocated as a minimally invasive approach to treat these disorders.

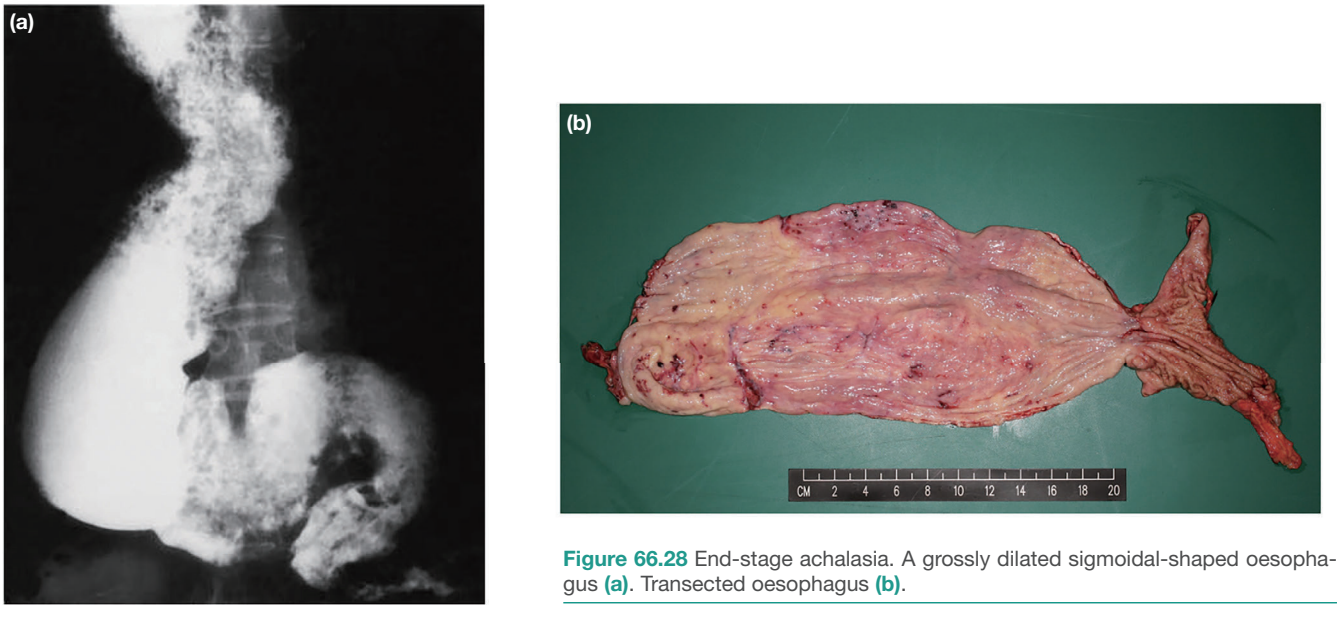

Figure 66.28 End-stage achalasia. A grossly dilated sigmoidal-shaped oesophagus **(a)**. Transected oesophagus **(b)**.

Figure 66.29 Barium contrast study showing a corkscrew oesophagus in a patient with diffuse oesophageal spasm.

Functional oesophageal disorders

According to the Rome IV classification, functional oesophageal disorders include a variety of oesophageal symptoms (heartburn, chest pain, dysphagia, globus) that are not explained by mechanical obstruction (stricture, tumour, EOO), major motor disorders (achalasia, OGJOO, absent contractility, distal oesophageal spasm, jackhammer oesophagus) or GORD. The mechanisms responsible are unclear but are likely to be more related to visceral hypersensitivity and hypervigilance. The diagnosis is generally by exclusion. Physiological and psychological factors should be considered.

Among all the oesophageal disorders defined under the Rome diagnostic criteria, functional heartburn and reflux hypersensitivity contribute to most diagnostic confusion with genuine GORD. Therefore, patients have to be carefully assessed before antireflux surgery is offered. Pharmacological agents such as PPIs, tricyclic antidepressants, SSRIs and other pain modulators can be part of the treatment strategy. Surgery has a very limited role in the treatment and usually results in a poor outcome.

Pharyngeal and oesophageal diverticula

Oesophageal diverticula can be classified as true diverticula, which involve a full-thickness oesophageal wall, and false diverticula, which involve mucosal outpouching only. Diverticula are usually described by their location as pharyngeal, midoesophageal and epiphrenic. Diverticula alone seldom produce troublesome symptoms unless large or secondary to an underlying oesophageal motility disorder. The most common symptoms are dysphagia, regurgitation, halitosis and recurrent aspiration.

Figure 66.30 Barium contrast study showing a Zenker's diverticulum.

Pharyngeal pouch (Zenker's diverticulum)

Zenker's diverticulum is a false pulsion diverticulum as it protrudes posteriorly above the cricopharyngeal sphincter through the natural weak point (the dehiscence of Killian) between the oblique and horizontal fibres of the inferior pharyngeal constrictor. The pathophysiology is believed to involve loss of coordination between pharyngeal contraction and opening of the upper sphincter (***Figure 66.30***).

Gustav Killian, 1860–1921, Professor of Laryngology, Freiburg and later Berlin, Germany.

When the diverticulum is small, symptoms largely reflect desynchronisation of swallowing with predominantly pharyngeal dysphagia. As the pouch enlarges, it tends to fill with food on eating, and the fundus descends into the mediastinum. Regurgitation of trapped food can occur and lead to aspiration. Another symptom is halitosis. Conventional surgical treatment involves an open left cervical incision (most diverticula point towards the left side) with diverticulectomy and cricopharyngeus myotomy. Another option is diverticular suspension, whereby the diverticulum is dissected and inverted with its apex pointing cranially. This will stop food from entering the pouch. The absence of a suture line lessens the chance of a postoperative leak. A cricopharyngeus myotomy is also an integral part of the surgery. Newer techniques include transoral introduction of a linear stapler to divide the septum in between the diverticulum and the true oesophageal lumen. This creates a common channel, and the myotomy is in effect performed by the stapler transection (***Figure 66.31***).

Midoesophageal diverticula (Rokitansky diverticulum)

Midoesophageal diverticula are usually small traction diverticula of no particular consequence. In granulomatous diseases with chronic inflammation, fibrosis or lymphadenopathy in the mediastinum can exert traction force onto the oesophageal wall and cause full-thickness outpouching. Rarely it may cause fistulation into the airway in uncontrolled pulmonary tuberculosis. Asymptomatic midoesophageal diverticulum does not warrant any treatment. HRM may be indicated in symptomatic patients to exclude pulsion diverticulum due to oesophageal motility disorder, e.g. hypercontractile oesophagus.

Epiphrenic diverticula

Epiphrenic diverticula are pulsion diverticula typically situated at the distal 10 cm of the oesophagus. They are commonly associated with oesophageal motility disorders, e.g. achalasia, or other causes of oesophageal outflow obstruction. Barium oesophagogram is a useful investigation depicting the size and anatomical relationship of the diverticulum and, at the same time, screening for oesophageal motility disorder (***Figure 66.32***). Large diverticula should be excised combined with a myotomy from the neck of the diverticulum to the cardia to relieve the functional obstruction. Concurrent fundoplication or repair of hiatus hernia may be necessary, depending on the size of the diverticulum or associated conditions. A laparoscopic approach is the preferred option to reduce morbidity.

OESOPHAGEAL PERFORATION

Oesophageal perforation is associated with high morbidity and mortality rates. It is an emergency and prompt treatment should be instituted because delayed diagnosis and treatment are associated with a marked increase in mortality rate.

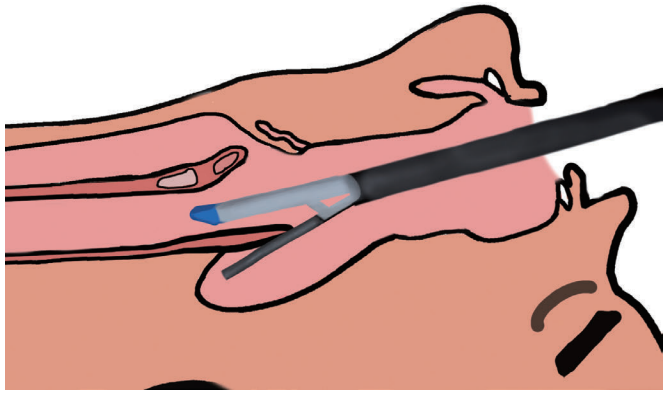

Figure 66.31 A linear stapler is introduced orally and the 'ridge' including the muscle is divided.

Aetiology

Iatrogenic perforation secondary to endoscopic procedures such as dilatation of strictures or achalasia is the most common cause. Other endoscopic procedures such as EMR/ESD/POEM may result in leakage if there is transmural disruption and mucosal defects are not closed properly. Spontaneous emetogenic perforation (Boerhaave's syndrome) results from a sudden increase in oesophageal pressure against a closed glottis from vomiting. Perforation from direct penetrating trauma is rare as the oesophagus is a deep-seated organ. Blunt external trauma rarely causes oesophageal perforation. Foreign body ingestion, especially with sharp objects, may perforate the oesophagus. Corrosive ingestion can also lead to transmural necrosis and disruption of the oesophageal wall. Patients with EOO may present with spontaneous perforation. Oesophageal cancer can perforate, and the prognosis is usually poor since it reflects the underlying advanced disease.

Presentation and diagnosis

Sometimes the history is obvious, such as after instrumentation or foreign body ingestion. At other times there may not have been any precipitating cause. Patients with Boerhaave's syndrome may have the classic triad of vomiting, chest pain and subcutaneous emphysema. There may or may not be associated haematemesis. Typically, the site of perforation is the lower oesophagus towards the left pleural cavity. Gastric juice as well as ingested food is forcefully ejected into the left chest. A left pleural effusion rapidly accumulates. Physical examination reveals subcutaneous emphysema on the chest wall, sometimes extending to the cervical region as well. In the presence of sepsis, the patient will run a fever, has tachycardia and appears tachypnoeic. Hamman's sign refers to a crunching sound on auscultation of the heart owing to surgical emphysema. Differential diagnoses usually include pneumonia, myocardial ischaemia or other intra-abdominal pathologies such as a perforated viscus when the pain is referred to the epigastrium.

Baron Carl von Rokitansky, 1804–1878, pathologist, philosopher and politician, Vienna, Austria, classified oesophageal diverticula as either traction or pulsion in 1840.

Louis Hamman, 1877–1946, physician, Johns Hopkins Hospital, Baltimore, MD, USA.

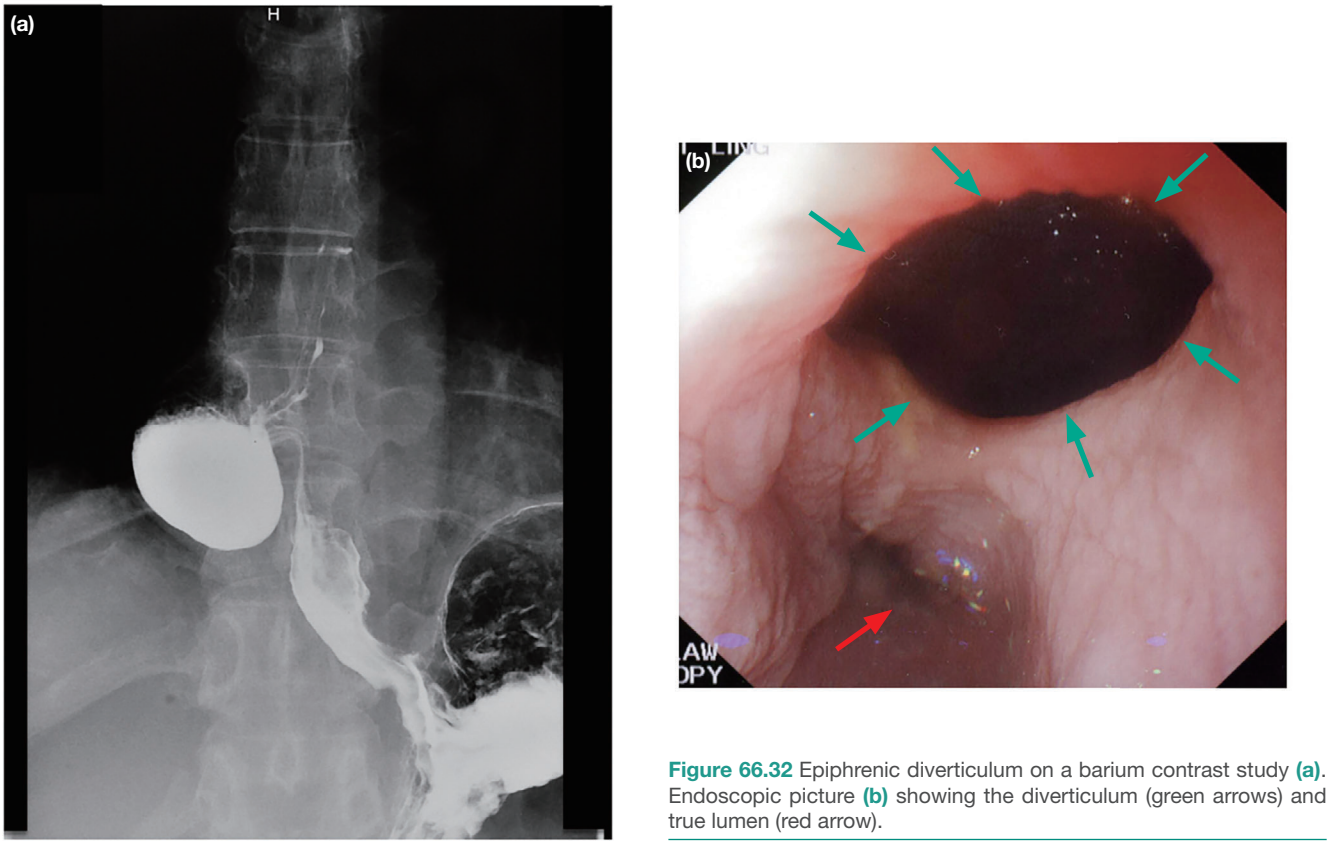

Figure 66.32 Epiphrenic diverticulum on a barium contrast study **(a)**. Endoscopic picture **(b)** showing the diverticulum (green arrows) and true lumen (red arrow).

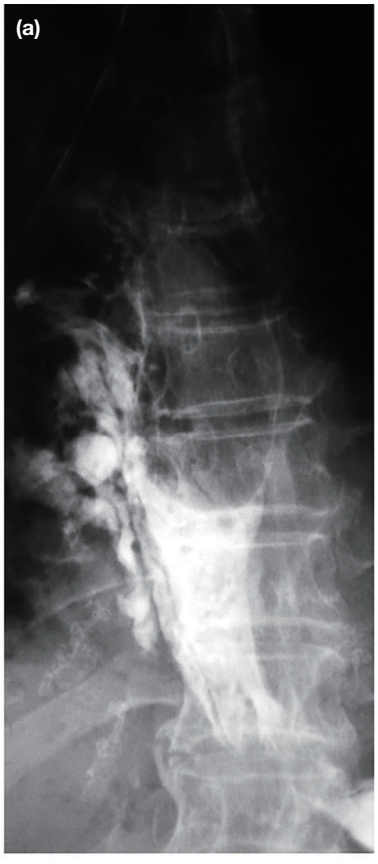
Patients with cervical oesophageal or pharyngeal perforation are usually much less septic than those with intrathoracic perforations and mediastinitis. A typical example would be foreign body perforation, such as by a sharp fishbone, having lodged at the postcricoid area and perforated the oesophagus. There may be a history of foreign body ingestion and neck pain and physical examination may reveal tenderness and subcutaneous emphysema.

Subcutaneous and mediastinal air, pneumothorax, hydropneumothorax and a widened mediastinum may be seen on the chest radiograph (***Figure 66.5***). Contrast swallow study using Gastrografin or a non-ionic contrast usually reveals the site of perforation. However, sick patients may not be able to tolerate oral contrast. A CT scan (preferably with intravenous as well as oral contrast) will be able to demonstrate the site (and aetiology) of perforation and the extent of mediastinitis, effusion and collections (***Figure 66.6***).



Management

In stable patients with a clear history and contained perforation, sometimes conservative expectant treatment can be successful. This usually applies to cervical/pharyngeal perforation when patients are much less septic. Antibiotics should be given; patients are kept nil by mouth and should wait for the perforation to heal by itself. In intrathoracic perforations, patients are usually sicker. They should be resuscitated with intravenous fluid and given antibiotics and oxygen supplement. Electrolyte disturbances are corrected if present. Septic shock is treated appropriately. The objectives of treatment are (i) seal the perforation if possible, (ii) adequate drainage, and (iii) supportive measures, including nutrition (alimentary preferred over parenteral), cardiorespiratory support and sepsis control.

In patients with significant pleural fluid and pneumothorax that result in respiratory compromise, a wide-bore chest tube is inserted to the appropriate side for drainage while waiting for more definitive investigations such as a CT scan. Endoscopy can be both diagnostic and therapeutic. The location and size of the perforation site should be ascertained. Foreign bodies are retrieved. Endoscopic sealing of the perforation site with clips and self-expanding metallic stents may be possible (***Figure 66.33***). The stent is usually removed around 4–6 weeks later. Healing is expected to have occurred. A nasogastric tube can be placed at the same time for nutritional support.

Surgical intervention is indicated in the presence of significant sepsis when drainage is not affected by other means (such as interventional radiology), and no effective closure of the perforation can be done otherwise. These conditions are usually present when the perforation is large, when the perforation is in the intrathoracic oesophagus, when the pleura is breached, when there is a large septic load and when the presentation is delayed.

When the diagnosis is delayed, closure of the perforation is unlikely to succeed; conversion of the perforation into a controlled fistula is another option. A simple way would be to place a T-tube through the defect and repair around it, in addition to adjacent drains. With modern supportive treatment, oesophageal diversion (cervical oesophagostomy; often an end

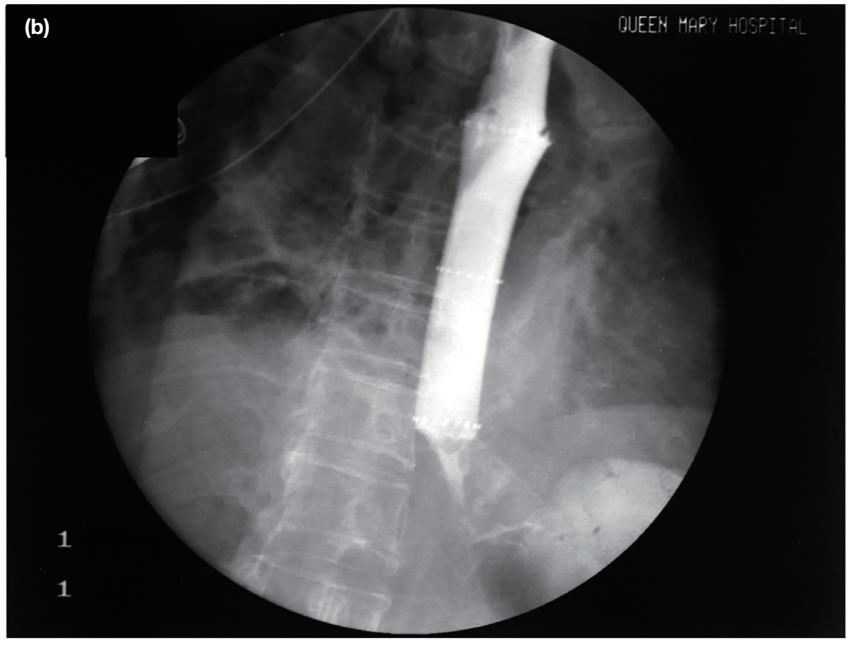


Figure 66.33 Stent for oesophageal perforation. **(a)** Leakage of oral contrast outside the oesophagus; **(b)** contrast flowing through the stent, no leakage is seen.

stoma is required for effective diversion and OGJ ligation) with later staged reconstruction is rarely needed. Oesophagectomy is even more uncommonly indicated, perhaps except for extensive caustic burn with perforation when the oesophagus is necrotic.

Summary box 66.6

Oesophageal perforation

- A potentially lethal condition due to sepsis
- Surgical emphysema, chest pain and vomiting constitute the classic triad of Boerhaave's syndrome
- Treatment aims at adequate drainage, closure of the perforation site if possible and supportive measures
- Delayed diagnosis and management lead to high morbidity and mortality rates

MALLORY-WEISS SYNDROME AND INTRAMURAL OESOPHAGEAL HAEMATOMA/DISSECTION

Forceful vomiting may lead to a tear at the OGJ, mostly immediately below the squamocolumnar junction. Patients present with haematemesis. Bleeding is rarely severe, and the diagnosis is readily made with endoscopy. Endoscopically the bleeding can be stopped by adrenaline (epinephrine) injection or endoscopic clips to stop bleeding and close the mucosal defect.

Intramural oesophageal dissection is characterised by the separation of the mucosa and/or submucosa from deeper muscular layers. This most commonly occurs in elderly patients taking anticoagulants or patients with coagulation disorders. It is often precipitated by vomiting. A break in the oesophageal mucosa is followed by an increase in intraoesophageal pressure that causes separation of mucosa and/or submucosa from the muscle layers. The mucosal break can also be caused by trauma such as foreign body impaction or air insufflation during endoscopy.

Patients present with acute onset of chest discomfort or odynophagia. If the haematoma ruptures into the oesophageal lumen haematemesis ensues. When the dissection or haematoma is confined to the oesophageal wall, treatment is conservative. Anticoagulation is corrected and the haematoma usually resolves in 7–14 days.

CAUSTIC INJURY

Caustic injury to the oesophagus can be mild, but also is potentially lethal. Most caustic ingestions occur in children, in whom it is usually accidental, or in adults with suicidal intent. The severity of the injury depends on the type, pH, quantity

George Kenneth Mallory, 1900–1986, pathologist, Boston University, Boston, MA, USA.
Soma Weiss, 1898–1942, Physician in Chief, Peter Bent Brigham Hospital, Boston, MA, USA.

and duration of exposure. The substance ingested can be a strong acid, causing coagulative necrosis with eschar formation, which may limit penetration to deeper layers, or strong alkali, leading to liquefactive necrosis. The latter potentially penetrates deeper into the oesophageal wall, producing a more severe injury pattern.

Diagnosis is usually not difficult. When the injurious agent is identified, it should be tested for its pH, and suicidal attempt considered. Patients may have pain in the neck, throat, chest or even the abdomen. Drooling of saliva, dysphagia and odynophagia can be present. Hoarseness of voice is an important sign to look for as it may signify laryngeal injury and potential airway obstruction. If the airway is judged to be compromised, careful assessment and emergency intubation using fibreoptic guidance, or even a surgical airway, are indicated. There is no role for gastric lavage or attempts to neutralise the acid or alkali. Initial treatment after securing an adequate airway is supportive, with intravenous fluid, oxygen supplementation and cardiorespiratory monitoring.

Once the patient is stabilised, an endoscopy and CT scan with intravenous contrast should be considered. Careful endoscopy allows assessment of the extent of the injury (***Figure 66.34***). The Zargar grading can be used (***Table 66.2***). In general, the longer and more circumferential the injury, the more likely that stricture will form. The stomach is assessed as well for injury, and a nasogastric/duodenal tube can be placed with endoscopic guidance. This can be used for alimentary nutritional support; if a stricture forms, there is still a potential route of access through to the stomach. A CT scan can assess oesophageal oedema and also surrounding soft-tissue infiltration.

Most caustic injuries can be managed conservatively with supportive measures. Deterioration requires surgical treatment, with emergency oesophagectomy. The oesophagus can be mobilised transhiatally or via a thoracoscopic approach. Immediate reconstruction is not recommended. A cervical oesophagostomy and a gastrostomy can be done and future reconstruction planned. A feeding jejunostomy is an alternative for nutritional support if the stomach also requires resection.

Delayed complications include stricture and malignancy. A stricture can form early and may be resistant to dilatation (***Figure 66.35***). There is not enough evidence to support routine use of systemic steroids, intralesional injection of steroid or topical mitomycin C to reduce stricture formation. Endoscopic dilatation should be gradual, as the perforation rate is higher than in other forms of strictures. Long strictures are often resistant to dilatation. Oesophagectomy or bypass surgery may be required. Oesophagectomy has the advantage of removing the oesophagus with its long-term risk of malignancy. However, surgery is difficult because of scarring and adhesions to the mediastinum, thus a bypass operation may be preferable. The gastric conduit is placed in the retrosternal route to reach the neck. When it is also damaged and cannot be used, a colonic interposition is the alternative. The native oesophagus can be left *in situ* as the risk of dilatation and resultant mucocele is low.

Table 66.2 Zargar endoscopic classification of caustic injury to the oesophagus.

Zargar classification grade	Description
0	Normal appearance
1	Oedema and hyperaemia
2a	Superficial ulceration and friability
2b	Deep ulceration or circumferential ulceration
3a	Multiple deep ulceration ad scattered necrosis
3b	Extensive necrosis
4	Perforation

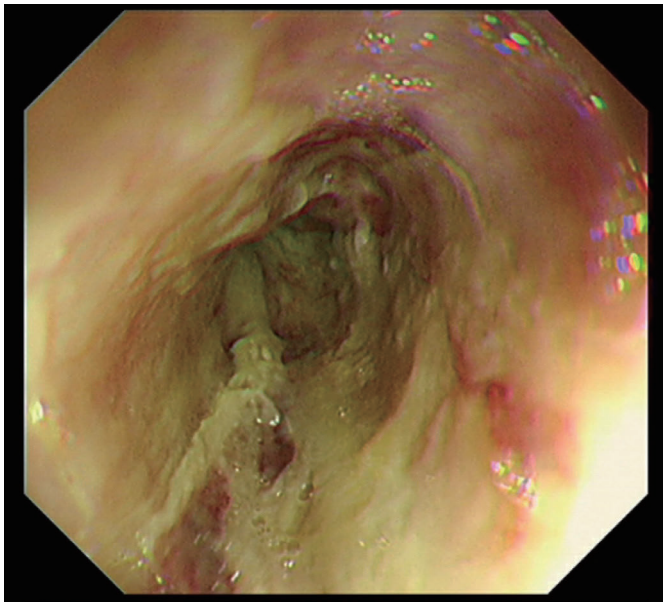

Figure 66.34 Endoscopy picture showing caustic burn to the oesophagus.

EOSINOPHILIC OESOPHAGITIS

EOO is defined as a chronic, immune/antigen-mediated oesophageal disease, characterised clinically by symptoms related to oesophageal dysfunction and histologically by eosinophil-predominant inflammation. However, there is overlap with GORD-related eosinophilia and other pathologies that may also be associated with similar oesophageal eosinophilia, such as achalasia, hypereosinophilic syndrome, Crohn's disease, coeliac disease, vasculitis, pemphigus, graft-versus-host disease and other connective tissue disorders. The incidence of EOO is increasing, ranging from 0.7/100 000 to 10.7/100 000 depending on the population studied. It is predominantly a disease among the white population in Western countries (white versus non-white ratio, 3:1).

Showkat Ali Zargar, contemporary, gastroenterologist, Sher-i-Kashmir Institute of Medical Sciences, Srinagar, India.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

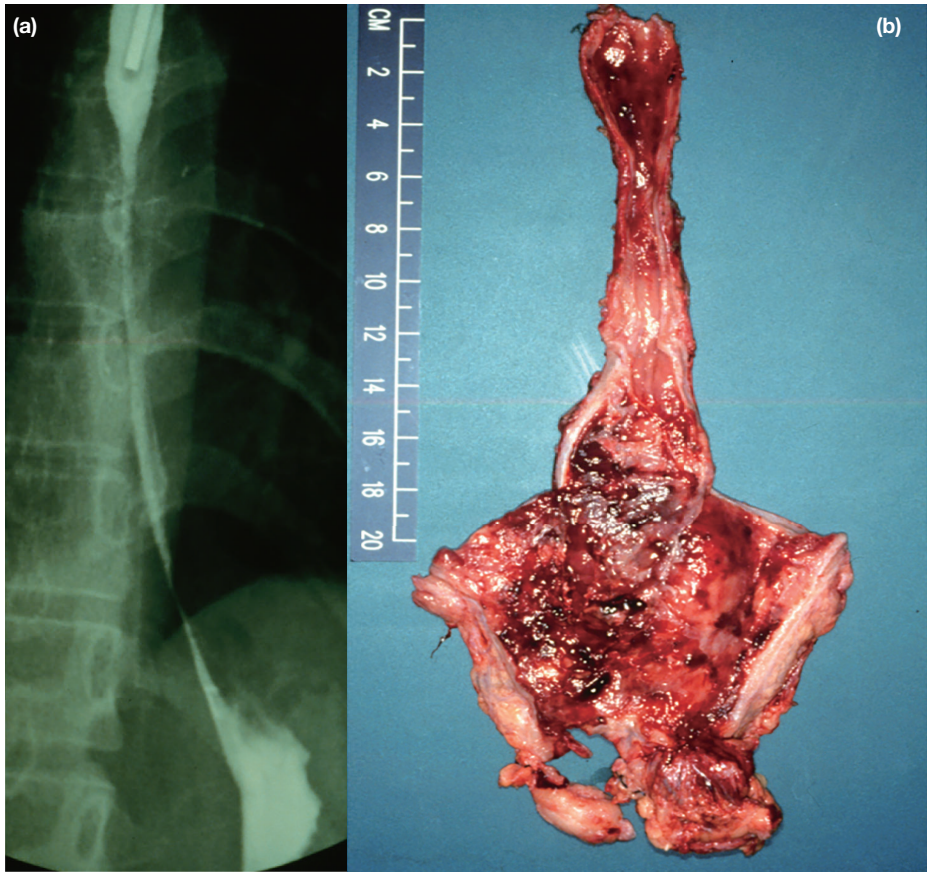

Figure 66.35 Contrast study showing a long undilatable stricture of the oesophagus secondary to caustic burn **(a)**. The patient underwent an oesophagogastrectomy and colonic interposition. Note that the oesophagus and the stomach were scarred **(b).**

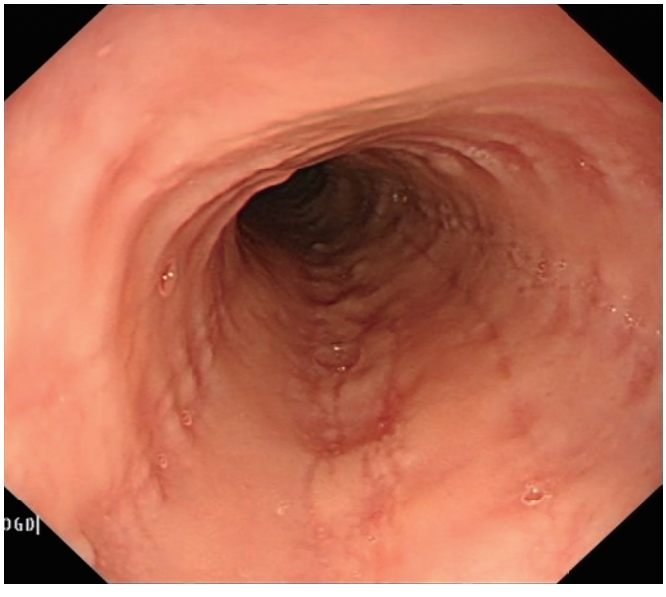

Figure 66.36 Endoscopic appearance of eosinophilic oesophagitis. The linear furrows and circular rings are evident.

EOO is believed to commence with food antigen initiation of cytokine-mediated signals that lead to eosinophilia, inflammation and subsequent remodelling by fibrosis. It is a progressive disease; thus, in infants or toddlers, it may present with irritability, food aversion and failure to thrive. In young children vomiting and regurgitation predominate. In older children or early adolescents, it may present with heartburn and dyspeptic symptoms, while in adults dysphagia and food impaction become the most common symptoms. The peak age of presentation is around 20–30 years. There is a clear association with other atopic disorders such as asthma, atopic rhinitis or dermatitis and food allergies.

Typical findings on endoscopy include the presence of rings, furrows, exudates, oedema, stricture, narrowing and 'crepe paper mucosa' (***Figure 66.36***). Biopsies of the oesophagus show 15 or more eosinophils per high-power field (hpf). The eosinophilic infiltration is isolated to the oesophagus. Biopsies should be taken at a minimum of two separate levels of the oesophagus together with suspicious areas. Usually gastric and duodenal biopsies are also taken to exclude eosinophilia at these sites. Barium contrast study may demonstrate narrowing and assess the diameter of the oesophagus better than endoscopy.

Treatment goals include reduction of oesophageal eosinophilia (to <15/hpf and preferably to <5/hpf), control of symptoms and normalisation of endoscopic findings, although these goals can only be completely achieved in a minority of patients. In children, the disease process is predominantly inflammatory, and associated symptoms such as nausea, vomiting and abdominal pain are relieved with appropriate medical treatments. In adults, reduction in inflammation per se may not relieve the fibrotic component (stricture and small-calibre oesophagus) and dilatation may be required.

Topical corticosteroids are the mainstay medical treatment for EOO; swallowing topically acting corticosteroids such as

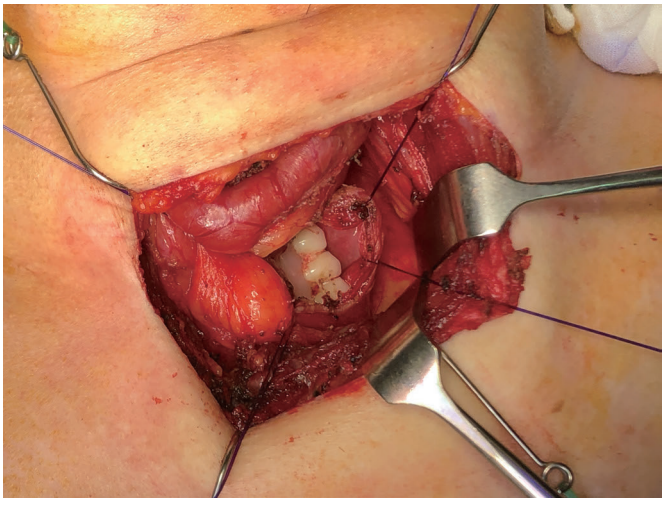

Figure 66.37 Open surgery was required to extract a broken denture stuck in the cervical oesophagus. The oesophagus was repaired in two layers.

budesonide or fluticasone is highly effective in resolving symptoms. Systemic steroids should be avoided. PPIs are effective in 40–50% of adults through blockage of cytokine release rather than acid suppression. Diet therapy is useful, eliminating gluten, milk, soy, egg, nuts and seafood as the most likely antigens.

Endoscopy is used for diagnostic purposes, to monitor treatment progress and therapeutically to deal with strictures. Careful gradual dilatations should be performed, although perforation rates appear similar to other types of strictures.

FOREIGN BODIES IN OESOPHAGUS

Swallowed foreign bodies are common and tend to impact at the three narrow portions of the oesophagus; namely, the cricopharyngeus/pyriform fossa, the midoesophagus where the aorta/left main bronchus crosses the oesophagus and at the OGJ. It is a common problem in children; in adults, it is more prevalent among the elderly with swallowing difficulties, those with dementia, those with unhealthy alcohol use and those with mental health disorders (***Figure 66.37***). Bones from fish, pork and chicken are common offenders. In complete obstruction, patients may not even be able to swallow fluids or their saliva.

A clear history may be volunteered, but in children, the elderly and those with mental health disorders the history may not be clear. Complaints should always be treated seriously even though they may sound implausible. A plain radiograph may reveal radio-opaque bodies and should be taken in two views. If in doubt, a CT scan is the best method to identify a foreign body.

Flexible endoscopy is the mainstay of treatment to extract using forceps, nets, baskets or a balloon inflated distal to the object. Airway protection may be needed. Sharp objects should be retrieved with the sharp end pointing distally to lessen the chance of perforation. An overtube can be used as needed. Batteries should always be removed as they may cause injury by direct electrical burn or by liquefactive necrosis from leaked battery content. A food bolus can usually be broken down and either retrieved or pushed into the stomach. Occasionally open surgery is required for foreign body retrieval.

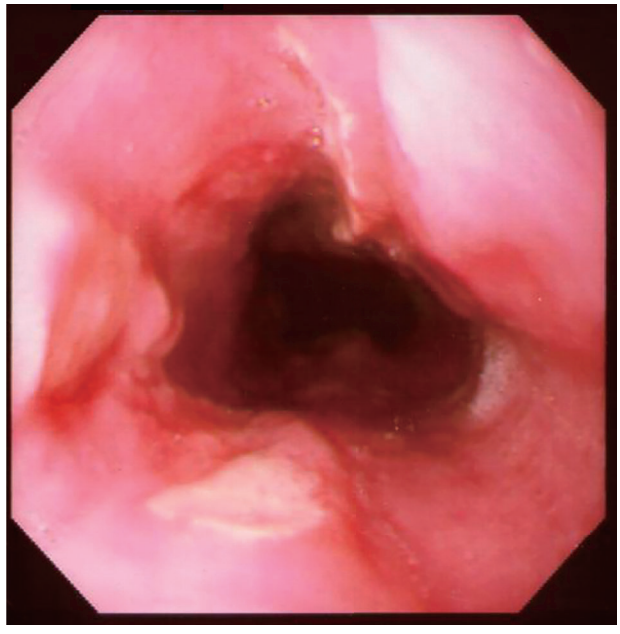

Figure 66.38 Pill-induced ulceration of the oesophagus. Note the 'kissing' ulcers on opposite sides.

Summary box 66.7

Foreign bodies

- Swallowed foreign bodies tend to lodge at the three relative constrictions of the oesophagus: the cricopharyngeus, where the left main bronchus crosses the oesophagus and at the OGJ
- Beware of underlying pathology, such as reflux stricture, eosinophilic oesophagitis and Schatzki's ring (see ***Miscellaneous conditions***)
- Flexible endoscopy can remove most foreign bodies successfully

OESOPHAGEAL ULCERATION/ INFECTIONS

GORD is the most common cause of oesophageal ulceration but there are a variety of other reasons, including iatrogenic related to endoscopic procedures, the presence of a nasogastric tube and medications such as tetracyclines, potassium chloride tablets, non-steroidal anti-inflammatory drugs and bisphosphonates. Typically, when a medication is lodged in the oesophagus there may be 'kissing' ulcers with ulceration on opposite sides of the oesophagus. Patients may present with odynophagia (***Figure 66.38***).

Infection of the oesophagus typically occurs in immunocompromised, elderly, debilitated or steroid-dependent patients. Candidiasis is the most common fungal infection, characteristically seen as adherent white pseudo-membranes

Richard Schatzki, 1901–1992, radiologist, Mount Auburn Hospital, Boston, MA, USA.

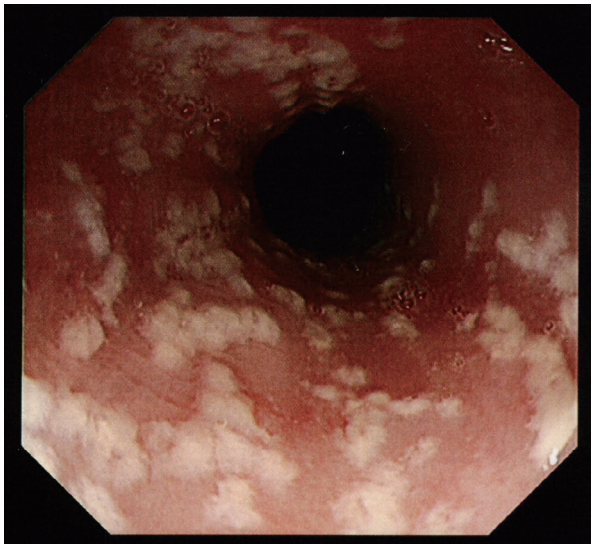

Figure 66.39 Oesophageal candidiasis.

(***Figure 66.39***). Viral infections include herpes simplex virus (HSV) or cytomegalovirus (CMV). HSV gives rise to punched-out ulcers with edges that appear vesicular, while CMV ulcers are more shallow. CMV inclusions can be found histologically. Special immunohistochemical stains are required to make the diagnosis. Tuberculous infection can also occur, such as bovine tuberculosis when infected unpasteurised milk is consumed. Treatment would depend on individual aetiology and underlying predisposing conditions.

OESOPHAGEAL INVOLVEMENT IN SYSTEMIC DISEASE

The oesophagus can be affected by a variety of systemic diseases; examples include systemic sclerosis/scleroderma, polymyositis, dermatomyositis, systemic lupus erythematosus and polyarteritis nodosa. Scleroderma most frequently affects women aged 40–65 years (female to male ratio, 8:2). The oesophagus is the most commonly affected part of the gastrointestinal tract, characterised by the excessive deposit of collagen, resulting in fibrosis. Symptoms are related to GORD (heartburn and regurgitation) as well as dysmotility (dysphagia and chest discomfort). On HRM the classical findings are poor oesophageal motility or even distal oesophageal aperistalsis (smooth muscle portion), with a hypotensive LOS. GORD can be severe because of the combination of dysmotility and hypotensive LOS, and complications such as peptic strictures and Barrett's oesophagus can be found in about one-third of patients. Management is directed at the control of GORD. PPIs remains the mainstay of treatment but standard doses may not be enough. Other medicines such as prokinetics and alginic acid may be added, though efficacy is limited. The results of surgical fundoplication are suboptimal because of poor oesophageal motility. Strictures are treated by standard endoscopic therapy.

Oesophageal varices

Oesophageal varices usually present with sudden, large-volume haematemesis secondary to portal hypertension, which is most commonly due to hepatic cirrhosis. Details of presentation and management can be found in ***Chapter 69***.

NEOPLASMS OF THE OESOPHAGUS

Benign pathologies

Benign epithelial lesions include papillomas, fibrovascular polyps, glycogen acanthosis, parakeratosis, lipomas, lymphangiomas and haemangiomas. They are benign, though parakeratosis is associated with malignancy of the oesophagus and head and neck region.

Inlet patches (also referred to as heterotopic gastric mucosa) are common and are most often found within a short distance of the postcricoid region (***Figure 66.40***). They consist of

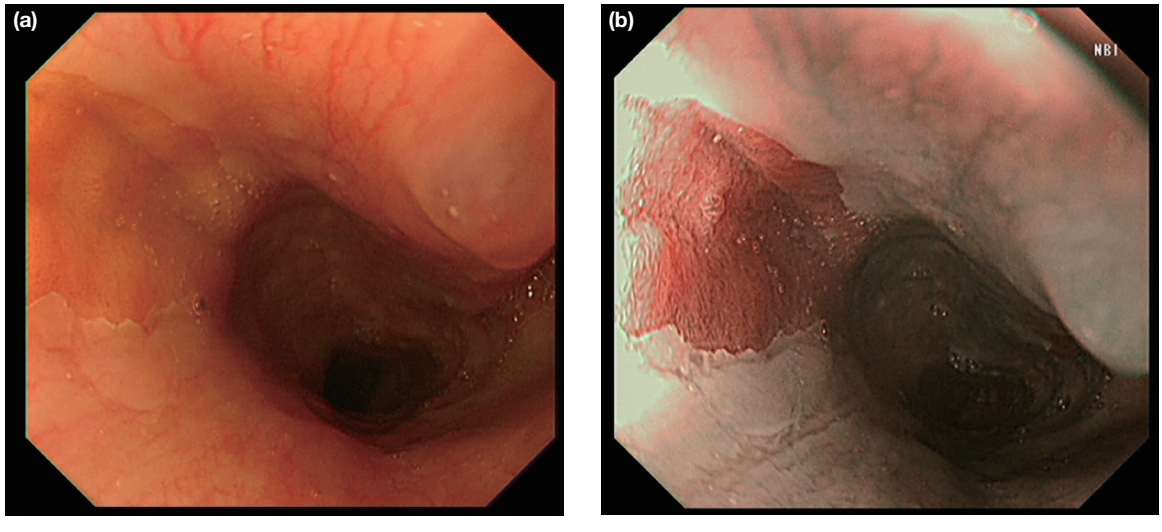

Figure 66.40 Inlet patch or heterotopic gastric mucosa in the upper oesophagus. **(a)** Inlet patch on white light endoscopy at 9–10 o'clock. **(b)** Using narrow-band imaging.

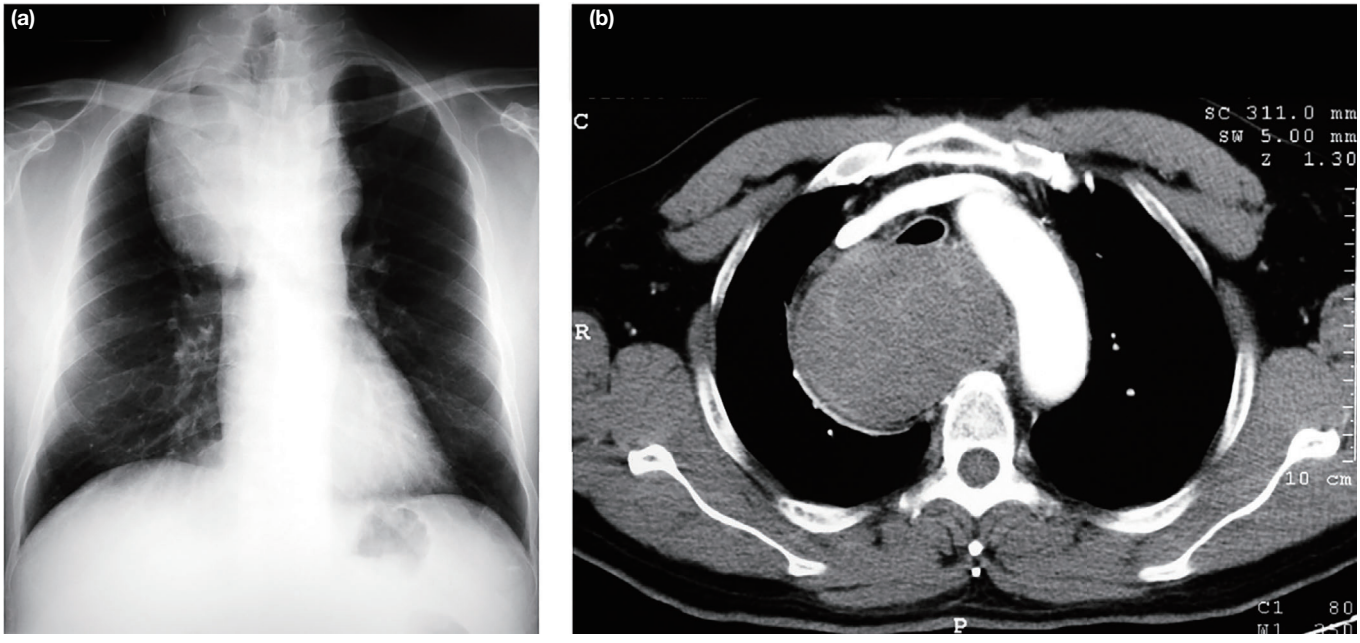

Figure 66.41 Large tumour of the upper oesophagus showing as an opacity on chest radiograph **(a)**. Computed tomography scan shows a homogeneous tumour causing tracheal compression **(b)**. The resected tumour was a Schwannoma.

embryonic gastric mucosa, though there are conflicting views as to whether they are truly embryonic or acquired in origin. The discovery of inlet patches is usually incidental on endoscopy. Biopsies will show corpus- or fundus-type gastric mucosa, sometimes even with parietal cells. Most are incidental and can be observed. An association with globus sensation, chronic cough and laryngopharyngeal reflux has been suggested. The patches can be ablated with RFA, argon plasma coagulation or multipolar electrocoagulation. Resolution of symptoms, however, is unpredictable.

Oesophageal duplication cysts are congenital anomalies that arise during early embryonic development. They are located within the oesophageal wall, covered by two muscle layers, and contain squamous epithelium or a lining compatible with that found in the embryonic oesophagus. Sometimes heterotopic gastric or pancreatic mucosa can be found. Most duplication cysts do not communicate with the oesophageal lumen, run parallel with the oesophagus and are asymptomatic unless large. Symptomatic duplication cysts can be resected.

Granular cell tumours are rare. On endoscopy they are typically sessile, yellowish-white and submucosal. They feel firm when prodded with a biopsy forceps. On EUS, they are hyperechoic and arise from the submucosal layer. They most likely arise from Schwann cells, suggesting a neural origin. Rarely they undergo malignant transformation. Schwannomas are often found incidentally; if large, surgical removal is indicated (***Figure 66.41***).

Leiomyomas are the most common solid benign tumours of the oesophagus (***Figure 66.42***). They are mostly found incidentally as a submucosal mass on endoscopy but may produce compressive symptoms when large. EUS shows a hypoechoic mass arising from the muscularis propria or the submucosal layer. They rarely become malignant; however, resection is indicated if enlarging on serial assessment. Small leiomyomas can be enucleated with a thoracoscopic approach, keeping the mucosa intact. Preoperative biopsy or EUS-guided fine-needle aspiration (FNA) is relatively contraindicated as the consequent scarring will increase the chance of breaching the mucosa during enucleation.

Endoscopic resection is possible using submucosal tunnelling endoscopic resection (STER); this creates a mucosal opening a short distance from the leiomyoma (3–5 cm proximally), allowing a submucosal tunnel to reach the lesion. The lesion is resected using ESD techniques and the specimen retrieved via the mouth. The mucosal opening is closed with clips (***Figure 66.43***). Because of the availability of STER, the threshold of removing smaller leiomyomas is reduced because of its minimal invasiveness. Larger lesions (perhaps larger than 5 cm) are technically challenging and are better removed thoracoscopically.

Leiomyosarcoma is rare and resection offers a chance of cure. Oesophageal gastrointestinal stromal tumours (GISTs) are uncommon and are usually found at the OGJ/proximal stomach. They should be managed along the same principles as GIST in the rest of the gastrointestinal tract.

Theodor Schwann, 1801–1882, physiologist, Berlin, Germany, later Leuven and Liège, Belgium.

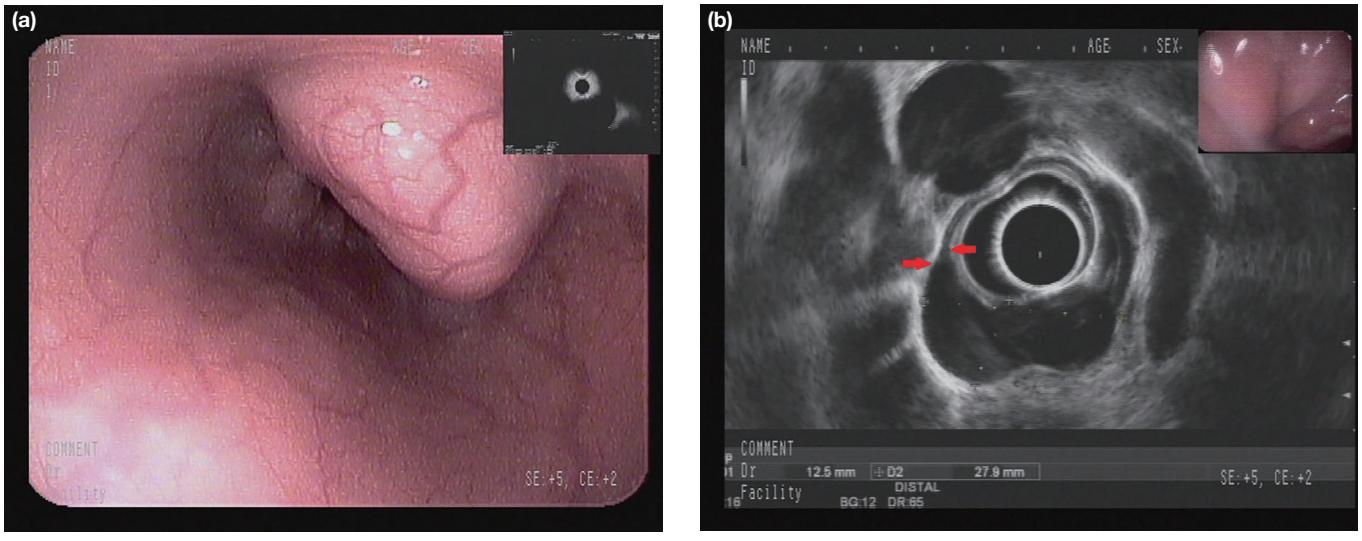

Figure 66.42 Leiomyoma of the oesophagus. **(a)** Endoscopic view of a submucosal lesion with intact mucosa. **(b)** Endoscopic ultrasound finding of a hypoechoic lesion arising from the muscularis propria layer (red arrows).

CARCINOMA OF THE OESOPHAGUS

Epidemiology

Oesophageal cancer is the eighth most common cancer worldwide and the sixth most common cause of cancer death. It most commonly presents in the sixth and seventh decades of life. Squamous cell carcinoma and adenocarcinoma are the most common cell types while other malignancies such as melanoma and small cell carcinomas are rare. Secondary malignancies are likewise rare; however, bronchogenic carcinoma or metastatic lymph nodes can invade the oesophagus.

Squamous cell cancer is the predominant histological cell type but there are significant geographical and ethnic variations, with the incidence of oesophageal cancer 50–100-fold higher in areas of high incidence than in the rest of the world. Squamous cell carcinoma incidence remains steady; however, among white populations, especially in developed Western countries, there has been an epidemiological shift since the 1990s from squamous cell carcinoma to adenocarcinoma such that the incidence of adenocarcinoma has surpassed that of squamous cell cancer.

Aetiology

The aetiological factors for the development of oesophageal cancer vary between the two main cell types (***Table 66.3***). Genetic predisposition may be important in the pathogenesis of oesophageal squamous cell cancer. While smoking and alcohol intake are independent contributing factors, genetic polymorphism is important in individuals with chronic alcohol consumption. Approximately 36% of East Asians show a physiological response to drinking that includes facial flushing, nausea and tachycardia. This facial flushing response is predominantly related to an inherited deficiency in the enzyme aldehyde dehydrogenase 2 (ALDH2). Alcohol is metabolised to acetaldehyde by alcohol dehydrogenase and the acetaldehyde is in turn metabolised by ALDH2 to acetate. Individuals with variants of the *ALDH2* gene may have a suboptimal level of the enzyme, leading to the accumulation of the carcinogen acetaldehyde.

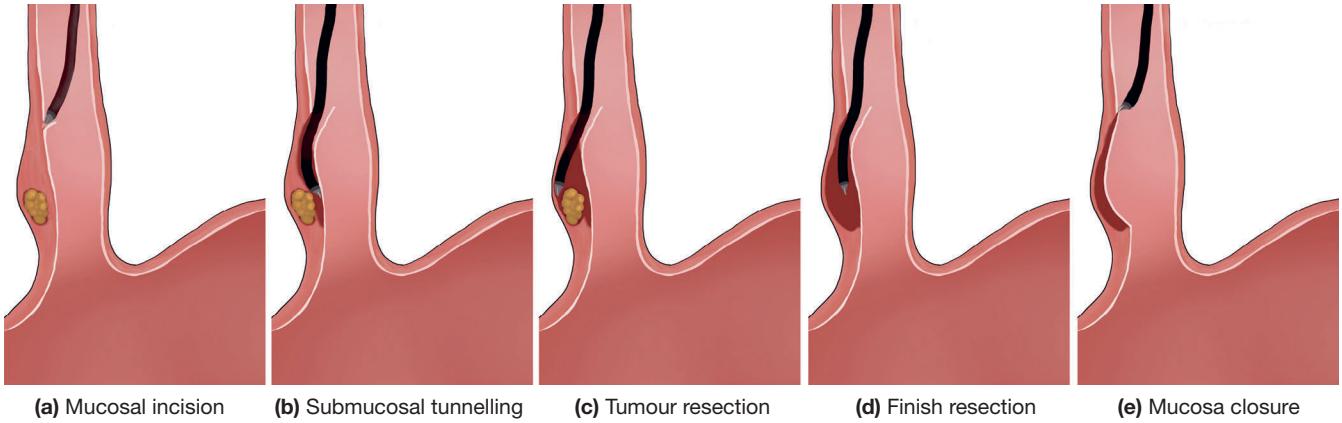

Figure 66.43 Submucosal tunnelling endoscopic resection (STER) technique to excise a leiomyoma.

TABLE 66.3 Aetiological factors for oesophageal cancer.

Factor	Squamous cell cancer	Adenocarcinoma
Smoking	+++	+
Alcohol	+++	–
Hot beverages	+	–
N-nitroso-containing food (e.g. pickled vegetables)	+	–
Chewing betel nut	+	–
Drinking yerba mate	+	–
Dietary deficiency of fresh green vegetables, fruits and vitamins	+	–
Low socioeconomic class	+	–
Fungal toxin or virus	+	–
History of radiation to mediastinum	+	+
Lye corrosive stricture	+	–
History of upper aerodigestive malignancy	+++	–
Plummer–Vinson syndrome	+	–
Achalasia	+	–
Obesity	–	++
Gastro-oesophageal reflux	–	+++
Barrett's oesophagus	–	++++

For squamous cell cancer, dietary and environmental factors are important. Nitrosamines and their precursors (nitrate, nitrite and secondary amines), commonly found in preserved food, such as pickled vegetables, have been identified as predisposing factors. Nutritional depletion of certain micronutrients, particularly vitamins A, C and E, niacin, riboflavin, molybdenum, manganese, zinc, magnesium and selenium, as well as dietary deficiencies of fresh fruit and vegetables, together with an inadequate protein intake, predisposes the oesophageal epithelium to neoplastic transformation. Other dietary risk factors include consumption of hot beverages, chewing betel nuts and drinking yerba mate in South American countries.

Patients with other aerodigestive malignancies are at particularly high risk, presumably because of exposure to similar environmental carcinogens. Using oesophageal cancer as the index tumour, multiple primary cancers are found in about 10% of patients, of which 70% are in the aerodigestive tract. The overall incidence of synchronous or metachronous oesophageal cancer in patients with primary head and neck cancer is estimated to be 3%.

The rise in incidence of adenocarcinoma coincides with the increase in obesity, GORD and Barrett's oesophagus in Western populations. GORD affects up to 44% of the general population in the USA and approximately 5–8% will develop Barrett's oesophagus, with an estimated annual rate of neoplastic transformation of 0.2–0.5% per year.

Pathology, clinical features and diagnosis

Oesophageal cancer has a poor prognosis, which is in part related to late presentation; patients with early disease have no symptoms and the cancer tends to metastasise early. Both squamous cell and adenocarcinoma develop from dysplastic mucosa. Most adenocarcinomas are mucin producing with intestinal-type features. Squamous cell cancers tend to be found in the middle and upper part of the oesophagus, while adenocarcinoma predominantly affects the lower oesophagus and OGJ. Both cell types may directly infiltrate adjacent organs and, depending on tumour location, can involve the trachea and bronchi (leading to haemoptysis, airway obstruction and even oesophagus–airway fistula), aorta (though aorto-oesophageal fistula is rare), diaphragmatic crura or pericardium.

The oesophageal wall has a rich network of submucosal lymphatics, and therefore longitudinal submucosal spread of cancer is common. Lymph node metastasis can involve the cervical area, the mediastinum as well as the perigastric/coeliac axis. Distant haematogenous spread can occur to non-regional lymph nodes, lungs, liver, brain and bones. Peritoneal metastasis is an important mode of spread of adenocarcinoma of the OGJ but is rare for squamous cell cancer.

Progressive dysphagia is the most common symptom, related to increasing luminal obstruction by cancer. Early symptoms may include a mild hold-up sensation that, if ignored, will progress from dysphagia to a solid, soft and eventually to a liquid diet. There may often be anorexia, weight loss, odynophagia and regurgitation symptoms. Hoarseness may indicate involvement of either recurrent laryngeal nerve. Aspiration and choking symptoms may be related not only to tumour obstruction but also to the presence of an oesophagus–airway fistula. Choking and cough on drinking water are typical of fistulation and associated haemoptysis is common. Blood loss is less common for squamous cell cancer than adenocarcinoma. Chronic blood loss can lead to iron deficiency anaemia. Acute gastrointestinal bleeding can occur, though it is rarely severe, except for aorto-oesophageal fistula, which usually presents with a smaller sentinel bleed followed by massive bleeding that is invariably fatal.

Early cancers are usually asymptomatic and are only picked up on endoscopy performed for other reasons, except in countries where a screening programme exists. For squamous cell dysplasia and cancer, chromoendoscopy using Lugol's iodine is a useful adjunct (***Figure 66.44***); the normal squamous mucosa will be stained brown, while dysplastic and early cancer remains unstained. NBI light consists of only two wavelengths: 415-nm blue light and 540-nm green light. The differential absorption and reflection of these spectra facilitates detection of mucosal abnormalities (see ***Chapter 9***). A classification of an intraepithelial papillary capillary loop (IPCL) system has been introduced to grade the severity of these early neoplastic changes (***Figure 66.45***).

For patients with advanced cancer, diagnosis is usually not difficult. A barium contrast study may demonstrate the tumour as an ulcerated or stenotic lesion with proximal

Yerba mate is a herbal tea made from the leaves and twigs of the *Ilex paraguariensis* plant.

dilatation (***Figure 66.46***). Endoscopy will visualise the tumour (***Figure 66.47***), allowing biopsies or brush cytology to confirm the histology. Attempts can be made to traverse the tumour stenosis. If significant dysphagia and weight loss are present, a nasogastric tube can be placed for nutritional build-up. The stomach is assessed for other pathologies in case it will be used to replace the oesophagus when oesophagectomy is performed.

Care should also be taken to assess the rest of the oesophagus, pharynx and larynx to ensure no synchronous tumours are present. The movement of the vocal cords should be assessed. For cancers of the mid- or upper oesophagus in proximity to the airway, a bronchoscopic examination is required to ensure no airway involvement, in which case oesophagectomy will be contraindicated (***Figure 66.48***).

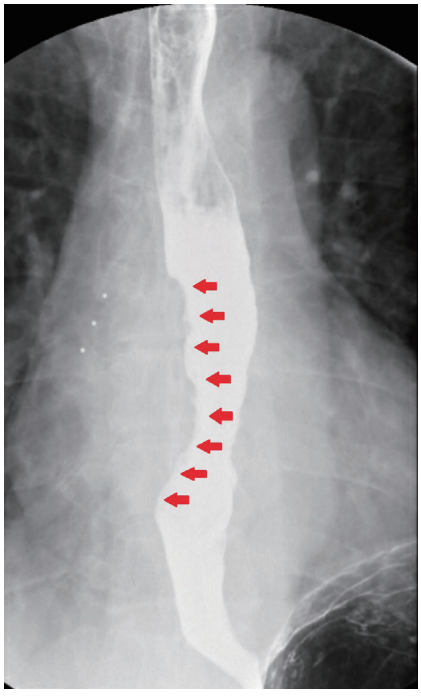

Figure 66.46 Barium contrast study showing midoesophageal cancer. Mucosal irregularity with mild luminal narrowing at the lower third of the oesophagus (arrows).

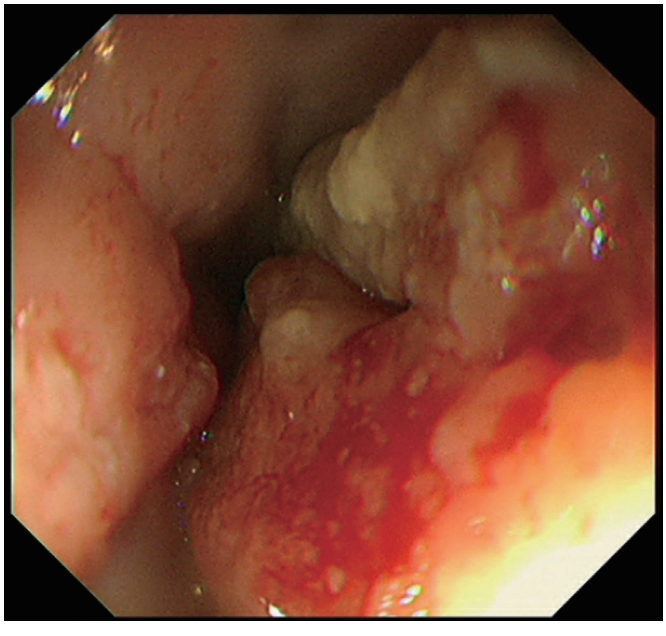

Figure 66.47 Endoscopic picture of an ulcerating cancer of the oesophagus.

Disease staging

Careful disease staging is essential to guide therapy. Current staging classification according to the American Joint Committee on Cancer (AJCC)/Union for International Cancer Control (UICC) (8th edition) is shown in ***Table 66.4***. The T stage advances as the tumour invades from mucosa deep to muscle, adventitia and beyond the oesophagus. Regional nodes

TABLE 66.4 TNM classification of oesophageal cancer.

T: Primary tumour	
Tx	Tumour cannot be assessed
T0	No evidence of primary tumour
Tis	High-grade dysplasia, defined as malignant cells confined to the epithelium by the basement membrane
T1	Tumour invades the lamina propria, muscularis mucosae or submucosa
	T1a: Tumour invades the lamina propria or muscularis mucosae
	T1b: Tumour invades submucosa
T2	Tumour invades the muscularis propria
T3	Tumour invades adventitia
T4	Tumour invades the adjacent structures
	T4a: Tumour invades the pleura, pericardium, azygos vein, diaphragm or peritoneum
	T4b: Tumour invades other adjacent structures, such as the aorta, vertebral body or airway
N: Regional lymph nodes[a]	
Nx	Regional nodal status cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one or two regional lymph nodes
N2	Metastasis in three to six regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes
M: Distant metastases	
M0	No distant metastasis
M1	Distant metastasis

[a]Regional nodes extend from the paratracheal/oesophageal nodes in the neck to the coeliac nodes.

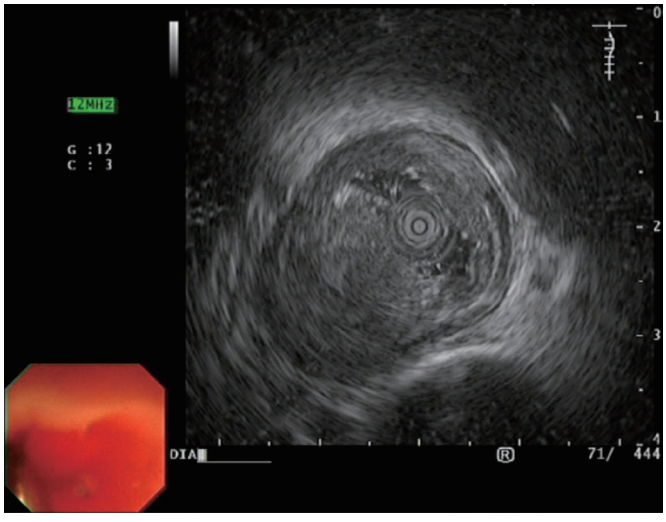

Figure 66.49 Endoscopic ultrasonography (EUS) picture of an oesophageal tumour. The layers of the oesophageal wall on EUS are obliterated. The tumour appears eccentric with extraoesophageal invasion (6 o'clock to 9 o'clock).

encompass the paratracheal nodes from the neck, through the mediastinum to the upper abdomen, including the coeliac nodes. The segregation of N1 to N3 is by the number of involved lymph nodes. Location is defined by the position of the epicentre of the tumour in the oesophagus (***Figure 66.1***). Stage groupings differ among squamous and adenocarcinomas. Separate groupings are assigned for clinical (cTNM), pathological (pTNM) and post-neoadjuvant (ypTNM) systems. Because of the complexity, these are not reproduced in this chapter but readers can refer to the staging manual.

Controversy exists as to whether adenocarcinoma of the OGJ should be staged as oesophageal or gastric cancer. According to the latest staging definitions, a tumour involving the OGJ with its epicentre no more than 2 cm into the gastric cardia is staged as adenocarcinoma of the oesophagus, while those with a centre located at more than 2 cm distal to the anatomical OGJ are staged as gastric cancer.

Endoscopic and percutaneous ultrasonography

The cT stage and paraoesophageal nodes are best staged using EUS. EUS is the only imaging modality able to distinguish the various layers of the oesophageal wall, usually seen as five alternating hyper- and hypoechoic layers using 12-MHz ultrasound (***Figure 66.49***). Infiltration to adjacent structures (cT4) is most accurately assessed. The accuracy of EUS for tumour and nodal staging averages 85% and 75%, respectively. The drawback is that many advanced cancers do not permit passage of a conventional echoendoscope, though most non-traversable tumours are likely to be at least cT3. Miniaturised ultrasonography catheter probes can be used to pass through the working channel of a conventional endoscope. EUS-guided FNA can be used to obtain cytological proof of involved lymph nodes. Bronchoscopic examination can assess airway involvement by the tumour. Percutaneous ultrasonography of cervical nodes is useful, as FNA can be obtained in the same setting.

Computed tomography scan

In diagnosing possible T4 cancer by CT scan, obliteration of the fat plane between the oesophagus and the aorta, trachea and bronchi, and pericardium is suggestive of invasion, but the paucity of fat in cachectic patients makes this criterion unreliable. Diagnosis of paraoesophageal nodes is less accurate than with EUS, but distant nodes are better assessed by CT scan.

Fluorodeoxyglucose–positron emission tomography scans

Squamous cell cancers are usually fluorodeoxyglucose (FDG) avid (***Figure 66.50***). Detection of the primary tumour is useful. Adenocarcinomas of the OGJ sometimes show limited or absent FDG accumulation regardless of tumour volume (FDG non-avidity). Positron emission tomography (PET) does not define the oesophageal wall and thus has no value in cT staging. Its spatial resolution is also insufficient to separate the primary tumour with juxtatumoral nodes because of interference from the primary cancer. It is mostly used for detecting regional and non-regional nodes, as well as distant metastases. The uptake by the tumour may have some prognostic value, and change in uptake after neoadjuvant treatment is similarly useful in predicting histological response and outcome.

Laparoscopy

Laparoscopic staging is useful in adenocarcinomas, especially those of the OGJ, but not for squamous cell cancer. Laparoscopy should be reserved for patients in whom confirmation of metastatic disease that is not otherwise obtainable is essential in deciding on treatment.

Treatment

Stage-directed therapy

Treatment principles depend on the disease stage and physiological reserve of patients. Patients should be discussed in a multidisciplinary team to decide on the best course of management. When distant metastatic disease is identified palliation is the aim.

Endoscopic treatment

The chance of nodal metastasis depends on the depth of infiltration of the primary tumour. Cancers that are confined to the mucosa (T1a) rarely metastasise, but squamous tumours that have infiltrated the submucosa (T1b) have a substantial risk of nodal spread. In adenocarcinoma, the corresponding risk is less. Such early cancers may be amenable to curative endoscopic treatment (***Figure 66.51***). EMR involves the injection of saline (or other solutions such as glycerol or hyaluronic acid) into the submucosal plane to raise the mucosal lesion; it is then sucked into a cap fitted onto the tip of the endoscope, looped by a snare wire and cut by electrocautery. The limitation of this method is the size of the cap, so it is generally recommended for smaller lesions. For larger lesions, if resected by EMR, piecemeal resection is required; therefore, it is associated with higher incomplete resection and recurrence rates. ESD is more complex. It involves first marking the margins

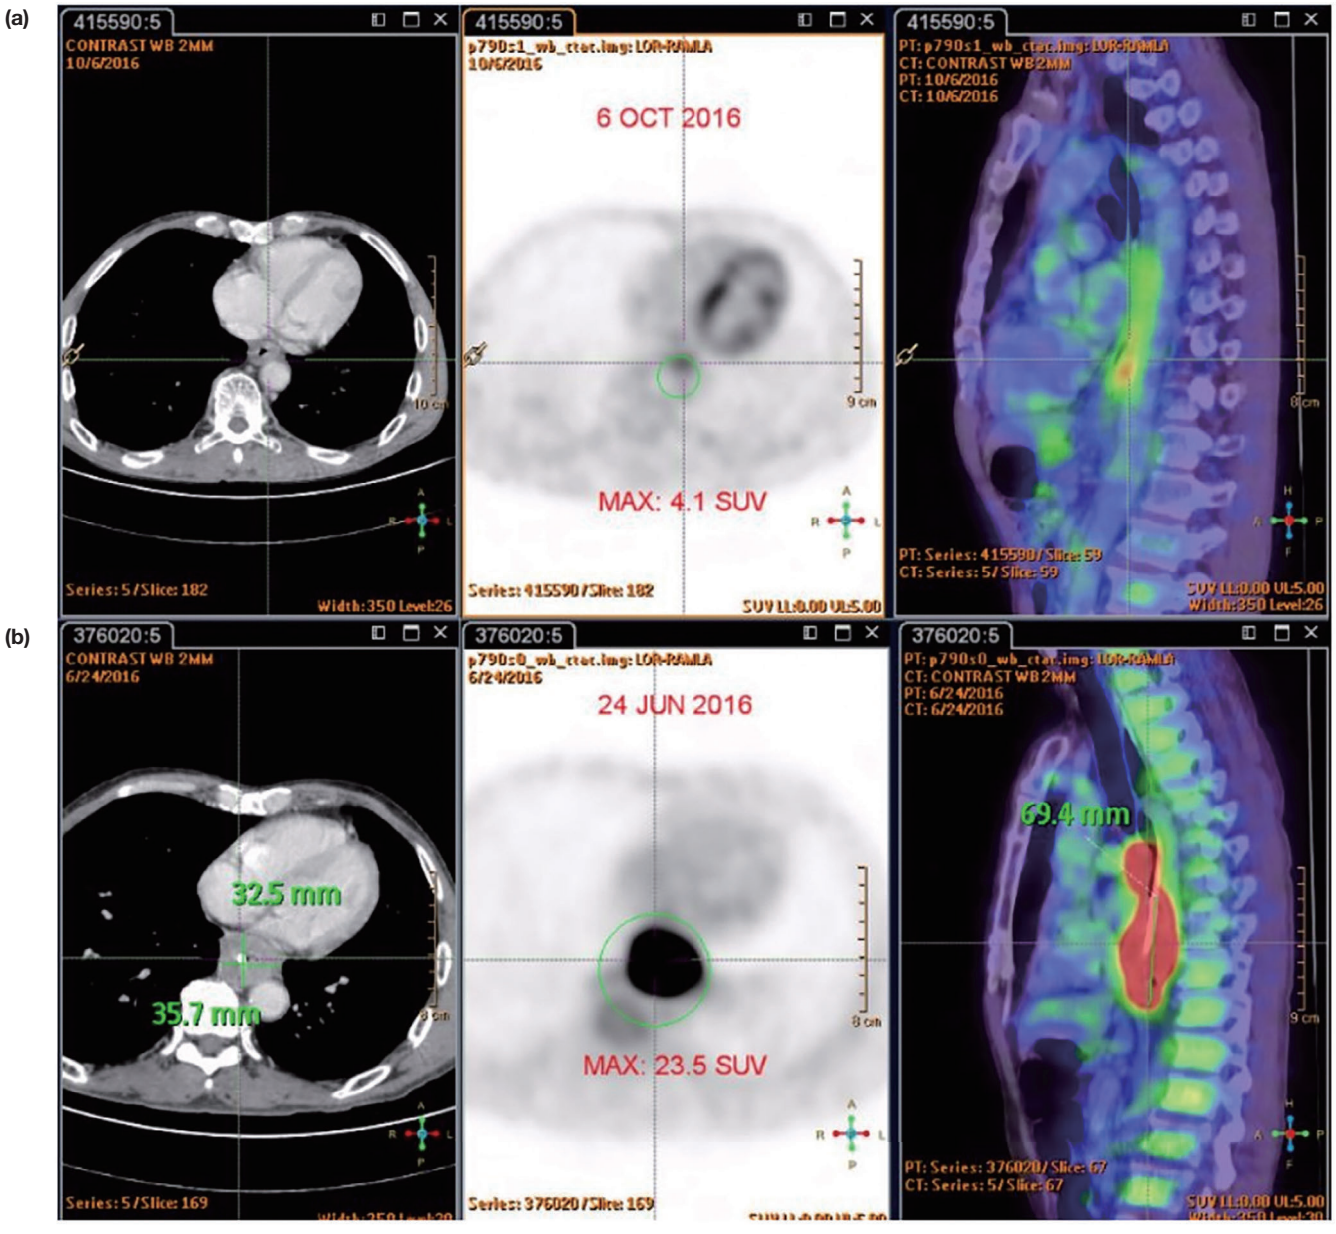

Figure 66.50 Positron emission tomography/computed tomography (CT) scan for staging of oesophageal cancer and assessment of response to neoadjuvant therapy. The patient underwent neoadjuvant chemoradiotherapy. The tumour had high fluorodeoxyglucose uptake (SUV_{max} 23.5) before treatment **(b)**. After chemoradiotherapy the SUV_{max} dropped to 4.1 with a corresponding reduction in size of the cancer seen on CT scan **(a)**.

of the lesion, then submucosal injection, cutting the mucosal edges along the line of marking, submucosal dissection of the tumour from its bed (superficial to the muscle layer) and lastly haemostasis. There are various 'knives' that can be inserted via the biopsy channel of the endoscope to carry out these procedures. Technically ESD is more demanding than EMR but is not limited by the size of the lesion for en bloc resection. There is an increased risk of postresection stricture formation if too much of the circumference of the mucosa (such as over two-thirds) is removed. This chance is somewhat reduced by steroid treatment (often endoscopic injection at the time of EMR/ESD, combined with oral medication for some time).

For early Barrett's cancer, EMR and ESD are options, and additional circumferential resection or ablation of the whole length of Barrett's mucosa can be done. For ablative therapy, RFA is most commonly used. RFA energy is delivered by the bipolar electrode and the energy causes frictional heating of cellular water molecules. After ablation, in the presence of a non-acid milieu (suppressed by a high-dose PPI), the epithelium would regenerate to be squamous cell mucosa. The advantage of RFA is that it is technically easy to operate but the drawback is that no surgical specimen for detailed histopathological examination is available. Other examples of ablative technique include cryotherapy or photodynamic therapy.

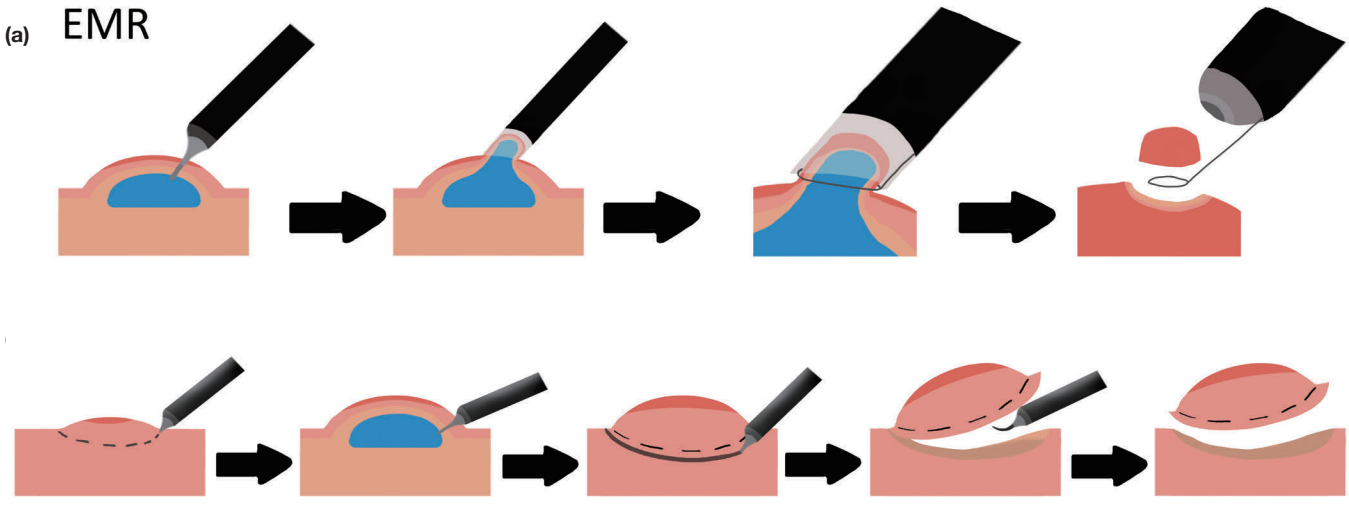

Figure 66.51 Schematic diagrams showing technique of **(a)** endoscopic mucosal resection – cap with submucosal injection and snare excision; **(b)** endoscopic submucosal dissection.

Because the pretreatment distinction of T1a and T1b disease may not be accurate, it may be prudent to perform endoscopic resection first in case of uncertain diagnosis. Should the resected specimen be found to be T1a with clear margins and without lymphovascular permeation in the pathological examination, the endoscopic treatment is deemed curative. If the tumour is found to be deeper than expected or if resection margins are not clear, further therapy can be planned.

Surgery

The primary indication for surgical resection is for potential cure, which can be achieved in patients whose tumours are confined to its wall and only limited local/regional disease is found. One should aim to maximise the chance of an R0 resection (macroscopic and microscopic clearance of proximal, distal and lateral margins), a parameter that has consistently been shown to result in the best long-term survival. Surgical resection alone is generally indicated for more advanced cancers when endoscopic treatment is unlikely to be curative (T1b, T2, N0). For patients with more advanced disease (≥T3, N+), multimodality treatment is usually preferred.

Patient selection and preparation

Oesophagectomy is a major procedure; patients should be assessed carefully for operative risk and their physiological status optimised. Cardiorespiratory assessments are essential. Patients must stop smoking and alcohol intake. Chest physiotherapy is instituted, and incentive spirometry is a good preoperative exercise. Patients with high-grade oesophageal tumour stenosis may have lost a substantial amount of weight. A fine-bore nasogastric tube can be placed for nutritional support while work-up is performed. Feeding jejunostomy is an alternative. Enhanced recovery after surgery (ERAS) programmes entail preoperative 'pre-habilitation' as well (***Table 66.5***). All measures are aimed to optimise patients for surgery. Immediate preoperative preparations include prophylactic antibiotics and deep vein thrombosis prophylaxis. Bowel preparation is not necessary unless a colonic interposition is intended.

Surgical techniques

Choice of surgical approach

The choice of the appropriate technique depends mainly on: (i) the location of the tumour, (ii) the intended extent of lymphadenectomy, and (iii) the reconstructive technique. The surgeon should be well versed in the methods adopted to different clinical situations. For ease of description, the following sections discuss the surgical approach by tumour location.

Cervical oesophageal cancer

Surgery involves removing the pharynx, larynx and oesophagus (pharyngo-laryngo-oesophagectomy); a gastric pull-up is used to anastomose with the neo-pharynx. In cases where involvement of the cervical oesophagus is limited, pharyngo-laryngo-cervical oesophagectomy can be carried out without the need for total oesophageal resection. The resultant gap can be bridged using either a free jejunal graft, or various musculocutaneous flaps. Definitive chemoradiotherapy has become the preferred alternative treatment to preserve the larynx. Surgery is therefore mostly reserved for salvage, when there is an incomplete response or for recurrent disease.

Intrathoracic oesophageal cancer

The surgical procedures usually performed are:

- Left thoracoabdominal incision. Via a large incision traversing the chest and upper abdomen, the whole left upper quadrant of the abdomen and left thoracic cavity are accessed at the same time for oesophagectomy, gastroplasty and anastomosis (***Figure 66.52a***).
- Lewis–Tanner (or Ivor Lewis) procedure. This is a two-phase oesophagectomy consisting of laparotomy for gastric mobilisation and tubularisation, followed by a right

Ivor Lewis, 1895–1982, surgeon, North Middlesex Hospital, London, later Rhyl, UK.
Norman Cecil Tanner, 1906–1982, surgeon, Charing Cross Hospital, London, UK.

TABLE 66.5 An enhanced recovery after surgery (ERAS) programme for oesophagectomy.

Preoperative	
Preoperative counselling	
Nutritional assessment	Nasogastric tube feeding for those with significant stenosis of the oesophagus, and oral supplement in those at risk of malnutrition
Preoperative exercise	General and incentive spirometry + pre-habilitation programme
Stop smoking and alcohol intake	
Chest physiotherapy	
Carbohydrate loading on day of surgery	No solid food 6 hours before and fluid 2 hours before surgery. Carbohydrate loading night before and finishes 2 hours before surgery
No need for bowel preparation unless colonic interposition is planned	
Intraoperative	
Prophylactic antibiotics	
DVT prophylaxis	Mechanical +/– pharmacological
Judicious use of intraoperative fluids	
Avoid hypothermia	
Minimally invasive surgery if possible	
Epidural analgesia	
Postoperative	
Nutrition	POD1 carbohydrate drink, gradual advancement to soft diet by POD5 (if no vocal cord palsy and assessment by speech therapist shows no risk of aspiration) PPN/TPN/feeding via jejunostomy in those at nutritional risk and oral intake insufficient
Nasogastric tube	Removal on POD1 (if no vocal cord palsy and assessment by speech therapist shows no risk of aspiration)
Analgesia	Epidural analgesia/patient-controlled analgesia/multimodal analgesia
Chest drain	Single closed small-calibre drain (19Fr Blake drain), removal POD3–4 when output <200–300 mL/day
Early mobilisation	From POD1, supervised by physiotherapist
Urinary catheter	Early removal as soon as close monitoring of urine output is not essential
Intravenous fluid	Balanced intravenous fluid to avoid over- and underhydration
DVT prophylaxis	

DVT, deep vein thrombosis; POD, postoperative day; PPN, peripheral parenteral nutrition; TPN, total parenteral nutrition.

thoracotomy for oesophageal resection. The gastroplasty is delivered into the right thoracic cavity for an oesophagogastrostomy near the apex of the chest (***Figure 66.52b***).

- McKeown or three-stage oesophagectomy. This consists of the mobilisation of the thoracic oesophagus and lymphadenectomy via a thoracotomy (usually right side), followed by abdominal and neck incisions for preparation of the oesophageal substitute (usually the stomach) and its delivery to the neck for a cervical anastomosis.
- Left thoracic resection (Sweet oesophagectomy). Via a single posterolateral incision on the left chest wall (usually fifth to sixth intercostal space), the oesophagus is mobilised. The diaphragm is opened and the gastroplasty prepared from this opening. The stomach is delivered to the left thoracic cavity for anastomosis.
- Transhiatal oesophagectomy. Through a cervical and abdominal approach, the oesophagus is mobilised via both directions, being stripped out bluntly from its mediastinal bed. The gastric conduit is delivered to the neck for cervical anastomosis (***Figure 66.53***).
- Minimally invasive surgical approaches. Traditional open procedures (described above) are increasingly replaced by minimally invasive methods, by a combination of video-assisted thoracoscopy (VATS) and laparoscopy or robotic techniques (***Figure 66.54***). Both thoracic and abdominal phases can be performed via minimally invasive techniques, or one phase can be minimally invasive and the other by open surgery (hybrid procedures). The anastomosis can be constructed in the chest or the neck.

Kenneth Charles McKeown, 1912–1995, surgeon, Darlington Memorial Hospital, Durham, UK.
Richard H Sweet, 1901–1962, surgeon, Massachusetts General Hospital, Boston, MA, USA.

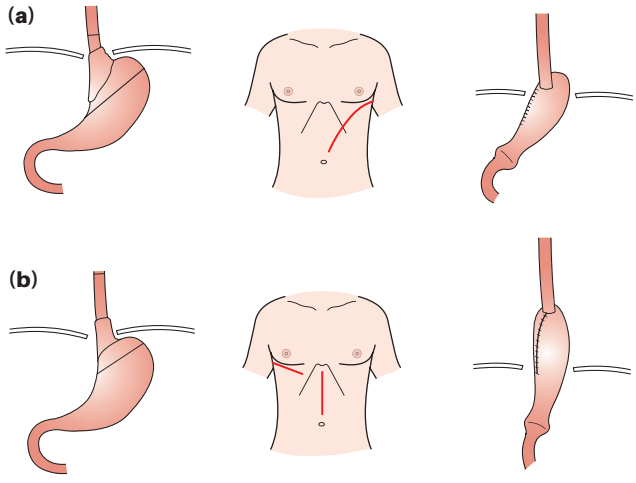

Figure 66.52 The common open approaches for surgery of the oesophagus: **(a)** left thoracoabdominal; **(b)** two-stage Lewis–Tanner (Ivor Lewis) approach. In the McKeown approach a third incision in the neck is made to allow anastomosis to the cervical oesophagus.

Oesophagogastric junction cancer

The options detailed above for intrathoracic cancers also apply to cancers of the OGJ. Suitability depends in part on the extent of oesophageal and gastric involvement by cancer and the intended extent of resection and lymphadenectomy. In addition, an extended total radical gastrectomy can be performed. The whole stomach and the lower oesophagus (accessed via the oesophageal hiatus from the abdomen) are resected and intestinal continuity is restored with a jejunal Roux loop (Roux-en-y reconstruction). In selected patients with early disease, a proximal gastrectomy can be performed as nodal spread to the distal stomach is rare.

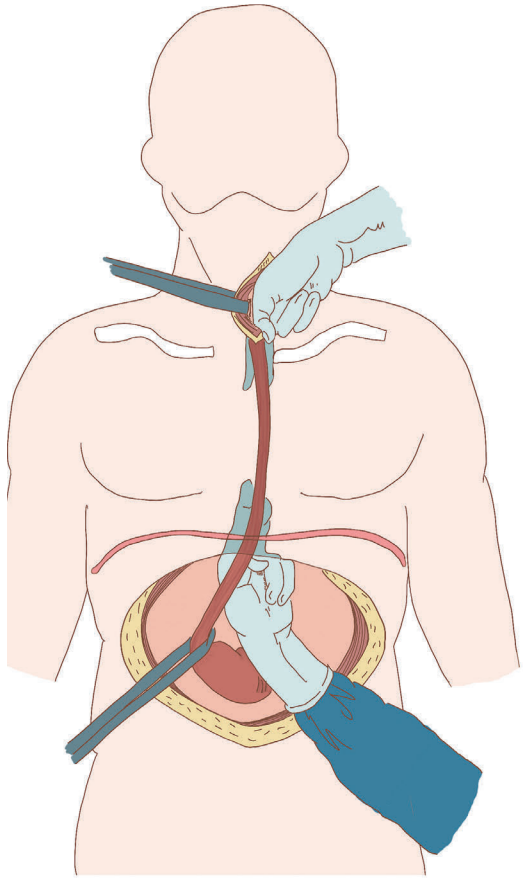

Figure 66.53 Transhiatal oesophagectomy whereby the oesophagus is mobilised blindly using fingers from the neck and hand inserted from the abdomen.

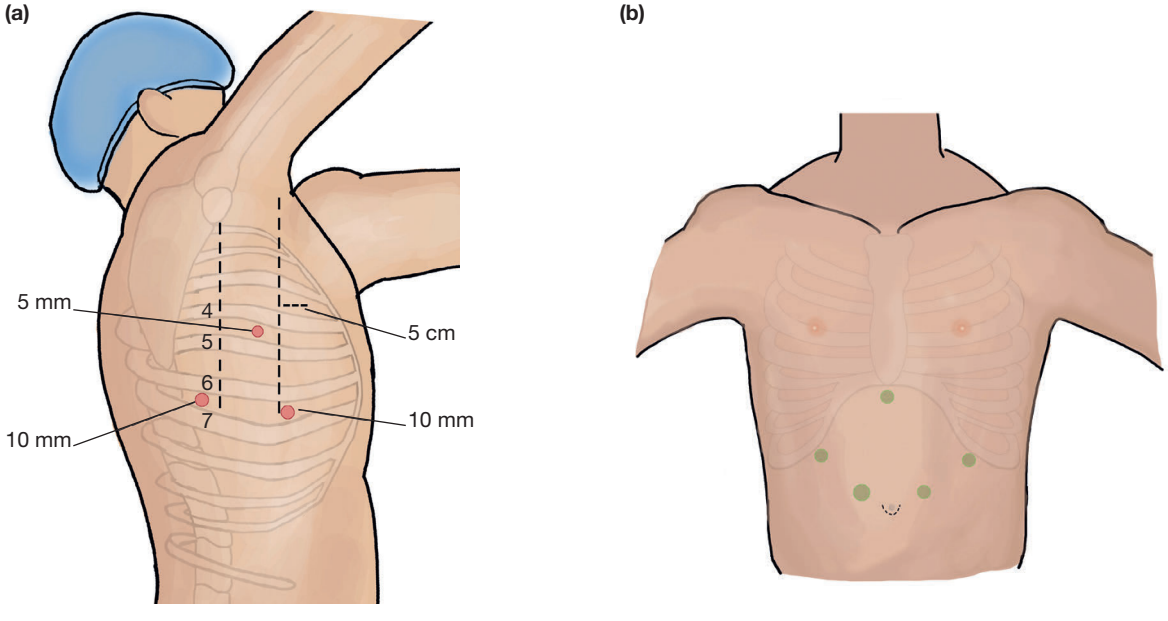

Figure 66.54 Port sites for video-assisted thoracoscopic oesophagectomy in the left lateral position **(a)** and laparoscopic gastric mobilisation **(b)**. Port sites can vary depending on the surgeon's preference.

César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

Extent of lymphadenectomy

Lymphadenectomy ensures adequate nodal sampling for staging, improves local disease control and increasingly there is evidence to show the prognostic impact of extended lymphadenectomy. The most appropriate extent of lymphadenectomy remains somewhat controversial. Transhiatal oesophagectomy does not allow adequate mediastinal nodal dissection (for the mid- and upper thoracic part oesophageal mobilisation is mostly a 'blind' procedure) and thus is often chosen by surgeons who perform only a limited lower mediastinal dissection for OGJ adenocarcinoma. Squamous cell cancers are mostly more proximally located and the transhiatal approach may be dangerous except in early cancers.

The extent of lymphadenectomy can be defined as 'fields'. Two-field dissection refers to lymphadenectomy of the mediastinum and upper abdomen around the coeliac trifurcation. The mediastinal 'field' is further classified as (i) standard: lymphadenectomy below the tracheal bifurcation, (ii) extended: standard lymphadenectomy plus right paratracheal nodal dissection including those around the right recurrent laryngeal nerve, and (iii) total: extended lymphadenectomy plus nodal dissection along the left recurrent laryngeal nerve chain (***Figure 66.55***). The third field refers to bilateral cervical lymphadenectomy, including those in the paratracheal as well as supraclavicular fossae.

The most appropriate extent of lymphadenectomy remains a contentious issue. For patients with squamous cell cancers, most surgeons would perform at least a total two-field lymphadenectomy since lymph node mapping data in Japan showed significant nodal metastases, especially around the bilateral recurrent laryngeal nerves. In selected patients and in particular those with upper thoracic cancers, additional third-field nodal dissection is performed (three-field lymphadenectomy). For oesophageal adenocarcinoma, most surgeons perform an infracarinal two-field lymphadenectomy. For OGJ tumours (in particular those with limited oesophageal extent and centre on the OGJ), surgeons are divided among those who prefer oesophagectomy and those who perform extended total gastrectomy with limited lower oesophageal resection and lymphadenectomy. The issue is unsettled. The extent of resection (and lymphadenectomy) has to be balanced against associated morbidities and physiological reserve of the individual patient.

Reconstruction

Restoration of intestinal continuity after oesophageal extirpation is mostly done using a gastric conduit. The right gastroepiploic vessels are its main blood supply. A pyloric drainage procedure is optional, with some surgeons advocating its use to facilitate gastric emptying, after the inevitable vagotomy. In the case of a previous gastrectomy, or if concomitant pathology (such as gastric cancer) requires its removal, the colon (right ileocolon, left or transverse colon) can be used. The surgery is more extensive and three anastomoses are required. The conduit can be placed in the right thoracic cavity (as in after a Lewis–Tanner oesophagectomy) or the neck for cervical

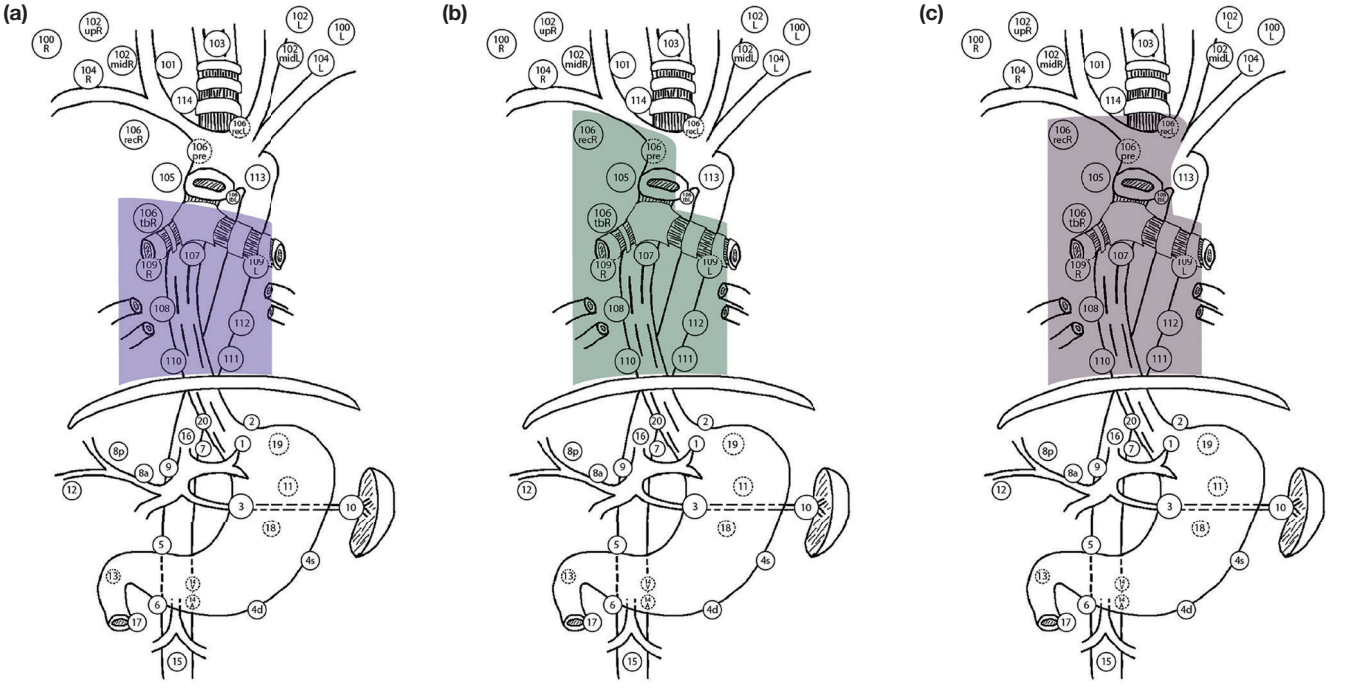

Figure 66.55 The lymph node station nomenclature according to the Japanese classification. Extent of mediastinal lymphadenectomy. **(a)** Standard mediastinal lymphadenectomy includes stations below the tracheal bifurcation. **(b)** Extended mediastinal lymphadenectomy includes standard lymphadenectomy + right paratracheal nodal dissection including those around the right recurrent laryngeal nerve. **(c)** Total mediastinal lymphadenectomy includes extended lymphadenectomy + left paratracheal area and nodes along the left recurrent laryngeal nerve. Two-field lymphadenectomy includes mediastinal dissection plus nodal dissection around the coeliac axis and three-field dissection includes cervical lymphadenectomy.

oesophagogastrostomy. In the case of a neck anastomosis, three choices of routes of reconstruction exist: posterior mediastinal, retrosternal or subcutaneous.

Perioperative care

For most patients, a standardised clinical pathway is helpful, along the lines of the ERAS protocol (***Table 66.5***). ERAS is a global perioperative quality improvement initiative based on attenuation of the stress response to surgical injury. The gastrointestinal system is central to many of the core ERAS elements, including carbohydrate loading, no prolonged fasting, avoidance of mechanical bowel preparation, avoidance of nasogastric intubation, maintaining fluid balance and early feeding. Employing these ERAS care practices leads to improved clinical outcome.

Management of complications

Complications are common as patients are often elderly with pre-existing morbidities and surgery is extensive. Atelectasis and pneumonia are managed by chest physiotherapy, adequate pain relief, avoidance of fluid overload, appropriate antibiotics and, if needed, sputum suction by bronchoscopy. Atrial fibrillation occurs in around 15–20% of patients; it is benign in most and is treated by antiarrhythmic medication. In some patients, it is a reflection of underlying serious complication, such as bronchopneumonia, or more importantly surgical morbidities, such as anastomotic leak or ischaemia of the conduit. Its occurrence should prompt appropriate investigations, such as endoscopy. Recurrent laryngeal nerve injury is not uncommon when superior mediastinal lymphadenectomy or neck nodal dissection is carried out. Postoperatively the patient will experience hoarseness of the voice, coughing becomes less effective and aspiration may be a problem when the diet is introduced. Active chest therapy and delay of oral intake may be necessary. Injection thyroplasty can temporarily improve glottic closure and coughing effort and lower the chance of aspiration. More definitive therapy may be needed if vocal cord function does not return.

Gross ischaemia of the conduit usually presents within the first 2–3 days after the operation and dictates taking down of the conduit, adequate drainage and staged reconstruction later once sepsis is under control (***Figure 66.56***). In selected cases immediate reanastomosis is an option if the patient is haemodynamically stable and an adequate length of healthy stomach remains.

Clinically apparent thoracic anastomotic leaks usually occur within the first week. Signs of sepsis and excessive output from the chest drain, which may be turbid in colour, may lead to the diagnosis. The location and magnitude of the leak can be visualised by a water-soluble contrast study. A carefully performed flexible endoscopic examination is also helpful and will not worsen the leak. For small, contained leaks, CT-guided drainage or use of a luminal vacuum Endo-Sponge™ may suffice. In septic patients with a sizeable leak, exploration is warranted to establish drainage. Direct repair is seldom possible.

For cervical anastomosis, leakage is suspected when there is inflammation and pain of the neck wound. Turbid infected discharge is found when the skin stitches are removed. Leaks that are truly confined to the neck are simply treated by laying the wound open with daily washing and frequent changes of dressing. Leaks that communicate with the mediastinum may require formal exploration and placement of mediastinal drains.

In all leaks, treatment with broad-spectrum antibiotics is required, guided by microbial culture and sensitivity. Nutritional support is essential. With an intrathoracic stomach, careful endoscopic placement of a fine-bore feeding tube into the duodenum for enteral feeding is useful. Injection of fibrin glue, placement of intraluminal stents, use of a luminal vacuum

Figure 66.56 (a) Cervical wound with erythema, swelling and discharge of purulent material, typical of a cervical anastomotic leak. **(b)** An ischaemic gastric conduit; 5 cm of the stomach appeared unhealthy and required resection.

Endo-Sponge™ or endoscopic clip closure of the defect are increasingly used to treat leaks; sealing of the leak allows early control of sepsis and resumption of oral alimentation. The stent can be removed afterwards, depending on the severity of the leak in the first place. Usually, 4–6 weeks will suffice for adequate healing.

A chylous leak is suspected when there is excessive chest drainage. A milk challenge, looking at the colour of the effluent before and after taking milk by mouth or via the nasogastric tube, will usually be obvious. This can be aided by biochemical testing of the drain fluid, measuring triglyceride level or chylomicrons. In a low-output fistula of less than 0.5–1 litre per day, conservative management with total parenteral nutrition or a mid-chain triglyceride diet may suffice. In case of persistence or if the output is more than 1 litre per day, prolonged conservative treatment is not recommended and early re-exploration is warranted. A lymphangiogram preoperatively will help locate the site of leakage, and intraoperative milk feed will also serve the same purpose. The site of the leak can then be clipped or sutured. Increasingly, however, the interventional radiological method of percutaneous embolisation has gained success and has reduced the need for surgical re-exploration.

Multimodality treatment strategies

Results from surgical resection alone have improved. Mortality from surgery is less than 5% in dedicated centres. The long-term prognosis remains suboptimal. Since the 1990s, multimodality treatment has gained impetus and is now routine for advanced disease. Neoadjuvant therapy is more popular than postoperative therapy, in the form of either neoadjuvant chemotherapy or chemoradiotherapy. In OGJ cancers, perioperative (pre- and postoperative chemotherapy) has advocates. The optimal regimen remains controversial. Recent advances in immunotherapy add to the armamentarium. Overall, after treatment in a multimodality programme, a 5-year survival rate of 40–50% is expected. The disease stage and the ability to perform an R0 resection are the most powerful predictors of outcome.

Palliation

In the presence of distant metastases, palliation is the aim. Dysphagia is the main symptom to relieve. Placement of a self-expanding metallic stent is simple and effective and allows immediate relief of dysphagia (***Figure 66.57***). The risks are stent migration, tumour ingrowth, airway compression and tracheal erosion if placed in the mid- and upper oesophagus. Other endoscopic methods, such as dilatation, laser treatment and photodynamic therapy, can be used.

Chemotherapy/radiotherapy/brachytherapy can help restore luminal patency; in case of bleeding from OGJ tumours, radiotherapy can be haemostatic. Immunotherapy has promise in selected patients.

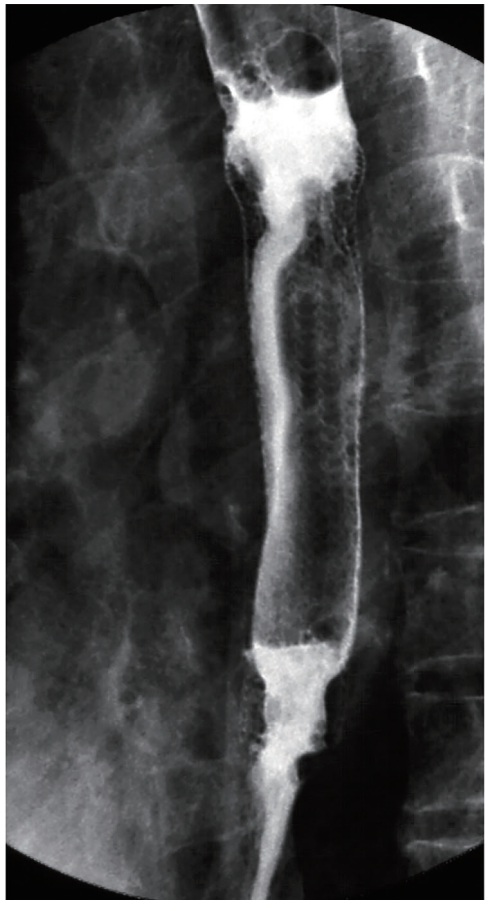

Figure 66.57 Self-expanding metallic stent in palliation of oesophageal cancer.

Summary box 66.8

Oesophageal cancer

- Squamous cell cancer still predominates in the East, while Barrett's adenocarcinoma is more common in the West
- Late presentation and early spread are reasons for poor prognosis
- Early diagnosis has the best chance of cure
- Lymphatic spread can be widespread, from the neck to the mediastinum and coeliac axis
- Adenocarcinomas around the OGJ are sometimes regarded as proximal gastric cancer and treatment is particularly controversial

MISCELLANEOUS CONDITIONS

Plummer–Vinson (in the USA) or Paterson–Brown-Kelly syndrome (UK) refers to the findings of a cervical oesophageal web, iron deficiency anaemia and dysphagia. It is also known as

Henry Stanley Plummer, 1874–1937, physician, Mayo Clinic, Rochester, MN, USA.
Porter Paisley Vinson, 1890–1959, surgeon, Mayo Clinic, Rochester, MN, USA.
Donald Ross Paterson, 1863–1939, ENT surgeon, Cardiff Royal Infirmary, Cardiff, UK.
Adam Brown-Kelly, 1865–1941, ENT surgeon, Victoria Infirmary, Glasgow, UK.

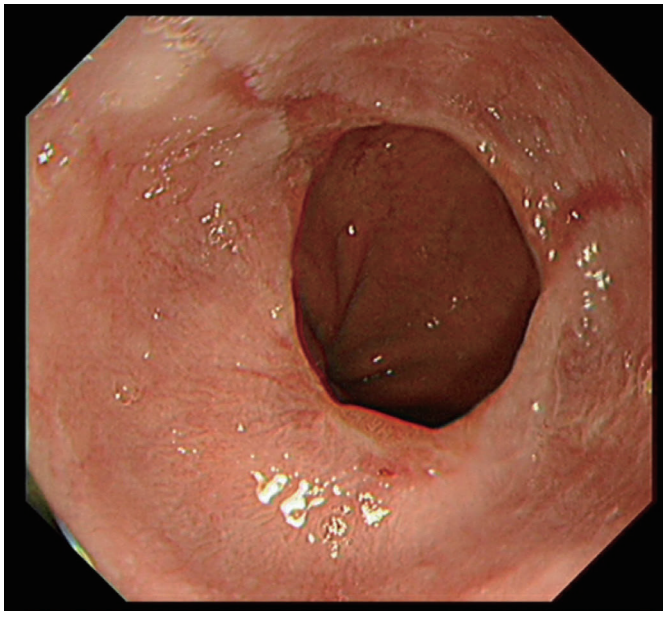

Figure 66.58 Schatzki's ring found on endoscopy. Note there is also oesophagitis.

sideropenic dysphagia. The pathophysiology remains elusive, and the association of iron deficiency is also controversial. Possible mechanisms include iron and nutritional deficiencies, genetic predisposition and autoimmunity. It is a rare disease, mainly affecting middle-aged women. There is a predisposition to postcricoid, cervical oesophageal cancer. A web is distinguished from a Schatzki's ring in that both the proximal and distal surfaces of the web are lined by squamous mucosa; in a Schatzki's ring, the proximal side is lined with squamous mucosa and the distal side by columnar mucosa, coinciding with its location at the squamocolumnar junction. Treatment is with iron therapy, diet modification and, if necessary, endoscopic dilatation of the cervical web.

A Schatzki's ring (also known as oesophageal B ring; an A ring is located a few centimetres proximal to the B ring, if found) is a mucosal band found at the squamocolumnar junction and is not an uncommon cause of food impaction in adults (***Figure 66.58***). Radiological studies using barium contrast by Schatzki demonstrated that, in individuals with a ring size of less than 13 mm, the symptom of dysphagia may occur. The exact aetiology of Schatzki's ring is uncertain but is believed to be related to GORD; hiatus hernia is more common. Treatment is by endoscopic dilatation if symptomatic with dysphagia.

PART 11 | Abdominal

CHAPTER 67

The stomach and duodenum

Learning objectives

To understand:

- The gross and microscopic anatomy and pathophysiology of the stomach and duodenum
- The critical importance of gastritis and *Helicobacter pylori* in upper gastrointestinal disease
- The causes of duodenal obstruction and the presentation of duodenal tumours

To be able to:

- Decide on the most appropriate investigation of patients with complaints relating to the stomach and duodenum
- Treat peptic ulcer disease and its complications
- Recognise the presentation of gastric cancer and understand the principles involved in treatment

INTRODUCTION

The stomach acts as a reservoir for ingested food, where it is mechanically broken down and the process of digestion begins before the ingested content passes into the duodenum.

ANATOMY OF THE STOMACH AND DUODENUM

Blood supply

Arteries

The stomach has an arterial supply on both the lesser and greater curves (***Figure 67.1***). On the lesser curve, the left gastric artery, a branch of the coeliac axis, forms an anastomotic arcade with the right gastric artery, which arises from the common hepatic artery. Branches of the left gastric artery pass up towards the cardia. The gastroduodenal artery, also a branch of the hepatic artery, passes behind the first part of the duodenum, which is highly relevant with respect to a bleeding duodenal ulcer. Here it divides into the superior pancreaticoduodenal artery and the right gastroepiploic artery. The superior pancreaticoduodenal artery supplies the duodenum and pancreatic head and forms an anastomosis with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The right gastroepiploic artery runs along the greater curvature of the stomach, eventually forming an anastomosis with the left gastroepiploic artery, a branch of the splenic artery. This vascular arcade, important during construction of a gastric conduit in oesophageal resection (see ***Chapter 66***), is often variably incomplete. The fundus of the stomach is supplied by the vasa brevia (or short gastric arteries), which arise from near the termination of the splenic artery.

Veins

In general, the veins accompany the arteries; those along the lesser curve drain into the portal vein and those on the greater curve drain into the splenic vein. On the lesser curve, the coronary vein is particularly important. It runs along the lesser curve towards the oesophagus and then passes left to right to join the portal vein. This vein becomes markedly dilated in portal hypertension.

Lymphatics

The lymphatics of the stomach are of considerable importance in surgery for gastric cancer and are described in detail in that section.

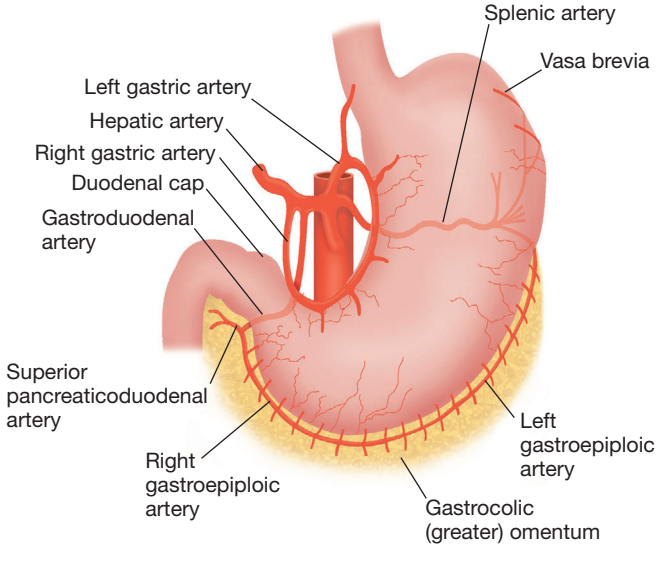

Figure 67.1 The arterial blood supply of the stomach.

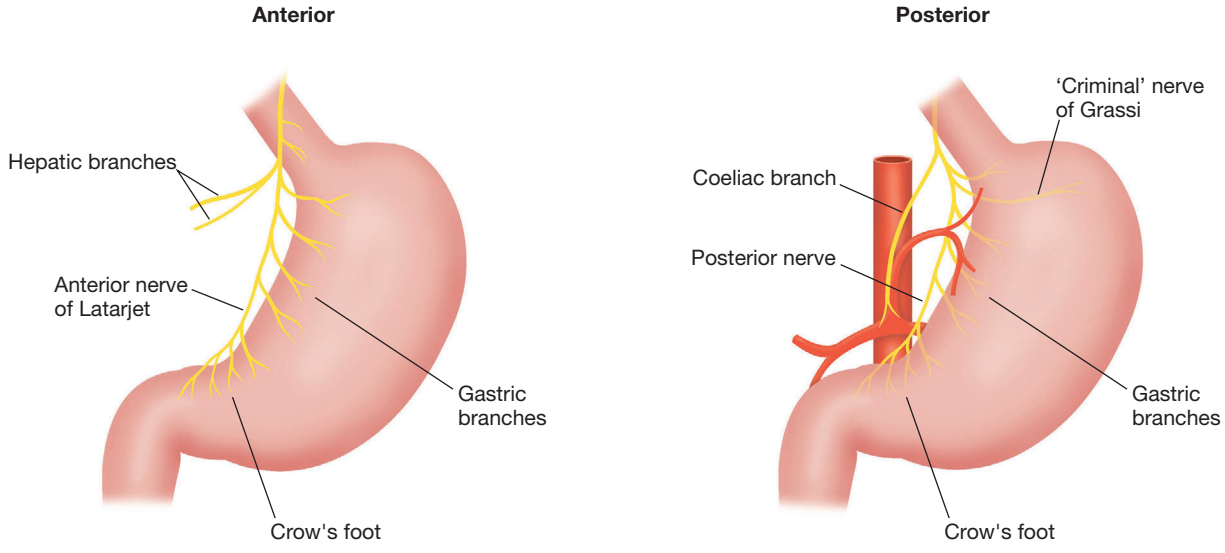

Figure 67.2 The anatomy of the anterior and posterior vagus nerves in relation to the stomach.

Nerves

The stomach and duodenum possess both intrinsic and extrinsic nerve supplies. The intrinsic nerves exist principally in two plexuses, the myenteric plexus of Auerbach and the submucosal plexus of Meissner. Compared with the rest of the gut, the submucosal plexus of the stomach contains relatively few ganglionic cells, as does the myenteric plexus in the fundus. However, in the antrum the ganglia of the myenteric plexus are well developed. The extrinsic supply is derived mainly from the vagus nerves (cranial nerve X), fibres of which originate in the brainstem. The vagal plexus around the oesophagus condenses into bundles that pass through the oesophageal hiatus (***Figure 67.2***), the posterior bundle being usually identifiable as a large nerve trunk. Vagal fibres are both afferent (sensory) and efferent. The efferent fibres are involved in the receptive relaxation of the stomach and the stimulation of gastric motility, as well as having the well-known secretory function. The sympathetic supply is derived mainly from the coeliac ganglia.

MICROSCOPIC ANATOMY OF THE STOMACH AND DUODENUM

The gastric surface epithelial cells are mucus producing. Mucus-secreting glands are found also in the duodenum. The specialised cells of the stomach (parietal and chief cells) are found in the gastric crypts (***Figure 67.3***). The stomach also has numerous endocrine cells.

Parietal cells

These are found in the body (acid-secreting portion) of the stomach and line the gastric crypts, being more abundant

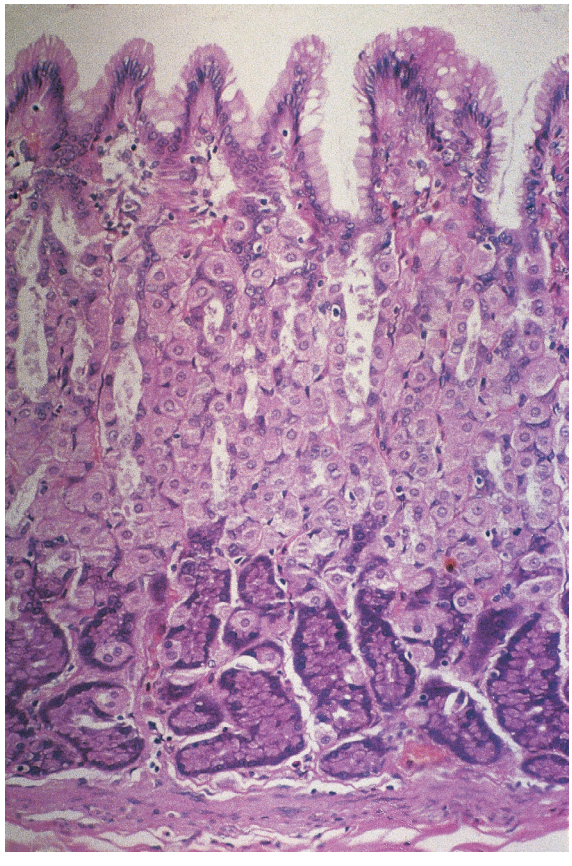

Figure 67.3 The histological appearance of a gastric gland. The mucus-secreting cells are seen at the mucosal surface, the eosinophilic parietal cells superficially in the glands and the basophilic chief cells in the deepest layer.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wrocław, Poland).
George Meissner, 1829–1905, Professor of Pathology, Gottingen, Germany.

Guiseppe Grassi, 1913–1980, surgeon, San Giovanni Hospital, Rome, Italy.

distally. They are responsible for the production of the hydrogen ions that form hydrochloric acid. The hydrogen ions are actively secreted by a hydrogen–potassium-ATPase proton pump, which exchanges intraluminal potassium for hydrogen ions. The potassium ions enter the lumen of the crypts passively, but the hydrogen ions are pumped against an immense concentration gradient (1 000 000:1). Proton pump inhibitors (PPIs) act by blocking the H^+/K^+ ATPase and thereby significantly reduce gastric acid secretion (see ***Gastric acid secretion***).

Chief cells

These lie proximally in the gastric crypts and produce pepsinogen. Two forms of pepsinogen are described: pepsinogen I and pepsinogen II. The ratio between pepsinogens I and II in the serum decreases with gastric atrophy. Pepsinogen is activated in the stomach to produce the digestive protease pepsin.

Endocrine cells

The stomach has numerous endocrine cells that are critical to its function. In the gastric antrum, the mucosa contains G cells, which produce gastrin. Throughout the body of the stomach, enterochromaffin-like (ECL) cells are abundant and produce histamine, a key factor in driving gastric acid secretion. In addition, there are large numbers of somatostatin-producing D cells throughout the stomach. Somatostatin has a negative regulatory role. The peptides and neuropeptides produced in the stomach are discussed in ***Gastric acid secretion***.

Duodenum

The duodenum is lined by a mucus-secreting columnar epithelium. In addition, Brunner's glands lie beneath the mucosa and are similar to the pyloric glands in the pyloric part of the stomach. Endocrine cells in the duodenum produce cholecystokinin and secretin.

PHYSIOLOGY OF THE STOMACH AND DUODENUM

The stomach mechanically breaks down ingested food and, together with the actions of acid and pepsin, forms chyme that passes into the duodenum. In contrast with the acidic environment of the stomach, the environment of the duodenum is alkaline, owing to secretion of bicarbonate ions from both the pancreas and the duodenum. This neutralises the acid chyme and adjusts the luminal osmolarity to approximately that of plasma. Endocrine cells in the duodenum produce cholecystokinin, which stimulates the pancreas to produce trypsin and the gallbladder to contract. Secretin is also produced by the endocrine cells of the duodenum. This hormone inhibits gastric acid secretion and promotes production of bicarbonate by the pancreas.

Summary box 67.1

Anatomy and physiology of the stomach

- The stomach acts as a reservoir for food and commences the process of digestion
- Gastric acid is produced by a proton pump in the parietal cells, which in turn is controlled by histamine acting on H_2-receptors
- The histamine is produced by the endocrine gastric ECL cells in response to a number of factors, particularly gastrin and vagus nerve stimulation
- PPIs abolish gastric acid production, whereas H_2-receptor antagonists only markedly reduce it
- The gastric mucous layer is essential to the integrity of the gastric mucosa

Gastric acid secretion

Secretion of gastric acid and pepsin tends to run in parallel, although the understanding of the mechanisms of gastric acid secretion is considerably greater than that of pepsin. Numerous factors are involved to some degree in the production of the gastric acid. These include neurotransmitters, neuropeptides and peptide hormones. This complexity need not detract from the fact that there are basic principles that are relatively easily understood (***Figure 67.4***). Hydrogen ions are produced in the parietal cell by the proton pump. Although numerous factors can act on the parietal cell, the most important of these is histamine, which acts via the H_2-receptor. Histamine is produced, in turn, by the ECL cells of the stomach and acts in a paracrine (local) fashion on the parietal cells. These relationships explain why PPIs can abolish gastric acid secretion, as they act on the final common pathway – hydrogen ion secretion. H_2-receptor antagonists have profound effects on gastric acid secretion, but this is not insurmountable. The ECL cell produces histamine

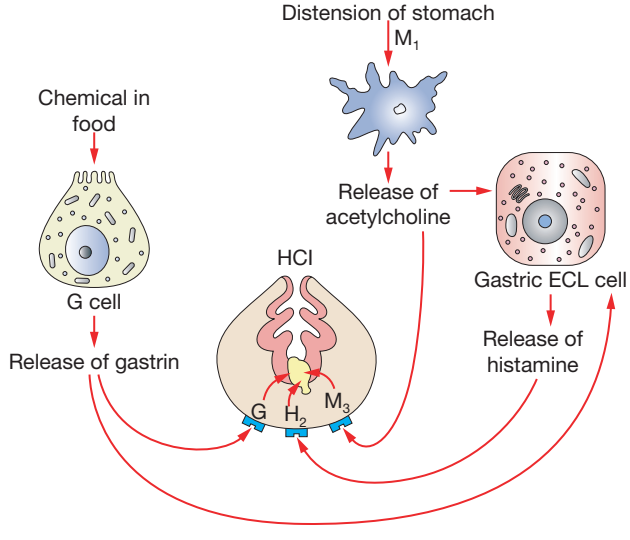

Figure 67.4 The parietal cell in relation to the mechanism of gastric acid secretion. ECL, enterochromaffin-like; G, gastrin receptor; H, histamine receptor; HCl, hydrochloric acid; M, muscarinic receptor.

in response to a number of stimuli, which include the vagus nerve and gastrin. Gastrin is released by the G cells in response to the presence of food in the stomach. The production of gastrin is inhibited by acid, creating a negative feedback loop. Various other peptides, including secretin, inhibit gastric acid secretion.

Classically, three phases of gastric secretion are described. The **cephalic phase** is mediated by vagal activity, secondary to sensory arousal as first demonstrated by Pavlov. The **gastric phase** is a response to food within the stomach, which is mediated principally, but not exclusively, by gastrin. In the **intestinal phase**, the presence of chyme in the duodenum and small bowel inhibits gastric emptying, and acidification of the duodenum leads to the production of secretin, which inhibits gastric acid secretion, along with numerous other peptides originating from the gut. The stomach also possesses somatostatin-containing D cells. Somatostatin is released in response to a number of factors, including acidification. This peptide acts probably on the G cell, the ECL cell and the parietal cell itself to inhibit the production of acid.

Gastric mucus and the gastric mucosal barrier

The gastric mucous layer is essential to the integrity of the gastric mucosa. It is a viscid layer of mucopolysaccharides produced by the mucus-producing cells of the stomach and the pyloric glands. Gastric mucus is an important physiological barrier that protects the gastric mucosa from mechanical damage and also the effects of acid and pepsin. It has considerable buffering capacity, enhanced by the presence of bicarbonate ions within the mucus. Many factors can lead to the breakdown of this gastric mucous barrier. These include bile, non-steroidal anti-inflammatory drugs (NSAIDs), alcohol, trauma and shock. Tonometry studies have shown that, of the entire gastrointestinal tract, the stomach is the most sensitive to ischaemia following a hypovolaemic insult and also the slowest to recover. This may explain the high incidence of stress ulceration in the stomach.

Peptides and neuropeptides in the stomach and duodenum

As with most of the gastrointestinal tract, the endocrine cells of the stomach produce peptide hormones and neurotransmitters. Previously, nerves and endocrine cells were considered distinct in terms of their products. However, it is increasingly realised that there is enormous overlap within these systems. Many peptides recognised as hormones may also be produced by neurones, hence the term neuropeptides. The term 'messenger' can be used to describe all such products. There are three conventional modes of action that overlap.

1. **Endocrine**. The messenger is secreted into the circulation, where it affects tissues that may be remote from the site of origin.
2. **Paracrine**. Messengers are produced locally and have local effects on tissues. Neurones and endocrine cells both act in this way.
3. **Neurocrine** (classical neurotransmitter). Messengers are produced by the neurone via the synaptic knob and pass across the synaptic cleft to the target.

Many peptide hormones act on the intrinsic nerve plexus of the gut (see ***Gastroduodenal motor activity***) and influence motility. Similarly, neuropeptides may influence the structure and function of the mucosa. Some of these peptides, neuropeptides and neurotransmitters are listed in ***Table 67.1***. The stomach is vital to regulation of appetite and weight control through a combination of mechanical and hormonal mechanisms (see ***Chapter 68***).

Gastroduodenal motor activity

The motility of the gastrointestinal tract is modulated by its intrinsic nervous system. Critical in this process is the migrating motor complex (MMC). In the fasting state, and after food has cleared, there is a period of quiescence in the small bowel lasting in the region of 40 minutes (phase I). There follows a series of waves of electrical and motor activity, also lasting about 40 minutes, propagated from the fundus of the stomach in a caudal direction at a rate of about three per minute (phase II). These pass as far the pylorus, but not beyond. Duodenal slow waves are generated in the duodenum at a rate of about 10 per minute, which potentiate into the small bowel. The amplitude of these contractions increases to a maximum in phase III, which lasts for about 10 minutes. This 90-minute cycle of activity is then repeated. From the duodenum, the MMC moves distally at 5–10 cm/min, reaching the terminal ileum after 1.5 hours.

Following a meal, the stomach exhibits receptive relaxation, which allows the proximal stomach to act as a reservoir. Most of the peristaltic activity is found in the distal stomach (the antral mill) and the proximal stomach demonstrates only tonic activity. The pylorus, which is most commonly open, contracts with the peristaltic wave and allows only a few millilitres of chyme to pass into the duodenum at a time. The antral contraction against the closed pylorus is important in the milling activity of the stomach. Although the duodenum is capable of generating 10 waves per minute, after a meal it only contacts after an antral wave reaches the pylorus. Coordination of the motility of the antrum, pylorus and duodenum means that only small quantities of food reach the small bowel at a time. This control of gastric emptying can be abolished after gastric surgery, leading to significant symptoms (discussed in ***Sequelae of peptic ulcer surgery***).

INVESTIGATION OF THE STOMACH AND DUODENUM

Flexible endoscopy

Flexible endoscopy is more sensitive than conventional radiology in the assessment of the majority of gastroduodenal

Ivan Petrovitch Pavlov, 1849–1936, Professor of Physiology, St Petersburg, Russia.

TABLE 67.1 Function and source of peptides and neuropeptides in the stomach.

Function	Source
Stimulate secretion	
Gastrin	G cells
Histamine	ECL cells
Acetylcholine	Neurones
Gastrin-releasing peptide	Neurones and mucosa
CCK	Duodenal endocrine cells
Inhibit secretion	
Somatostatin	D cells and neurones
Secretin	Duodenal endocrine cells

conditions, particularly peptic ulceration, gastritis and duodenitis. In upper gastrointestinal bleeding, endoscopy is far superior to any other investigation and offers the possibility of endoscopic therapy. In most circumstances it is the only investigation required.

It is generally a safe investigation, but it is important that all personnel undertaking these procedures are adequately trained. Careless and rough handling of the endoscope during intubation of a patient may result in perforations of the pharynx and oesophagus. Any other part of the upper gastrointestinal tract may also be perforated. An inadequately performed endoscopy is also dangerous as a serious condition may be overlooked. This is particularly the case in respect of early and curable gastric cancer, the appearances of which may often be extremely subtle and may be missed by inexperienced endoscopists. Spraying the mucosa with dye endoscopically may allow better discrimination between normal and abnormal mucosa, so allowing a small cancer to be more easily seen. In the future, advances in technology may allow 'optical biopsy' to determine the nature of mucosal abnormalities in real time (see ***Chapter 9***).

Summary box 67.2

Investigation of gastroduodenal symptoms

- Flexible endoscopy is the most commonly used and sensitive technique
- Great care is needed to avoid complications and missing important pathology
- Axial imaging, particularly multislice computed tomography (CT), is useful in staging gastric cancer
- Endoscopic ultrasonography is the most sensitive technique for evaluation of the 'T' stage of gastric cancer and assessment of duodenal tumours
- Laparoscopy is very sensitive in detecting peritoneal metastases, and laparoscopic ultrasound provides an accurate evaluation of lymph node and liver metastases

Upper gastrointestinal endoscopy can be performed without sedation, but when sedation is required incremental doses of a benzodiazepine are usually administered. Sedation is of particular concern in the case of gastrointestinal bleeding as it may have a more profound effect on the patient's cardiovascular stability. It has now become the standard to use pulse oximetry to monitor patients during upper gastrointestinal endoscopy, and nasal oxygen is often also administered. Hyoscine butylbromide (Buscopan) is useful to abolish duodenal motility for examinations of the second and third parts of the duodenum. Examinations of this type are best carried out using a side-viewing endoscope such as is used for endoscopic retrograde cholangiopancreatography.

Some patients are relatively resistant to sedation with benzodiazepines, particularly those who are accustomed to drinking alcohol. Increasing the dose of benzodiazepines in these patients may not result in any useful sedation, but merely make the patient more restless and confused. Such patients are better endoscoped fully awake using a local anaesthetic throat spray and a narrow-gauge endoscope. Whatever the circumstances, it is important that resuscitation facilities are available including agents that reverse the effects of benzodiazepines, such as flumazenil.

The technology associated with upper gastrointestinal endoscopy is continuing to advance. Instruments that allow both endoscopy and endoluminal ultrasonography to be performed simultaneously (see ***Ultrasonography***) are used routinely. Bleeding from the stomach and duodenum can be treated using a number of haemostatic measures, including injection with adrenaline (epinephrine), diathermy, heater probes, lasers and clip application.

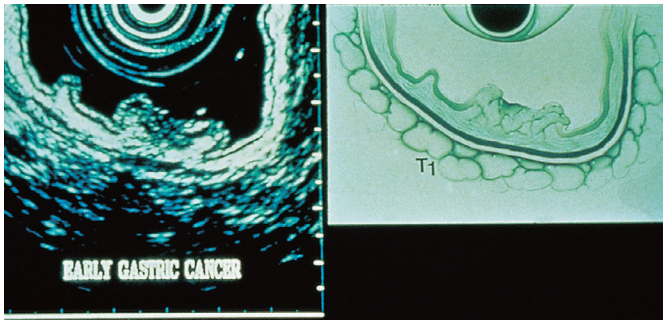

Figure 67.5 Endoscopic ultrasonography of the stomach. Five layers can be identified in the normal stomach. A gastric cancer is shown invading the muscle of the gastric wall (courtesy of KeyMed (Medical and Industrial Equipment Ltd)).

Contrast radiology

Upper gastrointestinal radiology is not used as much as in previous years, as endoscopy is a more sensitive investigation. Computed tomography (CT) imaging with oral contrast has replaced contrast radiology in many of the areas where anatomical information is sought, e.g. large hiatus hernias of the rolling type and chronic gastric volvulus. In these conditions it may be difficult for the endoscopist to determine exactly the anatomy or, indeed, negotiate the deformity to see the distal stomach (see ***Chapter 66***).

Ultrasonography

Standard ultrasonography can be used to investigate the stomach but used conventionally it is less sensitive than other modalities. In contrast, endoluminal ultrasonography and laparoscopic ultrasonography are probably the most sensitive techniques available in preoperative local staging of gastric cancer. In endoluminal ultrasonography, the transducer is usually attached to the distal tip of the instrument. Five layers (***Figure 67.5***) of the gastric wall may be identified on endoluminal ultrasonography and the depth of invasion of a tumour can be assessed (90% accuracy for the 'T' component of the staging). Enlarged lymph nodes can also be identified and the accuracy of the technique is about 80% in this situation. Laparoscopic ultrasonography is also a very sensitive imaging modality, to a large measure because of the laparoscopy itself (see ***Laparoscopy***).

Ultrasonography can be used to assess gastric emptying. Swallowed contrast that is designed to be easily seen using an ultrasound transducer is used. Emptying of the contrast is followed directly. The accuracy of the technique is similar to that of radioisotope gastric emptying studies (see ***Gastric emptying studies***).

Computed tomography scanning and magnetic resonance imaging

CT is increasingly used in the investigation of the stomach, especially in the context of gastric malignancies. Although it is much less accurate in 'T' staging than endoluminal ultrasonography (***Figure 67.6***), lymph node enlargement can be easily detected and is reasonably accurate in detecting nodal involvement with tumour. However it is important to understand that microscopic tumour deposits in lymph nodes cannot be detected and lymph nodes may undergo reactive enlargement but not contain tumour.

Hepatic metastases from gastric cancer may be difficult to identify as they are often of the same density as liver and may not handle the intravenous contrast differently. At present, magnetic resonance imaging (MRI) scanning does not offer any specific advantage in assessing the stomach, although it has a higher sensitivity for the detection of gastric cancer liver metastases than conventional CT imaging.

Computed tomography/positron emission tomography

Positron emission tomography (PET) is increasingly being used in the preoperative staging of gastro-oesophageal cancer as it will detect otherwise occult tumour spread in up to 10% of patients who might otherwise have undergone a major surgical resection (***Figure 67.7***). PET/CT may also be used to determine the response to neoadjuvant chemotherapy in oesophagogastric malignancies, although this is the subject of ongoing studies (see ***Chapter 8***).

Laparoscopy

Laparoscopy is routine in the assessment of patients with gastric cancer. Its particular value is in the detection of peritoneal disease, which is difficult by any other technique, unless the patient has ascites or bulky intraperitoneal deposits. The main limitation is evaluation of posterior extension but CT and endoluminal ultrasonography can provide this information. Samples are usually taken for peritoneal cytology unless laparotomy follows immediately.

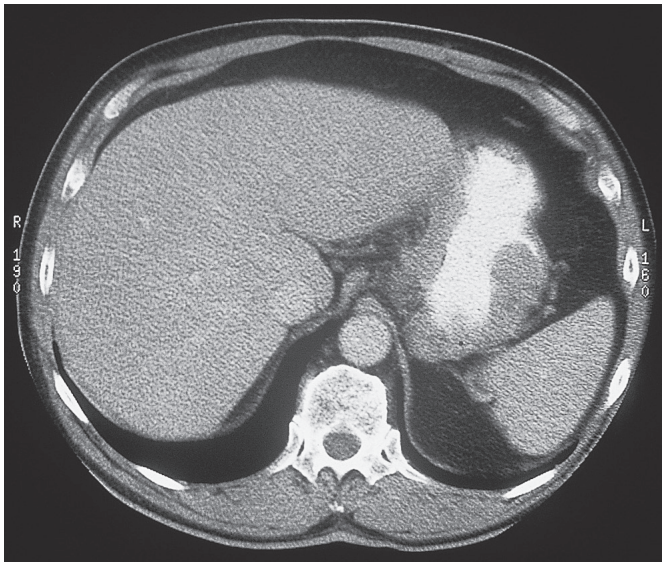

Figure 67.6 A computed tomography scan of the abdomen showing a gastric cancer arising in the body of the stomach.

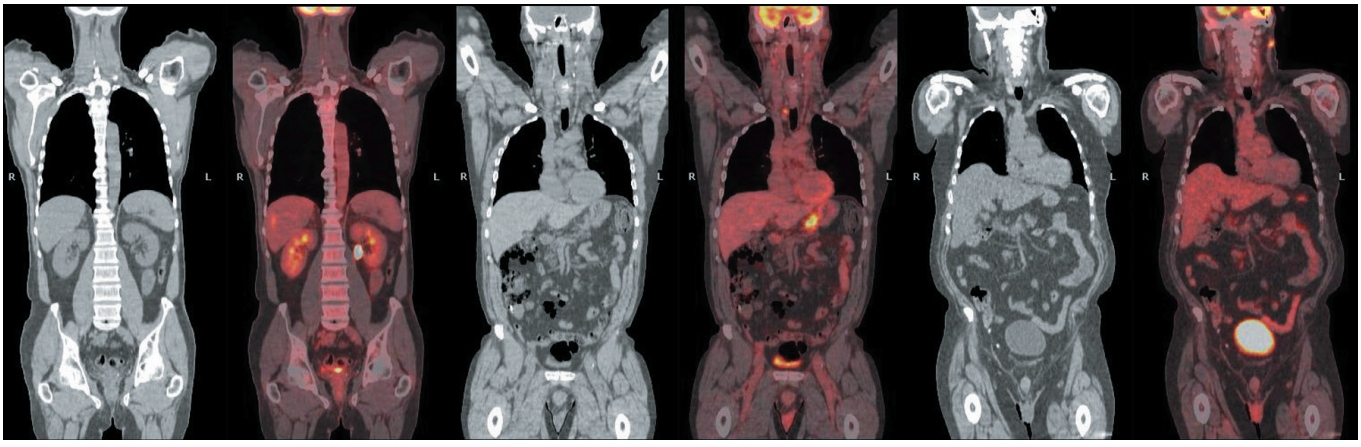

Figure 67.7 Computed tomography/positron emission tomography of a patient with gastric cancer. The middle pair of images shows the primary tumour. The two images on the left show unsuspected liver metastases, whereas the two on the right show a left cervical node positive for metastases.

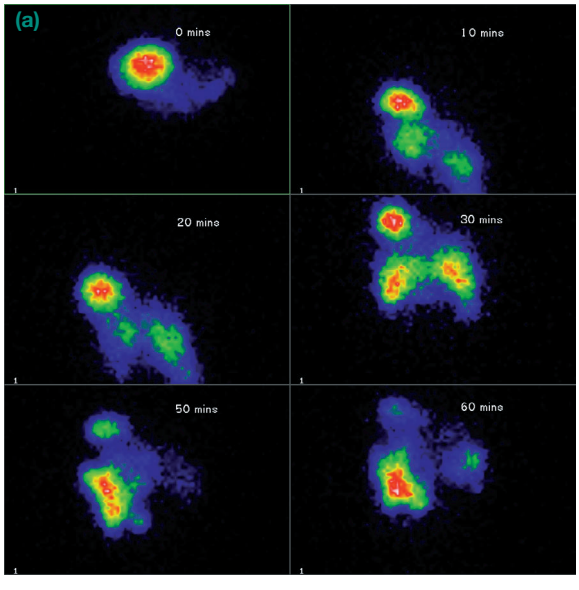
Gastric emptying studies



These are useful in the study of gastric dysmotility problems, particularly those that follow gastric surgery. The principle is that a radioisotope-labelled liquid and solid meal is ingested by the patient and emptying of the stomach is followed on a gamma camera. This allows the proportion of activity in the remaining stomach to be assessed. It is possible to follow liquid and solid gastric emptying independently (***Figure 67.8***).

Angiography

Angiography is used most commonly in the investigation of upper gastrointestinal bleeding not identified using endoscopy. Therapeutic embolisation may also be of value in the treatment of bleeding; in some centres, embolisation has replaced surgery in the majority of cases.

HELICOBACTER PYLORI

H. pylori is involved in the aetiology of a number of common gastroduodenal diseases, such as chronic gastritis, peptic ulceration and gastric cancer. Although Bizzozero identified the presence of spirochaetal organisms in gastric mucosa, it was not until the early 1980s that Warren and Marshall confirmed Koch's postulates with respect to *H. pylori* and gastritis. Both received the Nobel Prize in Medicine or Physiology in 2005.

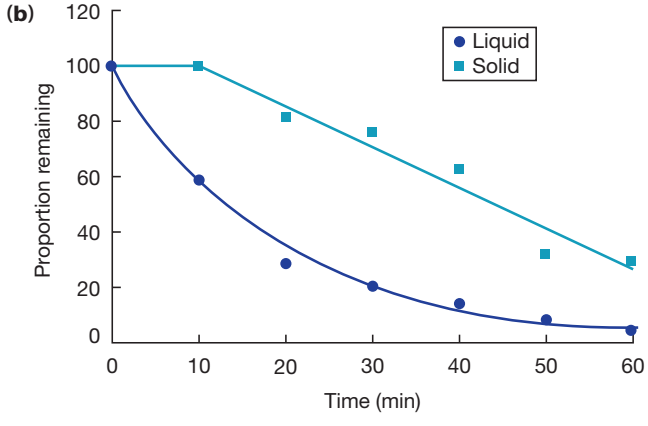


Figure 67.8 Dual-phase solid and liquid gastric emptying. The use of two isotopic labels allows the liquid and solid phases of the emptying to be followed separately. **(a)** Image acquisition. **(b)** Gastric emptying curves in a normal individual showing a typical lag period in the solid phase before linear emptying (courtesy of Dr V Lewington, Southampton, UK).

Giulio Bizzozero, 1846–1901, pathologist, University of Turin, Italy.
John Robin Warren, b. 1937, pathologist, Royal Perth Hospital, WA, Australia.
Barry Marshall, b. 1951, physician, University of Western Australia, WA, Australia.
Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, stated his 'postulates' in 1882 that define the conditions that must be met before an organism can be shown to be causative of a particular condition.

One of the characteristics of *H. pylori* is its ability to hydrolyse urea, resulting in the production of ammonia, a strong alkali. The effect of ammonia on the antral G cells is to cause release of gastrin via a negative feedback that is responsible for the modest, but inappropriate, hypergastrinaemia in patients with peptic ulcer disease, which, in turn, may result in gastric acid hypersecretion. The organism's obligate urease activity is utilised by various tests used to detect the presence of the organism, including the ^{13}C and ^{14}C breath tests and the CLO test (a commercially available urease test kit), which is performed on gastric biopsies. The organism can also be detected histologically (***Figure 67.9***), using the Giemsa or the Ethin–Starry silver stains, and cultured using appropriate media. Previous or current infection with the organism may also be detected serologically. Breath tests or faecal antigen tests are recommended for the pretreatment diagnosis of *H. pylori* infection in the community. Less accurate, hospital-based serology tests have a place within a non-invasive test-and-treat strategy.

Infection with *H. pylori* leads to disruption of the gastric mucous barrier by the enzymes produced by the organism, and the inflammation induced in the gastric epithelium is the basis of many of the associated disease processes. The association of the organism with chronic (type B) gastritis is not in doubt. Some strains of *H. pylori* produce cytotoxins, notably the Cag A and Vac A products. Production of cytotoxins seems to be associated with the ability to cause gastritis, peptic ulceration and gastric cancer. The effect of the organism on the gastric epithelium is to incite a classical inflammatory response that involves the migration and degranulation of acute inflammatory cells, such as neutrophils, and also the accumulation of chronic inflammatory cells, such as macrophages and lymphocytes.

It is evident how *H. pylori* infection results in chronic gastritis and also how this may progress to gastric ulceration, but for a while it remained unclear how the organism could be involved in duodenal ulceration, as the normal duodenum is not colonised. As mentioned above, the production of ammonia does increase the level of circulating gastrin and it has been shown subsequently that eradication of the organism in patients with duodenal ulcer disease will reduce the acid levels to normal.

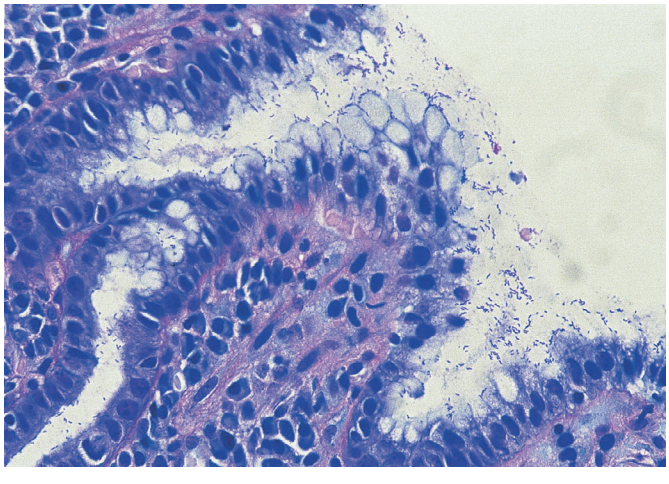

Figure 67.9 Antral mucosa showing colonisation with *Helicobacter pylori* (modified Giemsa stain).

However, the overlap in gastric acid secretion between normal subjects and those with duodenal ulcers is considerable and the modestly increased acid levels in patients with *Helicobacter*-associated antral gastritis are insufficient to explain the aetiology of duodenal ulceration.

The explanation can probably be found in the phenomenon of duodenal gastric metaplasia. Gastric metaplasia is the normal response of the duodenal mucosa to excess acidity. It can be thought of in the same way as any other metaplasia in the gastrointestinal tract: an attempt by the mucosa to resist an injurious stimulus. Although normal duodenal mucosa cannot be infected with *H. pylori*, gastric metaplasia in the duodenum is commonly infected and this infection results in the same inflammatory process that is observed in the gastric mucosa. The result is duodenitis, which is almost certainly the precursor of duodenal ulceration.

Infection with *H. pylori* may be the most common human infection. The incidence of infection within a population increases with age, and in many populations infection rates of 80–90% are not unusual. Up to 50% of the world's population may be infected with *Helicobacter*. It appears that most infection is acquired in childhood and the possibility of infection is inversely related to socioeconomic group. The means of spread has not been identified, but the organism can occur in the faeces and faecal–oral spread seems most likely. The organism is not normally found in saliva or dental plaque. There is evidence in different environments and in different population groups that the manifestations of the infection may be different. Predominantly antral gastritis, which is commonly seen in the West, results initially in increased levels of acid production and peptic ulcer disease, whereas gastritis affecting the body, common in the developing world, may lead to hypochlorhydria and gastric neoplasia.

It has been known since 1984 that *Helicobacter* infection is amenable to treatment with antibiotics. The profound hypochlorhydria produced by PPIs combined with antibiotics is also effective in eradicating the organism. Commonly used eradication regimes include a PPI and two antibiotics, such as metronidazole and amoxicillin. Very high eradication rates, in the region of 90%, can be achieved with combinations that include the antibiotic clarithromycin, although it may be that in the future antibiotic resistance will become a problem. Reinfection following successful eradication appears rare (<0.5%) but incomplete eradication is a more important clinical problem.

At present, eradication therapy is recommended for patients with duodenal ulcer disease, but not for patients with non-ulcer dyspepsia or in asymptomatic patients who are infected. However, recent data show that a proportion of patients with non-ulcer dyspepsia do respond to treatment. *H. pylori* is now classified by the World Health Organization as a class 1 carcinogen, and it may be that the further epidemiological studies on the risk of gastric cancer change current advice on treatment.

GASTRITIS

The great variety of names and classification systems used in gastritis is confusing. Thankfully, the understanding of gastritis has increased markedly following elucidation of the role of

H. pylori in chronic gastritis and there is broad agreement that gastritis should be classified according to the underlying aetiology. Gastritis describes any histologically confirmed inflammation of the gastric mucosa. In most modern classification systems, the amount of inflammatory infiltrate and the degree of gastric atrophy will be included.

Summary box 67.3

Helicobacter and gastritis

- *Helicobacter pylori* is critical in the development of gastritis, peptic ulceration and gastric cancer
- Infection appears to be acquired mainly in childhood and the infection rate is inversely associated with socioeconomic status
- Eradication, recommended specifically in patients with peptic ulcer disease, can be achieved in up to 90% of patients with a combination of a PPI and antibiotics, and reinfection is uncommon (<0.5%)
- Erosive gastritis is usually related to the use of NSAIDs
- Autoimmune gastritis is associated with development of pernicious anaemia and gastric cancer

Autoimmune gastritis

This is an autoimmune condition in which there are circulating antibodies to parietal cells that results in atrophy of the parietal cell mass, hence hypochlorhydria and ultimately achlorhydria. As intrinsic factor is also produced by parietal cells there is malabsorption of vitamin B_{12}, which, if untreated, may result in pernicious anaemia. The antrum is not affected; thus, hypochlorhydria leads to production of high levels of gastrin from antral G cells, resulting in chronic hypergastrinaemia with consequent hypertrophy of ECL cells in the body of the stomach not affected by autoimmune damage. Over time, microadenomas develop in the ECL cells, sometimes becoming identifiable tumour nodules that rarely can become malignant; endoscopic screening of such patients may be appropriate.

Helicobacter pylori gastritis

H. pylori gastritis, previously described as type B gastritis, affects the antrum and predisposes to peptic ulcer disease. *Helicobacter*-associated pangastritis is common, but gastritis affecting the corpus alone is not. Chronic pangastritis with atrophy is associated with intestinal metaplasia and has significant malignant potential when associated with dysplasia. Endoscopic screening may be appropriate.

Reflux gastritis

This is caused by enterogastric reflux. Its histological features are distinct from other types of gastritis. Although commonly seen after gastric surgery, it is occasionally found in patients with no previous surgical intervention or those who have had a cholecystectomy. Bile chelating or prokinetic agents may be useful in treatment and as a temporising measure to avoid revisional surgery that should be reserved for severe cases.

Erosive gastritis

This is caused by agents that disturb the gastric mucosal barrier; NSAIDs and alcohol are common causes. The NSAID-induced gastric lesion is associated with inhibition of cyclo-oxygenase type 1 (COX-1) receptor enzyme, reducing production of cytoprotective prostaglandins. Many of the anti-inflammatory activities of NSAIDs are mediated by COX-2 and use of specific COX-2 inhibitors reduces the incidence of gastritis.

Stress gastritis

This is a common sequel of serious illness or injury and is characterised by a reduction in the blood supply to the gastric mucosa. Although common, this is not usually recognised unless stress ulceration and bleeding supervene, in which case treatment can be difficult. Prevention is much easier than treating it, hence routine use of H_2 antagonists with or without barrier agents, such as sucralfate, in patients who are on intensive care. These measures have been shown to reduce the incidence of bleeding from stress ulceration.

Ménétrier's disease

This is an unusual condition characterised by gross hypertrophy of the gastric mucosal folds, mucus production and hypochlorhydria. The condition is premalignant and may present with hypoproteinaemia and anaemia. There is no treatment other than a gastrectomy. The disease seems to be caused by overexpression of transforming growth factor alpha (TGF-α). Like epidermal growth factor (EGF), this peptide also binds to the EGF receptor. The histological features of Ménétrier's disease may be reproduced in transgenic mice overexpressing TGF-α.

Lymphocytic gastritis

This type of gastritis is rare. It is characterised by the infiltration of the gastric mucosa by T cells and is probably associated with *H. pylori* infection. The pattern of inflammation resembles that seen in coeliac disease or lymphocytic colitis.

Other forms of gastritis

Eosinophilic gastritis appears to have an allergic basis and is treated with steroids and cromoglycate. Granulomatous gastritis is seen rarely in Crohn's disease and also may be associated with tuberculosis. Acquired immunodeficiency syndrome (AIDS) gastritis is secondary to infection with cryptosporidiosis. Phlegmonous gastritis is a rare bacterial infection of the stomach found in patients with severe intercurrent illness. It is usually an agonal event.

Pierre Eugène Ménétrier, 1859–1935, pathologist, Paris, France.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932 along with Leon Ginzburg and Gordon Oppenheimer.

PEPTIC ULCER

Although the name 'peptic' ulcer suggests an association with pepsin, this is essentially unimportant as, in the absence of acid, peptic ulcers do not occur. Nearly all peptic ulcers can be healed by using PPIs, which can render a patient virtually achlorhydric.

Common sites for peptic ulcers are the first part of the duodenum and the lesser curve of the stomach, but they also occur on the stoma following gastric surgery, in the oesophagus and even in a Meckel's diverticulum, which contains ectopic gastric epithelium. In general, the ulcer occurs at a junction between different types of epithelia, in the epithelium least resistant to acid damage.

In the past, much distinction has been made between acute and chronic peptic ulcers, but this difference can sometimes be difficult to determine clinically. It is probably best to consider that there is a spectrum of disease from the superficial gastric and duodenal ulceration, frequently seen at endoscopy, to deep chronic penetrating ulcers. This does not minimise the importance of acute stress ulceration. These ulcers can both perforate and bleed.

For many years, the cause of peptic ulceration remained an enigma. When comparing groups of patients with duodenal and prepyloric peptic ulcers with normal subjects, gastric acid levels are higher, but the overlap is considerable. Patients with gastric ulceration have relatively normal levels of gastric acid secretion. It is clear that acid is important as peptic ulceration occurs in the presence of very high acid levels, such as those found in patients with a gastrinoma (Zollinger–Ellison syndrome), and ulcers heal in the absence of acid. In patients with a gastrinoma it may be the only aetiological factor, but this is not the case in the majority of patients.

Summary box 67.4

Peptic ulceration

- Most peptic ulcers are caused by *H. pylori* or NSAIDs and changes in epidemiology mirror changes in these principal aetiological factors
- Duodenal ulcers are more common than gastric ulcers, but the symptoms are indistinguishable
- Gastric ulcers may be malignant and an ulcerated gastric cancer may mimic a benign ulcer
- Gastric antisecretory agents and *H. pylori* eradication therapy are the mainstays of treatment, and elective surgery is very rarely performed
- The long-term complications of peptic ulcer surgery may be difficult to treat
- The common complications of peptic ulcers are perforation, bleeding and stenosis
- The treatment of the perforated peptic ulcer is primarily surgical, although some patients may be managed conservatively

It is now widely accepted that infection with *H. pylori* and consumption of NSAIDs are the most important factors in the development of peptic ulceration. Cigarette smoking predisposes to peptic ulceration and increases the relapse rate after treatment.

Duodenal ulceration

Incidence

There have been marked changes in the demography of patients presenting with duodenal ulceration in the West. In part, this may relate to the widespread use of gastric antisecretory agents and *H. pylori* eradication therapy in patients with dyspepsia. Second, the peak incidence is now in a much older age group and, although still more common in men, gender difference is less marked. These changes mirror the changes, at least in part, in the epidemiology of *H. pylori* infection. In eastern Europe, the disease remains common, and the incidence is rising in resource-poor nations.

Pathology

Most ulcers occur in the first part of the duodenum (***Figures 67.10 and 67.11***). A chronic ulcer penetrates the mucosa into the muscle coat, leading to fibrosis. The resulting scarring may cause a deformity such as pyloric stenosis. When an ulcer heals, a residual scar can be observed in the mucosa. Sometimes there may be more than one duodenal ulcer. The situation in which there is both a posterior and an anterior duodenal ulcer is referred to as 'kissing ulcers'. Anterior ulcers tend to perforate

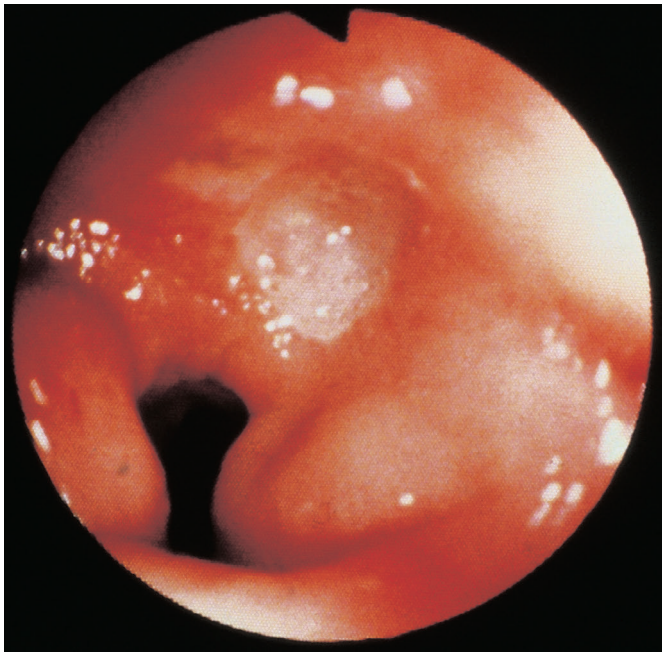

Figure 67.10 Duodenal ulcer at gastroduodenoscopy (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.

Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, Milwaukee, WI, USA.

Figure 67.11 Duodenal ulcer shown by barium meal.

while posterior duodenal ulcers tend to bleed, sometimes by eroding into the gastroduodenal artery. Occasionally, the ulceration may be so extensive that the entire duodenal cap is ulcerated and devoid of mucosa. With respect to the giant duodenal ulcer, malignancy in this region is so uncommon that under normal circumstances surgeons can be confident that they are dealing with benign disease, even though from external palpation it may not appear so. In the stomach the situation is different.

Histopathology

Microscopically, the base of the ulcer is covered with granulation tissue and there may be evidence of endarteritis obliterans. The pathological appearances of the healing ulcer must be carefully interpreted as some of the epithelial down growth can be misinterpreted as invasion.

Gastric ulcers

Incidence

As with duodenal ulceration, *H. pylori* and NSAIDs are the important aetiological factors. Gastric ulceration is also associated with smoking. Gastric ulceration is much less common than duodenal ulceration. The gender incidence is equal and patients with gastric ulcers tend to be older. Gastric ulceration is more prevalent in low socioeconomic groups and is considerably more common in resource-poor than in resource-rich countries.

Pathology

Gastric ulcers have similar features to duodenal ulcers but tend to be larger. Fibrosis may result in an 'hourglass' deformity of the stomach. Chronic ulcers may erode posteriorly into the pancreas, major vessels such as the splenic artery or rarely into other organs such as the transverse colon. Chronic gastric ulcers are more common on the lesser curve (especially at the incisura angularis; ***Figures 67.12 and 67.13***) than on the greater curve and, even when high on the lesser curve, they tend to be at the boundary between the acid-secreting and the non-acid-secreting epithelia. With atrophy of parietal cell mass, non-acid-secreting epithelium migrates up the lesser curvature.

Malignancy in gastric ulcers

In contrast to chronic duodenal ulcers, gastric ulcers are associated with malignancy. There are two clinical scenarios that should be distinguished: one in which a benign chronic gastric ulcer undergoes malignant transformation (rare) and the more common scenario in which a gastric ulcer is assessed as benign either endoscopically or on contrast radiology but biopsies reveal malignancy. In this situation, the patient has

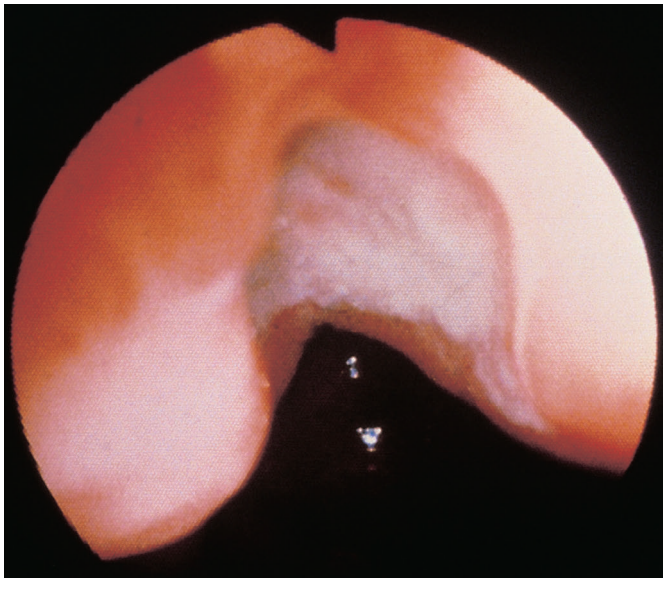

Figure 67.12 Benign incisural gastric ulcer shown at gastroscopy (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

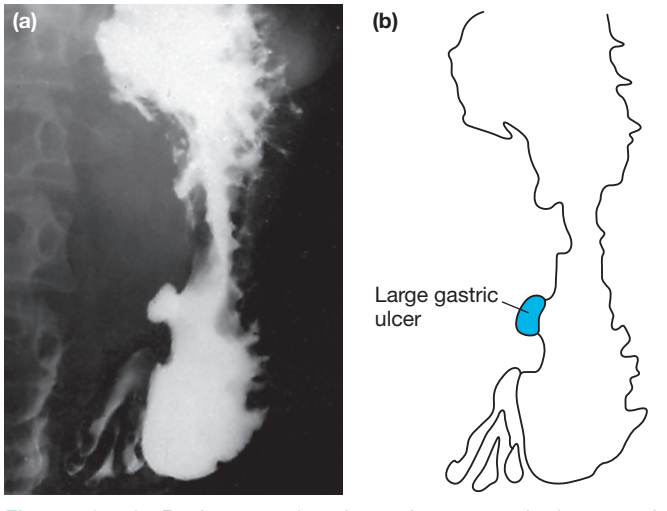

Figure 67.13 Benign gastric ulcer shown on barium meal. **(a)** Radiograph; **(b)** diagrammatic outline.

in fact presented with an ulcerated cancer and not a chronic peptic ulcer. Therefore, all gastric ulcers should be regarded as being malignant, no matter how classical the features of a benign gastric ulcer. Multiple biopsies should always be taken, perhaps as many as 10 well-targeted biopsies, before an ulcer can be tentatively accepted as being benign. Even then it is important that further biopsies are taken while the ulcer is healing and when healed. Modern antisecretory agents can frequently heal the ulceration associated with gastric cancer but, clearly, are ineffective in treating the malignancy itself.

At operation, even experienced surgeons may have difficulty distinguishing between the gastric cancer and a benign ulcer. Operative strategies differ so radically that it is essential that a confident diagnosis be made before operation. At operation for a perforated gastric ulcer, even if it is considered that the ulcer is benign, the ulcer should be excised and submitted for histological examination.

Other peptic ulcers

A prepyloric gastric ulcer was in the past difficult to treat, a problem overcome with the introduction of PPIs. Pyloric channel ulcers are similar to duodenal ulcers. Both prepyloric and pyloric ulcers may be malignant and biopsy is essential. Stomal ulcers occur after a gastroenterostomy (now most commonly found after bariatric surgery; see ***Chapter 68***) or a gastrectomy of the Billroth II type. The ulcer is usually found on the jejunal side of the stoma.

Clinical features of peptic ulcers

The clinical features of gastric and duodenal ulceration cannot be differentiated on the basis of symptoms. The demographic characteristics of groups of patients with gastric and duodenal ulceration do differ but this does not allow discrimination.

Pain

Epigastric pain, often described as gnawing and sometimes radiating to the back, is characteristic. Eating may sometimes relieve the discomfort. The pain is normally intermittent rather than intractable. Symptoms may disappear for weeks or months only to return again. This periodicity may be related to the spontaneous healing of the ulcer.

Vomiting

While this occurs, it is not a notable feature unless stenosis has occurred.

Alteration in weight

Weight loss or, sometimes, weight gain may occur. Patients with gastric ulceration are often underweight but this may precede occurrence of the ulcer.

Bleeding

Bleeding may be chronic and presentation with microcytic anaemia is not uncommon. All such patients should be investigated with endoscopy. Acute presentation with haematemesis and melaena is discussed in ***Haematemesis and melaena***.

Clinical examination

Examination of the patient may reveal epigastric tenderness but, except in gastric outlet obstruction, there is unlikely to be much else to find (see ***Chapter 63***).

Investigation of the patient with suspected peptic ulcer

Gastroduodenoscopy

In the stomach, any abnormal lesion should be biopsied, and in the case of a suspected benign gastric ulcer numerous biopsies must be taken in order to exclude, as far as possible, the presence of a malignancy. Commonly, biopsies of the antrum will be taken to see whether there is histological evidence of gastritis and a *Campylobacter*-like organism (CLO) test performed to determine the presence of *H. pylori*. A 'U' manoeuvre should be carried out to inspect the incisura, lesser curve and gastro-oesophageal junction (GOJ), given the increasing incidence of cancer at the GOJ (see ***Chapter 66***). Similarly, if a stoma is present, for instance after gastroenterostomy or Billroth II gastrectomy, it is important to enter both afferent and efferent loops. Almost all stomal ulcers will be close to the junction between the jejunal and gastric mucosa. Attention should be given to the pylorus to note whether there is any prepyloric or pyloric channel ulceration, and also whether it is deformed, which is often the case with chronic duodenal ulceration. In the duodenum, care must be taken to view all of the first part and the endoscope advanced into the second part.

Treatment of peptic ulceration

The vast majority of uncomplicated peptic ulcers are treated medically. Surgical treatment of uncomplicated peptic ulceration has decreased markedly and is now seldom performed. Surgical treatment was aimed principally at reducing gastric acid secretion and, in the case of gastric ulceration, removing the diseased mucosa. When originally devised, medical treatment also aimed to reduce gastric acid secretion, initially using the highly successful H_2-receptor antagonist and, subsequently, PPIs. This has now largely given way to *H. pylori* eradication therapy.

Medical treatment

It is reasonable to suggest modifications to the patient's lifestyle, particularly the cessation of cigarette smoking; however, pharmacological measures form the mainstay of treatment.

H_2-receptor antagonists and proton pump inhibitors

H_2-antagonists revolutionised the management of peptic ulceration. Most duodenal ulcers and gastric ulcers can be healed by a few weeks of treatment. There remained, however,

Christian Albert Theodor Billroth, 1829–1894, Professor of Surgery, Vienna, Austria.

a group of patients who were relatively refractory to conventional doses of H_2-receptor antagonists. This is largely now irrelevant as PPIs can effectively render a patient achlorhydric and all benign ulcers will heal using these drugs, the majority within 2 weeks. Symptom relief is rapid, most patients being asymptomatic within a few days. Like H_2-antagonists, PPIs are safe and relatively devoid of serious side effects. The problem with all gastric antisecretory agents is that, following cessation of therapy, relapse is almost universal.

Eradication therapy

Eradication therapy is now routinely given to patients with peptic ulceration. If *H. pylori* is the principal aetiological factor (essentially in patient not taking NSAIDs) then complete eradication of the organism will cure the disease. Reinfection as an adult is uncommon. Eradication therapy is therefore the mainstay of treatment for peptic ulceration. It is extremely economical by comparison with prolonged courses of antisecretory agents or surgery. It is also considerably safer than surgical treatment.

There are some patients with peptic ulcers in whom eradication therapy may not be appropriate, and this includes patients with NSAID-associated ulcers. Such patients should avoid these drugs if possible; if not, they should be coprescribed with a potent antisecretory agent. Similarly, patients with stomal ulceration are not effectively treated with eradication therapy and require prolonged prescription of antisecretory agents. Patients with Zollinger–Ellison syndrome should be treated in the long term with PPIs unless the tumour can be adequately managed by surgery.

Ulcers that fail to heal

The introduction of antisecretory agents and effective treatments for *H. pylori* have revolutionised the management of peptic ulcers. Despite these advances, peptic ulceration fails to heal in a small minority of patients. Endoscopic re-evaluation should be regarded as mandatory to confirm healing of all gastric ulcers. Furthermore, endoscopy permits the differentiation between a refractory ulcer and persistent symptoms despite ulcer healing. The most common cause of failed healing is persistent *H. pylori* infection. Biopsies should be repeated at the time of endoscopy as false-negative results with breath tests may be expected soon after eradication therapy and serum antibody titres may not fall for 6 months after successful eradication. Failure of eradication is usually due to poor compliance or bacterial resistance and bacteriological culture will guide further attempts at *H. pylori* eradication. The ingestion of NSAIDs should once again be addressed. A diagnosis of Zollinger–Ellison syndrome (described in detail in ***Zollinger–Ellison syndrome***) should be suspected in *H. pylori*-negative, non-NSAID-related peptic ulceration and serum gastrin levels should be measured. Very rarely a recently described autoimmune immunoglobulin G4-related (IgG4) phenomenon is the cause of resistant and recurrent gastric ulceration.

Operations for duodenal ulceration

Procedures for the treatment of duodenal ulcers have the common aim of excluding acid from the duodenum. This is achieved by diversion of acid away from the duodenum, reducing the secretory potential of the stomach or both. All procedures achieve this aim to some extent, but with varying degrees of morbidity and postoperative side effects. There is now no role for acid-reducing operations in the routine management of peptic ulcer disease, but occasionally operations that involve gastrectomy have to be performed in the emergency situation.

Gastrectomy-based procedures

Gastrectomy in the form of either Billroth I (***Figure 67.14***) or Billroth II/Pólya (***Figure 67.15***) has been performed for

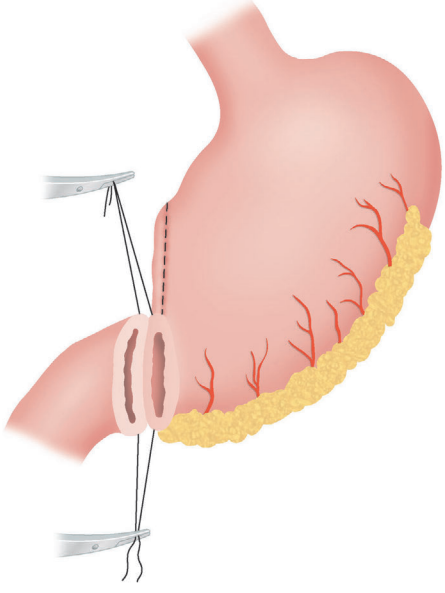

Figure 67.14 Billroth I gastrectomy. The lower half of the stomach is removed and the cut stomach anastomosed to the first part of the duodenum.

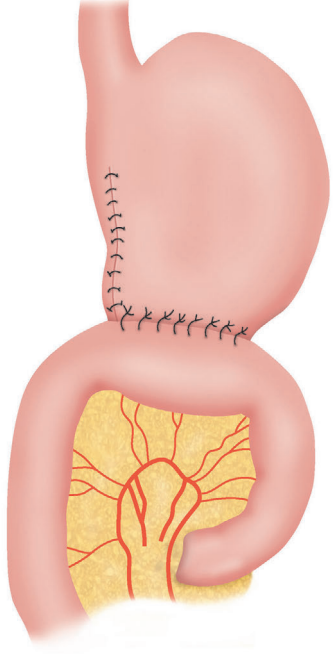

Figure 67.15 Billroth II. Two-thirds of the stomach is removed, the duodenal stump is closed and the stomach anastomosed to the jejunum.

duodenal ulcer since the end of the nineteenth century. Both operations remove the gastric antrum, hence reducing acid. The Pólya gastrectomy diverts the gastric secretions away from the duodenum. There is no elective role for these procedures in the treatment of duodenal ulcer, but the safer Pólya procedure is occasionally needed in the management of complex ulcer disease presenting as an emergency.

Gastrojejunostomy

Gastrojejunostomy (***Figure 67.16***) was developed as an operation for duodenal ulcer, in which role it was very unsuccessful. Although reflux of alkali into the stomach allowed healing in some cases, the exposure of jejunal mucosa to acid resulted in stomal ulceration. Gastroenterostomy, however, remains a commonly performed operation, usually to bypass malignant obstruction due to tumours in the distal stomach, duodenum or pancreas. This is performed through opening the lesser sac and performing an anastomosis between the most dependent part of the antrum and the first jejunal loop. An isoperistaltic anastomosis is most commonly performed.

Vagotomy-based procedures

The principle of the operation is that section of the vagus nerves, which are critically involved in the secretion of gastric acid, reduces the maximal acid output by approximately 50%. Truncal vagotomy (cutting the vagal verves at the lower oesophagus) was first introduced in the mid-twentieth century and, for many years, combined with a gastric drainage procedure, was the mainstay of treatment of duodenal ulceration (***Figure 67.17***). Because the vagal nerves are motor to the stomach, denervation of the antropyloroduodenal segment results in gastric stasis in a substantial proportion of patients on whom truncal vagotomy alone is performed. The most popular drainage procedure was the Heineke–Mikulicz pyloroplasty (***Figure 67.18***). It is simple to perform and involves longitudinal division of the pyloric ring. The incision is closed transversely. Gastrojejunostomy (***Figure 67.16***) is an alternative drainage procedure to pyloroplasty. In highly selective vagotomy, only the parietal cell mass of the stomach is denervated (***Figure 67.19***).

Operations for gastric ulcer

In contrast to surgery for duodenal ulcer, where the principal objective is to reduce duodenal exposure to gastric acid, in gastric ulcer surgery the ulcer is usually excised so that malignancy can then be confidently excluded. The standard operation is the Billroth I (***Figure 67.14***) but as with duodenal ulceration such surgery is now performed only for complications of gastric ulcer.

Sequelae of peptic ulcer surgery

There are a number of sequelae of peptic ulcer surgery, which include recurrent ulceration, small stomach syndrome, bilious vomiting, early and late dumping, diarrhoea and malignant transformation. These sequelae principally follow from the more destructive operations that are now seldom performed. However, a substantial number of patients have side effects from operations undertaken in the past. Approximately 30% of patients can expect to suffer a degree of dysfunction following peptic ulcer surgery (***Table 67.2***); in about 5% of such patients, the symptoms will be intractable.

TABLE 67.2 Operative mortality, side effects and incidence of recurrence following duodenal ulcer operations.

Operation	Operative mortality (%)	Significant side effects (%)	Recurrent ulceration (%)
Gastrectomy	1–2	20–40	1–4
Gastroenterostomy alone	<1	10–20	50
Truncal vagotomy and drainage	<1	10–20	2–7
Selective vagotomy and drainage	<1	10–20	5–10
Highly selective vagotomy	<0.2	<5	2–10
Truncal vagotomy and antrectomy	1	10–20	1

Recurrent ulceration and gastrocolic fistula

As with other peptic ulcers, recurrent ulcers may present with complications, particularly bleeding and perforation. In this respect, the complication of gastrojejunal–colic fistula requires particular mention. In this rare condition, an anastomotic ulcer in the gastrojejunostomy penetrates into the transverse colon. Patients suffer from diarrhoea that is severe and follows every meal. They have foul breath and may vomit formed faeces. Severe weight loss and dehydration are rapid in onset; for this reason the condition may be mistaken for malignancy. The major factor producing the nutritional disturbance is the severe contamination of the jejunum with colonic bacteria. A number of imaging techniques can be used to detect the fistula, most commonly CT with oral contrast or indeed a barium enema. Endoscopy may not convincingly demonstrate the fistula and, in about one-half of such cases, the barium meal will not reveal the problem. The treatment of gastrocolic fistula consists of first correcting the dehydration and malnutrition and then performing revisional surgery.

Small stomach syndrome

Early satiety follows most ulcer operations to some degree, including highly selective vagotomy. In this latter circumstance, although there is no anatomical disturbance of the stomach there is loss of receptive relaxation. Fortunately, this problem does tend to get better with time and revisional surgery is not necessary.

Bile vomiting

Bile vomiting can occur after any form of vagotomy with drainage or gastrectomy. Commonly, the patient presents with vomiting a mixture of food and bile or sometimes some bile alone after a meal. Often eating will precipitate abdominal pain and reflux symptoms are common. Bile-chelating agents can be tried but are usually ineffective. In intractable cases, revisional surgery may be indicated. The nature of that revisional surgery depends very much on the original operation. Following gastrectomy, Roux-en-Y diversion is probably the best treatment. In patients with a gastroenterostomy, this can

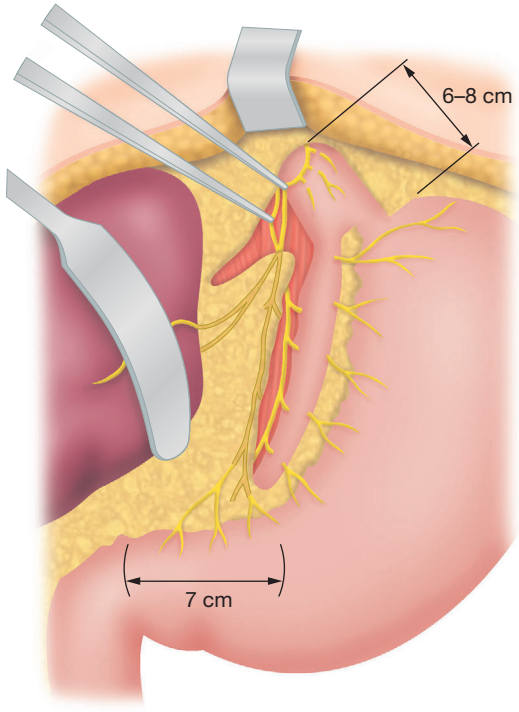

Figure 67.19 Highly selective vagotomy. The anterior and posterior vagus nerves are preserved but all branches to the fundus and body of the stomach are divided.

be taken down and, in most circumstances, a small pyloroplasty can be performed. In patients with a pyloroplasty, reconstruction of the pylorus has been attempted but, in general terms, the results of this operation have been rather poor. Antrectomy and Roux-en-Y reconstruction may be the better option.

Early and late dumping

Although considered together because the symptoms are similar, early and late dumping have different aetiologies A common feature, however, is early rapid gastric emptying. Many patients have both early and late dumping.

Early dumping

Early dumping consists of abdominal and vasomotor symptoms that are found in about 10% of patients following gastrectomy or vagotomy and drainage. It also affects a small percentage of patients following highly selective vagotomy owing to the loss of receptive relaxation of the stomach. The small bowel is filled with foodstuffs from the stomach, which have a high osmotic load that leads to the sequestration of fluid from the circulation into the gastrointestinal tract. This can be observed by the rise in the packed cell volume while the symptoms are present. All of the symptoms shown in ***Table 67.3*** can be related to this effect on the gut and the circulation.

The principal treatment is dietary manipulation. Small, regular meals based on fat and protein are best. Avoiding fluids with a high carbohydrate content also helps. Fortunately, the syndrome tends to improve with time; however, a group of patients have intractable dumping. The somatostatin analogue octreotide given before meals is useful in some individuals and the long-acting preparation may also be useful; however, it does not help diarrhoea, which many patients with dumping also suffer.

TABLE 67.3 Features of early and late dumping.

	Early	Late
Incidence	5–10%	5%
Relation to meals	Almost immediate	Second hour after meal
Durations of attack	30–40 minutes	30–40 minutes
Relief	Lying down	Food
Aggravated by	More food	Exercise
Precipitating factor	Food, especially carbohydrate rich and wet	As early dumping
Major symptoms	Epigastric fullness, sweating, light-headedness, tachycardia, colic, sometimes diarrhoea	Tremor, faintness, prostration

Revisional surgery may be occasionally required. In patients with a gastroenterostomy, the drainage may be taken down or, in the case of a pyloroplasty, repaired. Alternatively, antrectomy with Roux-en-Y reconstruction is often effective, although the procedure is of greater magnitude; following gastrectomy, it is the revisional procedure of choice (***Figure 67.20***).

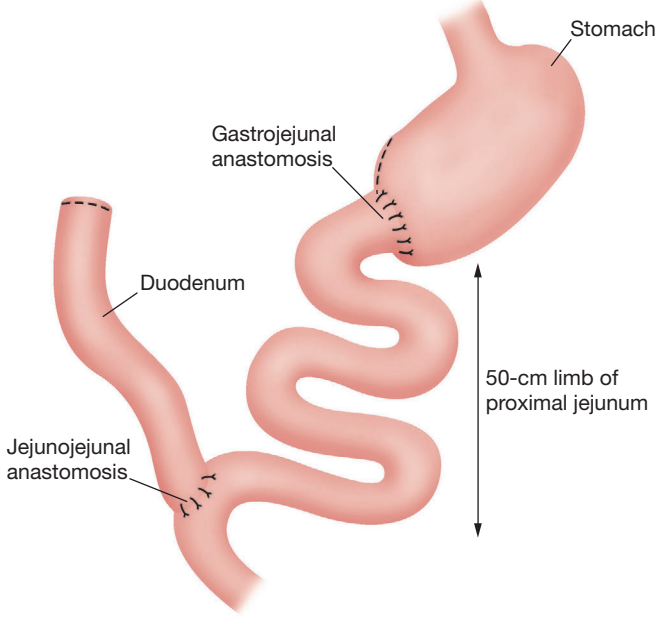

Figure 67.20 Roux-en-Y reconstruction following Billroth I gastrectomy. Note the length of the proximal jejunal limb required to minimise bilious reflux.

César Roux, 1857–1934, Professor of Surgery and Gynecology, Lausanne, Switzerland.

Late dumping

This is due to reactive hypoglycaemia. The carbohydrate load in the small bowel causes a rise in the plasma glucose, which, in turn, causes insulin levels to rise, causing a secondary hypoglycaemia. This can be easily demonstrated by serial measurements of blood glucose in a patient following a test meal. The treatment is essentially the same as for early dumping. Octreotide is very effective in dealing with this problem.

Postvagotomy diarrhoea

This can be the most devastating symptom to afflict patients having peptic ulcer surgery. Most patients will have some looseness of bowel action (with the exception of highly selective vagotomy), but it may be intractable in approximately 5%. The cause is uncertain but is related to rapid gastric emptying, denervation of the upper gastrointestinal tract and an exaggerated gastrointestinal peptide response. Many patients with severe diarrhoea do not have other symptoms of dumping and likewise some patients with dumping do not experience significant diarrhoea. In general, patients should be managed as for early dumping and antidiarrhoeal preparations may be of value. Octreotide is not effective and the results of revisional surgery are unpredictable.

Malignant transformation

Partial gastrectomy or vagotomy and drainage are independent risk factors for development of gastric cancer as bile reflux gastritis, intestinal metaplasia and gastric cancer are linked. The lag phase between operation and the development of malignancy is at least 10 years. Highly selective vagotomy does not seem to be associated with an increased long-term incidence of gastric cancer.

Nutritional consequences

Nutritional disorders are more common after gastrectomy than after vagotomy and drainage. Weight loss is common after gastrectomy and patients may never return to their original weight. Taking more frequent small meals is often useful.

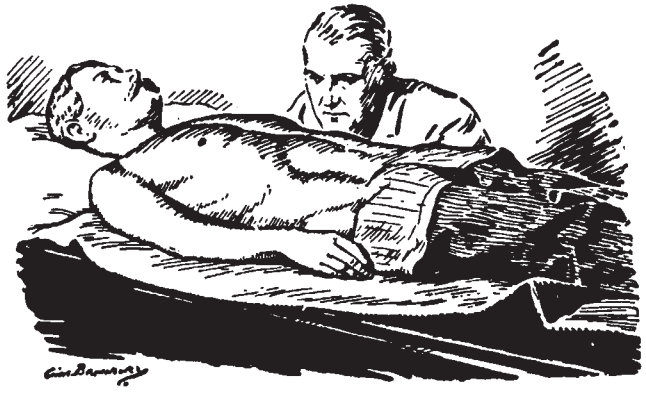

Figure 67.21 A sketch of Mr Hamilton Bailey watching for abdominal movement on respiration. In the case of a classically presenting perforated ulcer, the abdominal movement is restricted or absent.

Iron deficiency anaemia occurs after both gastrectomy and vagotomy and drainage. Reduced iron absorption is probably the most important factor. Vitamin B_{12} deficiency occurs after total gastrectomy; however, it may be years before megaloblastic anaemia is clinically apparent. Vitamin B_{12} supplementation after total gastrectomy is essential. Rarely, vitamin B_{12} deficiency may occur after lesser forms of gastrectomy. In such patients the cause is probably a combination of reduced intrinsic factor production and bacterial colonisation, which results in vitamin B_{12} being metabolised in the gut, preventing absorption.

Bone disease is seen principally after gastrectomy and mainly in women. The condition is essentially indistinguishable from the osteoporosis commonly seen in postmenopausal women. It is only the frequency and magnitude of the disorder that distinguish it. Treatment is with dietary supplementation, calcium and vitamin D, and exercise.

Gallstones

Following truncal vagotomy, the biliary tree is denervated, leading to cholestasis and gallstone formation. Symptomatic patients require cholecystectomy; however, this may induce or worsen other postpeptic ulcer surgery syndromes such as bilious vomiting and postvagotomy diarrhoea.

Complications of peptic ulceration

The common complications of peptic ulcer are perforation, bleeding and stenosis. Bleeding and stenosis are considered below in the relevant sections.

Perforated peptic ulcer

Epidemiology

Despite the widespread use of gastric antisecretory agents and eradication therapy, the incidence of perforated peptic ulcer has changed little. However, there has been a steady increase in the age of the patients with this complication and an increase in the numbers of females, such that perforations now occur most commonly in elderly female patients. NSAIDs appear to be responsible for most of these perforations.

Clinical features

The classical presentation of perforated duodenal ulcer is instantly recognisable (***Figure 67.21***). The patient, who may have a history of peptic ulceration, develops sudden-onset severe generalised abdominal pain due to the irritant effect of gastric acid on the peritoneum. Although the contents of an acid-producing stomach are relatively low in bacterial load, bacterial peritonitis supervenes over a few hours, usually accompanied by a deterioration in the patient's condition. Initially, the patient may be shocked with a tachycardia, but a pyrexia is not usually observed until some hours after the event. The abdomen exhibits a board-like rigidity, and the patient is disinclined to move because of the pain. The abdomen does not move with respiration. Patients with this form of presentation need an operation, without which the patient will deteriorate with a septic peritonitis.

Henry Hamilton Bailey, 1894–1961, surgeon, The Royal Northern Hospital, London, UK.

This classical presentation of the perforated peptic ulcer is observed less commonly than in the past. Very frequently the elderly patient will have a less dramatic presentation, perhaps because of the use of potent anti-inflammatory drugs (steroids). The board-like rigidity seen in the abdomen of younger patients may also not be observed and a higher index of suspicion is necessary to make the correct diagnosis. In other patients, the leak from the ulcer may be contained such that they present with pain in the epigastrium and right iliac fossa as the fluid may track down the right paracolic gutter. Sometimes perforations will seal owing to the inflammatory response and adhesion within the abdominal cavity, and so the perforation may be self-limiting. All of these factors may combine to make the diagnosis of perforated peptic ulcer difficult.

Investigations

An erect chest radiograph will reveal free gas under the diaphragm in more than 50% of cases with perforated peptic ulcer (***Figure 67.22***), but CT imaging is now most commonly used and is more accurate. All patients should have serum amylase performed, as distinguishing between peptic ulcer, perforation and pancreatitis can be difficult. Measuring the serum amylase, however, may not remove the diagnostic difficulty. It can be elevated following perforation of a peptic ulcer, although, fortunately, the levels are not usually as high as the levels commonly seen in acute pancreatitis. A CT scan will normally be diagnostic in both conditions.

Treatment

The initial priorities are resuscitation and analgesia. Analgesia should not be withheld for fear of removing the signs of an intra-abdominal catastrophe. In fact, adequate analgesia makes the clinical signs more obvious. It is important, however, to titrate the analgesic dose. Following resuscitation, the treatment is principally surgical. Laparotomy is performed, usually through an upper midline incision if the diagnosis of perforated peptic ulcer can be made with confidence. Alternatively, laparoscopy may be used. The most important component of the operation is a thorough peritoneal toilet to remove all of the fluid and food debris. If the perforation is in the duodenum, it can usually be closed by several well-placed sutures, closing the ulcer in a transverse direction as with a pyloroplasty. It is important that sufficient tissue is taken in the suture to allow the edges to be approximated, and the sutures should not be tied so tight that they tear out. It is common to place an omental patch over the perforation in the hope of enhancing the chances of the leak sealing. If the perforation is difficult to close primarily it is frequently possible to seal the leak with an omental patch alone, and many surgeons now employ this strategy for all perforations.

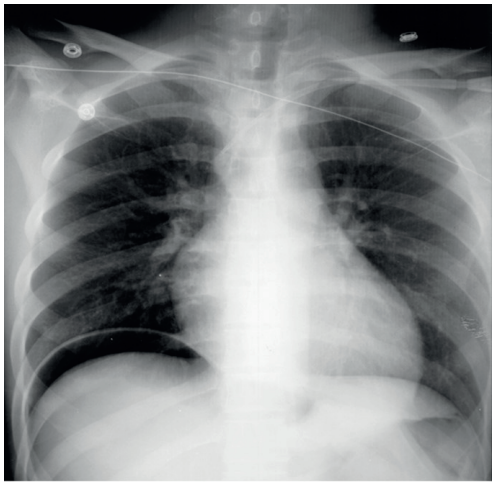

Figure 67.22 Erect chest radiograph showing air under the right diaphragm in a patient with a perforated duodenal ulcer.

When securing the omental patch, it is important not to tie the sutures too tight so as to obliterate the omental blood supply. Gastric ulcers should, if possible, be excised and closed, so that malignancy can be excluded. Occasionally a patient is seen who has a massive duodenal or gastric perforation such that simple closure is impossible; in these patients a distal gastrectomy with Roux-en-Y reconstruction is the procedure of choice (***Figure 67.20***).

Perforated peptic ulcers can often be managed by minimally invasive techniques if the expertise is available. The principles of operation are the same: thorough peritoneal toilet and closure of the perforation by intracorporeal suturing.

Following operation, it is important that the stomach is kept empty postoperatively by nasogastric suction, and that gastric antisecretory agents are commenced to promote healing in the residual ulcer. *H. pylori* eradication is mandatory.

A minority of patients who have small leaks from a perforated peptic ulcer and relatively mild peritoneal contamination may be managed with intravenous fluids, nasogastric suction and antibiotics. Any deterioration should prompt immediate surgical intervention.

Patients who have had one perforation may have another. Therefore, they should be managed aggressively to ensure that this does not happen. Lifelong treatment with PPIs is a reasonable option, especially in those who have to continue with NSAID treatment.

HAEMATEMESIS AND MELAENA

Upper gastrointestinal haemorrhage remains a major medical problem with an incidence of over 100/100 000 per year in Western practice. The incidence increases with age. Haemorrhage is strongly associated with NSAID use. Despite improvements in diagnosis and the proliferation in treatment modalities over the last few decades, an in-hospital mortality of 5–10% can be expected. This rises to 33% when bleeding is first observed in patients who are hospitalised for other reasons. In patients in whom the cause of bleeding can be found, the most common causes are peptic ulcer, erosions, Mallory–Weiss tear and bleeding oesophageal varices (***Table 67.4***).

Whatever the cause, the principles of management are identical. First, the patient should be adequately resuscitated

George Kenneth Mallory, 1900–1986, Professor of Pathology, Boston, MA, USA.
Soma Weiss, 1899–1942, Professor of Medicine, Boston, MA, USA.

and, following this, should be investigated urgently to determine the cause of the bleeding. Intravenous access should be established and, for those with severe bleeding, central venous pressure monitoring should be established and bladder catheterisation performed. Blood should be cross-matched and the patient transfused as clinically indicated, usually when >30% of blood volume has been lost (see ***Chapter 2***). There is no evidence for the use of intravenous PPI prior to endoscopy. As a general rule, most gastrointestinal bleeding will stop, albeit temporarily, but there are sometimes instances when this is not the case. In these circumstances, resuscitation, diagnosis and treatment should be carried out simultaneously. There are occasions when life-saving manoeuvres have to be undertaken without the benefit of an absolute diagnosis. In some patients, bleeding is secondary to a coagulopathy. The most important current causes are liver disease and anticoagulation therapy. In these circumstances the coagulopathy should be corrected, if possible, with fresh-frozen plasma or concentrated clotting factors with haematology advice.

Upper gastrointestinal endoscopy should be carried out by an experienced operator as soon as practicable after the patient has been stabilised. In patients in whom the bleeding is relatively mild, endoscopy may be carried out on the morning after admission; this is usually guided by local policy. In all cases of severe bleeding, it should be carried out immediately. A number of scoring systems have been advocated for the assessment of rebleeding and death after upper gastrointestinal haemorrhage. The Rockall score (***Table 67.5***) can be used in a pre-endoscopy format to stratify patients to safe early discharge and, post endoscopy, it can relatively accurately predict rebleeding and death.

Bleeding peptic ulcers

The epidemiology of bleeding peptic ulcers mirrors that of perforated ulcers. In recent years, the population affected has become older and bleeding is commonly associated with the ingestion of NSAIDs. Diagnosis can normally be made endoscopically, although occasionally the nature of the blood loss precludes accurately identifying the lesion. However, the more experienced the endoscopist, the less likely this is to be a problem.

Medical and minimally interventional treatments

Medical treatment has limited efficacy. All patients are commonly started on either an H_2 antagonist or a proton pump inhibitor, and recent evidence confirms the benefit of PPI administration to prevent rebleeding after endoscopy. Meta-analysis of studies suggests that tranexamic acid, an inhibitor of fibrinolysis, may reduce overall mortality.

Therapeutic endoscopy can achieve haemostasis in approximately 70% of cases, with the best evidence supporting a combination of adrenaline injection with heater probe and/or clips. Therapeutic endoscopy will probably never be effective

TABLE 67.5 The Rockall scoring system of bleeding severity.

in patients who are bleeding from large vessels and with which the majority of the mortality is associated.

In patients where the source of bleeding cannot be identified or in those who rebleed after endoscopy, angiography with transcatheter embolisation may offer a valuable alternative to surgery in expert centres. The risk of significant ischaemia following embolisation is low because of the rich collateral blood supply of the stomach and duodenum. The surgeon should be mindful that rescue surgery after failed embolisation is associated with poor outcome and it may be advantageous to proceed directly to surgery.

Surgical treatment

Patients who continue to bleed require surgery except in expert centres with experience of angiographic embolisation where attempts may be made to arrest bleeding and avoid surgery. The surgical team should be immediately available, and an operation should not be delayed if bleeding persists. Patients with a visible vessel in the ulcer base, a spurting vessel or an ulcer with a clot in the base are likely to require surgical treatment. Frail and elderly patients are more likely to die as a result of bleeding than younger patients; thus, paradoxically, they should have early surgery. In general, a patient who has required more than six units of blood needs surgical treatment.

The aim of the operation is to stop the bleeding. Preoperative endoscopy can usually identify the site of bleeding, which is most often from a peptic ulcer in the duodenum. At operation it is important that the duodenum is fully mobilised before it is opened as it makes the ulcer much more accessible and also allows the surgeon's hand to be placed behind the gastroduodenal artery, which is commonly the source of major bleeding. Following mobilisation, the duodenum, and usually the pylorus, is opened longitudinally as in a pyloroplasty. This allows good access to the ulcer, which is usually found posteriorly or superiorly. Accurate haemostasis is important and can be achieved initially by direct pressure. It is the vessel within the ulcer that is bleeding and this should be controlled using well-placed sutures on a small round-bodied needle that underrun the vessel. The pyloroplasty is then closed with interrupted sutures in a transverse direction in the usual fashion. In the case of a large ulcer, the first part of the duodenum may be destroyed, making primary closure impossible. In this circumstance one should proceed to distal gastrectomy with Roux-en-Y reconstruction. The duodenal stump may then be closed with T-tube drainage or around a drain to create a controlled fistula.

The management of bleeding gastric ulcers is essentially the same. The stomach is opened at an appropriate site anteriorly and the vessel in the ulcer under-run. Consideration is then given to local excision of the ulcer. If the ulcer is not excised, the ulcer margins must be biopsied to exclude malignancy. Gastrectomy for bleeding is associated with a high perioperative mortality, even if the incidence of recurrent bleeding is less.

Bearing in mind that most patients nowadays are elderly and unfit, the minimum surgery that stops the bleeding is probably optimal (damage control surgery). Acid can be inhibited by pharmacological means and appropriate eradication therapy will prevent ulcer recurrence. Definite acid-lowering surgery is not now required. Patients on long-term NSAIDs can be managed as outlined in ***Treatment of peptic ulceration***.

Stress ulceration

This commonly occurs in patients with major injury or illness who have undergone major surgery or who have major comorbidity. Many such patients are found in intensive care units. The incidence has reduced in recent years owing to the widespread use of prophylactic acid inhibition and nasogastric or oral administration of sucralfate. Endoscopic means of treating stress ulceration may be ineffective and operation may be required. The principles of management are the same as for a chronic ulcer.

Gastric erosions

Erosive gastritis has a variety of causes, especially NSAIDs. Fortunately, most such bleeding settles spontaneously, but it can be a major problem to treat. In general terms, although there is a diffuse erosive gastritis, there is one (or more) specific lesion that has a significant-sized vessel within it. This should be dealt with appropriately, preferably endoscopically, but sometimes surgery is necessary.

Mallory–Weiss tear

This is a longitudinal tear at the GOJ, which is induced by repetitive and strenuous vomiting. Doubtless, many such lesions occur and do not cause bleeding. When it is a cause of haematemesis, the lesion may often be missed as it can be difficult to see because it is just below the GOJ, a position that can be difficult for the inexperienced endoscopist. Occasionally these lesions continue to bleed and require surgical treatment (see also ***Chapter 66***).

Dieulafoy lesion

This is essentially a gastric arterial venous malformation that has a characteristic histological appearance. Bleeding due to this malformation is one of the most difficult causes of upper gastrointestinal bleeding to treat. The lesion itself is covered by normal mucosa and, when not bleeding, it may be invisible. If it can be seen while bleeding, all that may be visible is profuse bleeding coming from an area of apparently normal mucosa. If this occurs, the cause is instantly recognisable. If the lesion can be identified endoscopically (***Figure 67.23***) bleeding can be stopped by injection of sclerosant or application of endoscopic clips. If it is identified at operation, only local excision is necessary.

Tumours

All gastric neoplasms may present with chronic or acute upper gastrointestinal bleeding. Bleeding is not normally torrential

Georges Dieulafoy, 1851–1919, physician and surgeon, Hôtel-Dieu de Paris, Paris, France, later President of the French Academy of Medicine (1910).

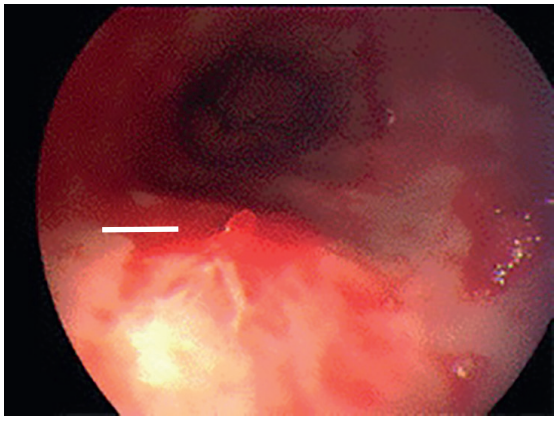

Figure 67.23 Endoscopic view of actively bleeding Dieulafoy lesion in the gastric fundus.

but can be unremitting. Treatment is that of the underlying tumour as discussed in ***Gastric cancer***.

Portal hypertension and portal gastropathy

The management of bleeding gastric varices is very challenging. Fortunately, most bleeding from varices is oesophageal and is much more amenable to sclerotherapy, banding and balloon tamponade. Gastric varices may also be injected, although this is technically more difficult. Banding can also be used, again with difficulty. The gastric balloon of the Sengstaken–Blakemore tube can be used to arrest the haemorrhage from the fundus of the stomach or GOJ (***Figure 67.24***). Intravenous infusion of octreotide (somatostatin analogue) or terlipressin (Glypressin), a vasopressin analogue, reduces portal pressure in patients with varices and is of value in arresting haemorrhage.

Acute surgery on bleeding varices should be avoided, if possible, because of high operative mortality; it has been superseded in most centres by transjugular intrahepatic portosystemic shunt (TIPSS) insertion (see ***Chapter 69***).

Portal gastropathy

Portal gastropathy refers to changes in the gastric mucosa as a result of portal hypertension. The mucosa is friable and may exude blood, even in the absence of well-developed visible varices. The treatment is as for portal hypertension.

Aortic enteric fistula

This diagnosis should be considered in any patient with haematemesis and melaena that cannot be otherwise explained. Contrary to expectation, the bleeding from such patients is not always massive. Very often there is nothing much to distinguish between the bleeding from the aortic enteric fistula and any other recurrent upper gastrointestinal bleeding. The vast majority of patients will have had an aortic graft; however, it is occasionally seen in patients with an untreated aortic aneurysm. A CT scan with intravenous contrast will confirm the diagnosis. Treatment requires aortic aneurysm or aortic graft excision/replacement and carries a high mortality (see ***Chapter 61***).

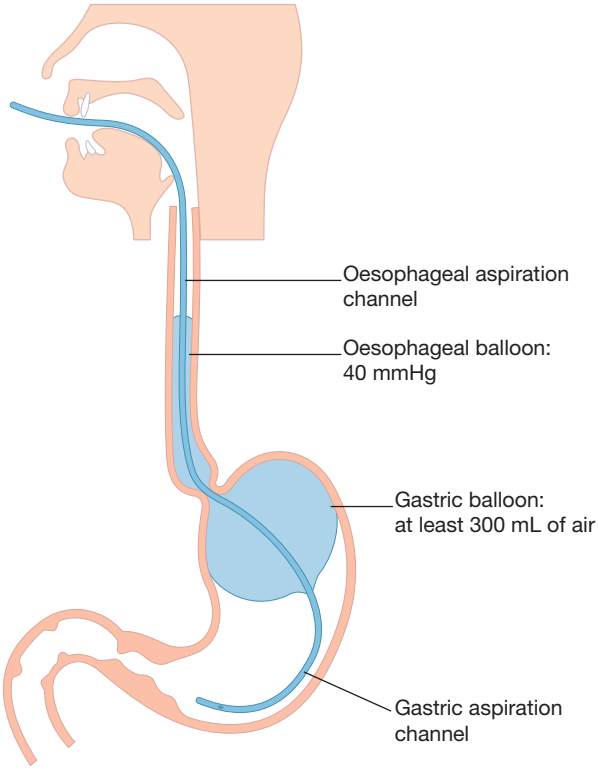

Figure 67.24 Balloon tamponade of gastric and oesophageal varices with a Sengstaken–Blakemore tube. The balloons should be deflated every 12 hours to prevent pressure necrosis.

GASTRIC OUTLET OBSTRUCTION

The two common causes of gastric outlet obstruction are gastric cancer (see ***Gastric cancer***) and pyloric stenosis secondary to peptic ulceration. With the decreasing incidence of peptic ulceration gastric outlet obstruction should be considered malignant until proven otherwise. In this circumstance the metabolic consequences may be somewhat different from those of benign pyloric stenosis because of the relative hypochlorhydria found in patients with gastric cancer.

Clinical features

In benign gastric outlet obstruction, there is usually a long history of peptic ulcer disease. The vomitus is characteristically of undigested food and is totally lacking in bile. Weight loss is a feature, and the patient appears unwell and dehydrated. On examination the distended stomach may be visible and a succussion splash may be audible.

Robert William Sengstaken Sr, 1923–1978, surgeon, Garden City, New York, NY, USA.
Arthur Blakemore, 1897–1970, surgeon, The Columbia College of Physicians and Surgeons, New York, NY, USA.

Summary box 67.5

Gastric outlet obstruction

- Gastric outlet obstruction is most commonly associated with longstanding peptic ulcer disease and gastric cancer
- The metabolic abnormality of hypochloraemic alkalosis is usually only seen with peptic ulcer disease and should be treated with isotonic saline with potassium
- Endoscopic biopsy is essential to exclude malignancy
- Aggressive medical therapy for peptic ulcer disease often leads to resolution
- Endoscopic dilatation of the gastric outlet may be effective in benign stenosis
- Operation is frequently required, with a drainage procedure being performed for benign disease or appropriate resection of malignancy

Metabolic effects

Vomiting hydrochloric acid results in hypochloraemic alkalosis. Initially the sodium and potassium may be relatively normal; however, as dehydration progresses, more profound metabolic abnormalities arise, partly related to renal dysfunction. Initially, the urine has a low chloride and high bicarbonate content, reflecting the primary metabolic abnormality. With time the patient becomes progressively hyponatraemic and more profoundly dehydrated. Because of the dehydration, sodium is retained and potassium and hydrogen ions are excreted. This results in the urine becoming paradoxically acidic and hypokalaemia ensues. Alkalosis leads to a lowering in the circulating ionised calcium, and tetany can occur.

Management

Treating the patient involves correcting the metabolic abnormalities and dealing with the mechanical obstruction. The patient should be rehydrated with intravenous isotonic saline with potassium supplementation. Replacing the sodium chloride and water allows the kidney to correct the acid–base abnormality. The metabolic abnormalities may be less if the obstruction is due to malignancy, as the acid–base disturbance is less pronounced.

The stomach should be emptied using a wide-bore tube. A large nasogastric tube may not be sufficiently large to deal with the contents of the stomach, and it may be necessary to pass an orogastric tube and lavage the stomach until it is completely emptied. This allows investigation with endoscopy and contrast radiology. Biopsy of the area around the pylorus is essential to exclude malignancy.

Early cases may settle with conservative treatment, as oedema around the ulcer diminishes as the ulcer is healed. Traditionally, severe cases are treated surgically, usually with a gastroenterostomy rather than a pyloroplasty. Endoscopic treatment with balloon dilatation may be most useful in early cases and may have to be repeated several times. A duodenal stent insertion may be considered in patients with unresectable malignancy.

GASTRIC POLYPS

A number of conditions manifest as gastric polyps. Their main importance is that they may actually represent early gastric cancer. Biopsy is essential.

The most common type of gastric polyp is metaplastic. These are associated with *H. pylori* infection and regress following eradication therapy. Inflammatory polyps are also common. Fundic gland polyps deserve particular attention. They are associated with use of PPIs and are also found in patients with familial adenomatous polyposis (FAP). Neither metaplastic nor fundic gland polyps have proven malignant potential; however, true adenomas do and should be removed.

GASTRIC CANCER

Carcinoma of the stomach is a major cause of mortality worldwide. Its prognosis tends to be poor, with cure rates little better than 5–10%, although better results are obtained in Japan, where the disease is common. Gastric cancer is actually an eminently curable disease and early diagnosis is key to success. Unfortunately, late presentation is common and the cause of poor overall survival figures. The only curative treatment is resectional surgery.

Summary box 67.6

Gastric cancer

- Gastric cancer is one of the most common causes of cancer death
- The outlook is generally poor, owing to the advanced stage at presentation
- Better results are obtained in Japan, which has a high population incidence, screening programmes and high-quality surgical treatment
- The aetiology of gastric cancer is multifactorial
- *H. pylori* is important in distal but not proximal gastric cancer
- Early gastric cancer is associated with high cure rates
- Gastric cancer can be classified into intestinal and diffuse types, the latter having a worse prognosis
- Spread may be by lymphatics, blood, transcoelomic or direct
- Distant metastases are uncommon in the absence of lymph node involvement
- Radical surgery and removal of second tier of nodes (around the principal arterial trunks) may be advantageous
- Chemotherapy improves survival in patients having surgery and in advanced disease

Incidence

There are marked variations in the incidence of gastric cancer worldwide. In the UK, it is approximately 15 per 100 000 per year; in the USA, 10 per 100 000 per year; and in Eastern Europe, 40 per 100 000 per year. In Japan, the disease is much more common, with an incidence of approximately 70 per 100 000 per year. There are areas in China where the incidence even higher. These underlying epidemiological data make it clear that this is an environmental disease. In general, men are more affected by the disease than women and, as with most solid organ malignancies, the incidence increases with age.

At present, marked changes are being observed in the West in terms of the incidence and site of gastric cancer and the population affected, changes that to date have not been observed in Japan. First, the incidence of gastric cancer is continuing to fall at about 1% per year. This reduction exclusively affects carcinoma arising in the body and distal stomach. In contrast, there appears to be an increase in the incidence of carcinoma in the proximal stomach, particularly the GOJ. Carcinoma of the distal stomach and body of the stomach is most common in low socioeconomic groups, whereas the increase in proximal gastric cancer seems to affect principally higher socioeconomic groups. Proximal gastric cancer does not seem to be associated with *H. pylori* infection, in contrast with carcinoma of the body and distal stomach.

Aetiology

Gastric cancer is a multifactorial disease. Epidemiological studies point to a role for *H. pylori*; however, there is insufficient evidence to support eradication programmes in asymptomatic patients. *H. pylori* seems to be principally associated with carcinoma of the body, stomach and distal stomach rather than the proximal stomach.

Patients with pernicious anaemia and gastric atrophy are at increased risk, as are those with gastric adenomatous polyps. Patients who have had peptic ulcer surgery, particularly those who have had drainage procedures such as Billroth II or Pólya gastrectomy, gastroenterostomy or pyloroplasty, are at approximately four times the average risk; this is thought to be related to bile reflux and intestinal metaplasia. Carcinoma is associated with cigarette smoking and dust ingestion from a variety of industrial processes. Diet appears to be important, as illustrated by the example of the decline in the incidence of gastric cancer among Japanese families living in the USA. The high incidence of gastric cancer in some pockets in China is probably environmental and probably diet related. Excessive salt intake, deficiency of antioxidants and exposure to *N*-nitroso compounds are also related. The aetiology of proximal gastric cancer remains an enigma. It is not associated with *H. pylori* but is associated with obesity and higher socioeconomic status. Genetic factors are also important but not fully elucidated (see ***The molecular pathology of gastric cancer***).

Clinical features

The features of advanced gastric cancer are usually obvious. Unfortunately, early gastric cancer has no specific features to distinguish it from benign dyspepsia and a high index of suspicion is necessary.

In advanced cancer, early satiety, bloating, distension and vomiting may occur. The tumour frequently bleeds, resulting in iron deficiency anaemia. Obstruction leads to dysphagia, epigastric fullness or vomiting. Weight loss can be profound. With pyloric involvement the presentation may be of gastric outlet obstruction, although the alkalosis is usually less pronounced than when duodenal ulceration leads to obstruction. Non-metastatic effects of malignancy are seen, particularly thrombophlebitis (Trousseau's sign) and deep venous thrombosis. These features result from the effects of the tumour on thrombotic and haemostatic mechanisms.

Site

The proximal stomach is now the most common site for gastric cancer in the West. Because the lower oesophagus is also a very common site of adenocarcinoma approximately 60% of all malignancies in the upper gastrointestinal tract occur in proximity to the GOJ (see ***Chapter 66***). Adenocarcinoma at this site has doubled in incidence in the UK over the last 30 years. This high prevalence of proximal gastric cancer is not seen in Japan, where distal cancer still predominates, as it does in most of the rest of the world.

Pathology

The most useful clinicopathological classification of gastric cancer is the Laurén classification. In this system there are principally two forms of gastric cancer: intestinal gastric cancer and diffuse gastric cancer (often with signet ring cells). In intestinal gastric cancer, the tumour resembles a carcinoma elsewhere in the tubular gastrointestinal tract and forms polypoid tumours or ulcers; it probably arises in areas of intestinal metaplasia. In contrast, diffuse gastric cancer infiltrates deeply into the stomach without forming obvious mass lesions but spreads widely in the gastric wall. Not surprisingly, this has a much worse prognosis. A small proportion of gastric cancers are of mixed morphology.

Gastric cancer can be divided into early gastric cancer and advanced gastric cancer. Early gastric cancer is defined as cancer limited to the mucosa and submucosa with or without lymph node involvement (T1, any N); it can be protruding, superficial or excavated as described in the Japanese classification (***Figures 67.25 and 67.26***). This type of cancer is eminently curable with 5-year survival rates in the region of 90%. In Japan, approximately one-third of gastric cancers diagnosed are in this stage. However, early gastric cancer diagnosis in the UK is relatively uncommon as dyspeptic patients are not always referred for endoscopy at an appropriate stage.

Advanced gastric cancer involves the muscularis. Its macroscopic appearances have been classified by Borrmann into four types (***Figures 67.27 and 67.28***). Types III and IV are commonly incurable.

The molecular pathology of gastric cancer

Understanding of the molecular pathology of gastric cancer has been revolutionised by the application of next-generation

Armand Trousseau, 1801–1867, physician, Hôtel-Dieu de Paris, Paris, France. The sign led him to suspect that he personally had gastric cancer, however it proved to be pancreatic cancer on post-mortem.
Pekka August Laurén, 1922–2016, pathologist, University of Turku, Finland.
Robert Borrmann, 1870–1943, pathologist, Bremen, Germany.

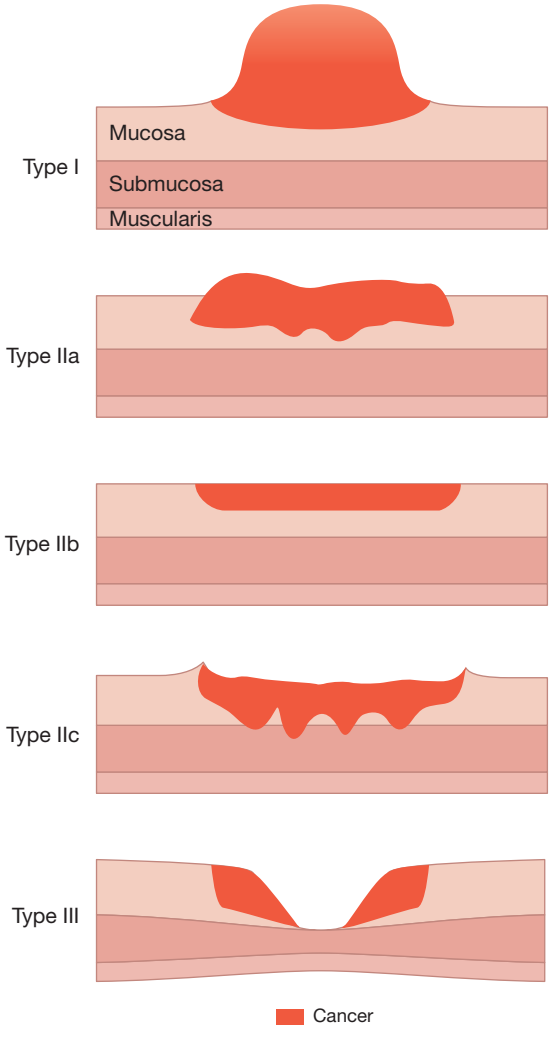

Figure 67.25 Japanese classification of early gastric cancer: type I, protruding; type II, superficial, a, elevated, b, flat, c, depressed; type III, ulcerated.

sequencing platforms to the disease. The Cancer Genome Atlas (TCGA) group described four molecular subtypes of gastric cancer: Epstein–Barr virus positive, microsatellite unstable, genomically stable and chromosomal instability. Recognition of these subgroups and their underlying common gene mutations and driver events is leading to the development of targeted therapies, including immunotherapies. Similar genetic classifications are now available for other tumours of the gastrointestinal tract, meaning that novel treatments can be applied across tumour types.

A range of mutations in genes related to genome integrity (e.g. *BRCA2*, *TP53*, *ARID1A*), chromatin remodelling (e.g. *SMARCA1*, *CHD3*, *CHD4*) and cell–cell adhesion and motility (e.g. *RHOA*, *CDH1*) have been described in gastric cancer. In addition, cell signalling pathways commonly mutated in other solid organ tumours are also often found perturbed in gastric cancer. For example, the Wnt pathway may be amenable to specific small-molecule inhibitors. Unsurprisingly gastric cancer exhibits a range of mutations in receptor tyrosine kinases and PI3K/MAPK signalling (see ***Chapter 11***).

The rapid development of sequencing technologies, including single-cell platforms and the development of real-time sequencing, offers the promise of precision therapy for gastric cancer in the future, but currently treatment is still based on surgery with or without conventional chemo/radiotherapy.

Staging

The International Union Against Cancer (UICC) staging system is shown in ***Table 67.6***. Important changes have been made in the seventh and eighth editions of the TNM staging system that are worthy of discussion. In an attempt to reflect the current evidence base and to improve outcome prediction for individual patients, all gastric tumours whose epicentre is within 5 cm of the GOJ and extend into the oesophagus are now classified according to the oesophageal system. Tumours whose epicentre is within 5 cm of the GOJ but do not extend into the oesophagus, and all other gastric cancers, are staged using the revised gastric staging system. In addition, any tumour that perforates the serosa is now classified as T4 disease.

Spread of carcinoma of the stomach

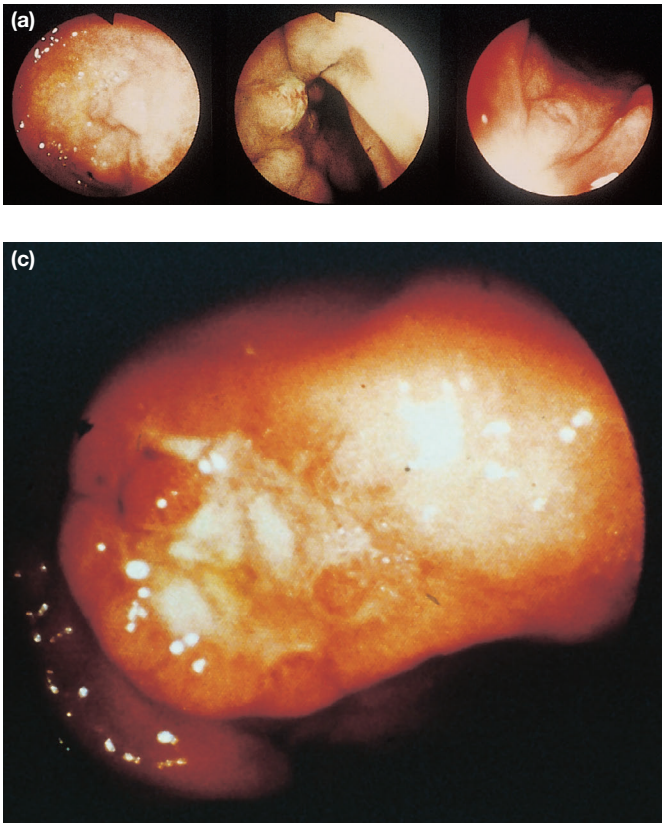
Gastric cancer is an excellent example of the various distant metastases that are uncommon in the absence of lymph node metastases. The intestinal and diffuse types of gastric cancer spread differently. The diffuse type spreads via the submucosal and subserosal lymphatic plexus and penetrates the gastric wall at an early stage.

Direct spread

The tumour penetrates the muscularis, serosa and ultimately adjacent organs such as the pancreas, colon and liver.

Lymphatic spread

This is by both permeation and emboli to the affected tiers (see ***Lymphatic drainage of the stomach***) of nodes. This may be extensive, the tumour even appearing in the supraclavicular nodes (Troisier's sign). Unlike malignancies such as breast cancer, nodal involvement does not imply systemic dissemination.



Blood-borne metastases

This occurs first to the liver and subsequently to other organs, including lung and bone. This is uncommon in the absence of nodal disease.

Transperitoneal spread

This is a common mode of spread once the tumour has reached the serosa of the stomach and indicates incurability. Tumours can manifest anywhere in the peritoneal cavity and

commonly give rise to ascites. Advanced peritoneal disease may be palpated either abdominally or rectally as a tumour 'shelf'. The ovaries may sometimes be the sole site of transcoelomic spread (Krukenberg's tumours). Tumour may spread via the abdominal cavity to the umbilicus (Sister Joseph's nodule). Transperitoneal spread of gastric cancer can be detected most effectively by laparoscopy and cytology.

Lymphatic drainage of the stomach

Understanding the lymphatic drainage of the stomach is the key to understanding radical surgery for gastric cancer. The lymphatics of the antrum drain into the right gastric lymph node superiorly and right gastroepiploic and subpyloric lymph nodes inferiorly. The lymphatics of the pylorus drain to the right gastric suprapyloric nodes superiorly and the subpyloric lymph nodes situated around the gastroduodenal artery inferiorly. The efferent lymphatics from suprapyloric lymph nodes converge on the para-aortic nodes around the coeliac axis, whereas the efferent lymphatics from the subpyloric lymph nodes pass to the main superior mesenteric lymph nodes situated around the origin of the superior mesenteric artery. The lymphatic vessels related to the cardia communicate freely with those of the oesophagus.

The prognosis of operable cases of carcinoma of the stomach depends on whether or not there is histological evidence of regional lymph node involvement. Retrograde (downwards) spread may occur if the upper lymphatics are blocked. In Japan, lymph node dissection is highly advanced and the Japanese Research Society for Gastric Cancer has assigned a number to each lymph node station to aid pathological staging (***Figure 67.29***).

Operability

Patients with incurable disease should not subjected to futile radical surgery, hence the value of preoperative CT/PET and laparoscopic staging. Haematogenous metastases, involvement of the distant peritoneum, M1 nodal disease and fixation to structures that are not resectable are unequivocal features of incurable disease. Involvement of another organ per se does not imply incurability, provided it can be excised.

Neoadjuvant chemotherapy

Most operable patients should have neoadjuvant chemotherapy as there is level 1 evidence of improved survival. Since the early 2000s a platinum-based triplet regime containing epirubicin (e.g. epirubicin, cisplatin and 5-fluorouracil [5-FU]; ECF) has been the standard of care. Recently epirubicin has been replaced by docetaxel after publication of the FLOT4 trial; this was a direct comparison of ECF with FLOT (fluorouracil, leucovorin, oxaliplatin, docetaxel) chemotherapy that showed a significant survival advantage for FLOT (50 months versus 35 months). Unfortunately, only a minority of patients receive a clinically meaningful survival advantage and mechanisms to predict response are urgently required to prevent the ineffective and harmful treatment of the majority. Evidence for the use of perioperative (before and after surgery) chemotherapy is less robust, as in all major trials (MRC-MAGIC and FLOT4) fewer than 50% of patients received the postoperative component.

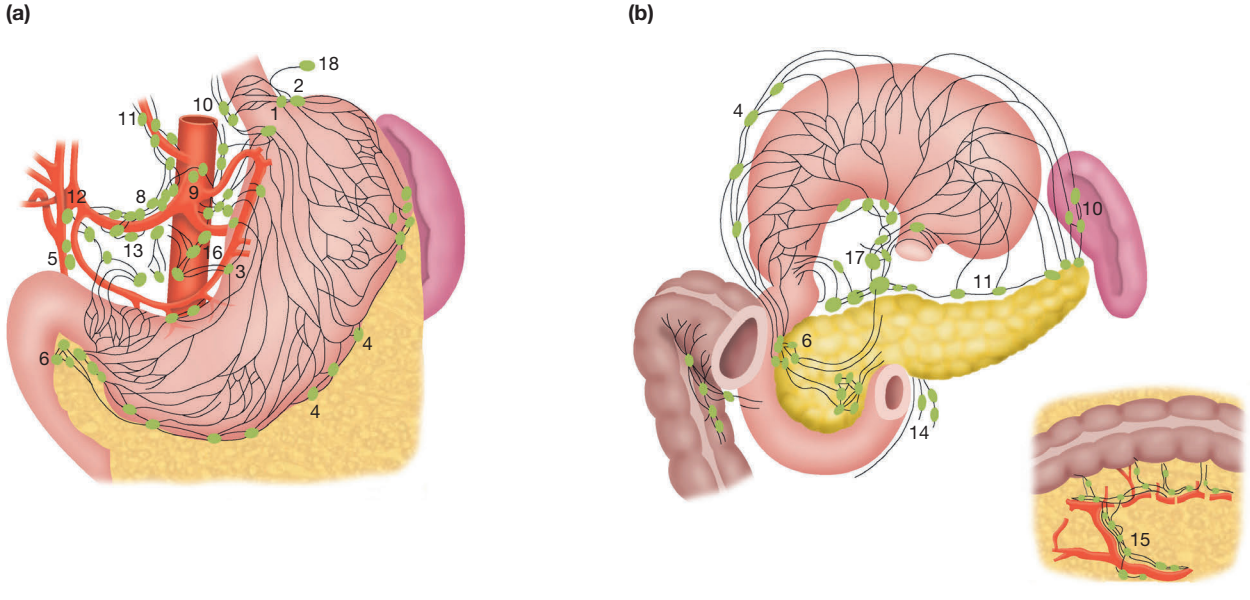

Figure 67.29 Lymphatic drainage of the stomach and nodal stations by the Japanese classification: **(a)** the anterior view of the stomach; **(b)** the posterior view.

Friedrich Ernest Krukenberg, 1870–1946, ophthalmologist, Halle, Germany, wrote a classic paper on malignant tumours of the ovary in 1896.
Sister Mary Joseph (Julia Dempsey), 1856–1939, Nursing Superintendent, St Mary's Hospital, Rochester, MN, USA, noted the presence of umbilical nodules in many patients with advanced gastric cancer. She drew this to the attention of Dr William Mayo, founder of the Mayo Clinic.

Total gastrectomy

This is best performed through a long upper midline incision. The stomach is removed en bloc, including the tissues of the entire greater omentum and lesser omentum (***Figure 67.30***). In commencing the operation, the transverse colon is completely separated from the greater omentum. The dissection may then be commenced proximally or, more usually, distally. The subpyloric nodes are dissected, and the first part of the duodenum is divided, usually with a surgical stapler. The hepatic nodes are dissected to clear the hepatic artery; this dissection also includes the suprapyloric nodes. The right gastric artery is divided at its origin from the hepatic artery. The lymph node dissection is continued to the origin of the left gastric artery, which is divided at its origin. Dissection is continued along the splenic artery, removing all nodes on the superior aspect of the pancreas and accessible nodes in the splenic hilum.

Separation of the stomach from the spleen, if it is not going to be removed, allows access to the nodal tissues around the upper stomach and GOJ. The oesophagus can then be divided at an appropriate point using a combination of stay sutures and a soft non-crushing clamp, usually of the right-angled variety. It is important that the resection margins are well clear of the tumour (>5 cm). Frozen section should be performed if involvement of either proximal or distal resection margin is in doubt.

Gastrointestinal continuity is reconstituted by means of a Roux loop. The alimentary limb of the Roux loop should be at least 50 cm long to avoid bile reflux oesophagitis. The simplest means of effecting the oesophagojejunostomy is to place a purse-string suture in the cut end of the oesophagus and, using a circular stapler introduced through the blind end of the Roux loop, staple the end of the oesophagus onto the side of the Roux loop. The blind open end of the Roux loop may then be closed either with sutures or with a linear stapler. Recent evidence supports long-term intestinal and nutritional benefits of construction of a jejunal pouch. The anastomosis can also be fashioned end to end. The Roux loop may be placed in either an antecolic or retrocolic position. The end-to-side jejunojejunostomy is undertaken at a convenient point (***Figure 67.31***).

The differentiation between a D1 and a D2 operation depends upon the tiers of nodes removed. Different tiers need to be removed depending on the positions of primary tumour (***Table 67.7***). In general, a D1 resection involves the removal of the perigastric nodes and a D2 resection involves the clearance of the major arterial trunks. In practice the majority of specialist centres will perform a radical total gastrectomy, conserving the spleen and pancreas, with D2 lymphadenectomy sparing station 10 lymph nodes.

Subtotal gastrectomy

For tumours in the distal stomach, it is unnecessary to remove the whole stomach. However, the operation is very similar to that of a total gastrectomy except that the proximal stomach is preserved, the blood supply being derived from the short gastric arteries. Following the resection, the simplest form of reconstruction is to close the stomach from the lesser curve, near the GOJ, with either sutures or staples and then perform an anastomosis of the greater curve to the jejunum. Although this can be performed as in a Billroth II/Pólya-type gastrectomy, this reconstruction may result in quite marked enterogastric reflux and bile reflux oesophagitis; the preferred reconstruction is to use a Roux loop.

Palliative surgery

In patients with significant symptoms of either obstruction or bleeding, palliative resection is appropriate. A palliative gastrectomy need not be radical as it is sufficient to remove the tumour and reconstruct the gastrointestinal tract. Sometimes it is impossible to resect an obstructing tumour in the distal stomach and other palliative procedures need to be considered. A high gastroenterostomy is a poor operation that very frequently does not allow the stomach to empty adequately and may produce the additional problem of bile reflux. A Roux loop with a wide anastomosis between the stomach and jejunum may be a better option, although even this may not allow the stomach to empty well. For inoperable tumours situated in the cardia, palliative intubation or stenting can be used (see ***Chapter 66***).

Postoperative complications of gastrectomy

Radical gastrectomy is complex major surgery and predictably there is a large number of potential complications of the operation. Leakage of the oesophagojejunostomy can often be managed conservatively as the Roux-en-Y reconstruction means that it is mainly saliva and ingested food that leaks. Some patients may establish a fistula from the wound or drain site and others may need radiologically or surgically placed drains. It is unusual to detect a major anastomotic leak in the absence of clinical signs and the use of postoperative water-soluble contrast swallows is no longer routine in most centres.

Leakage from the duodenal stump is usually due to a degree of distal obstruction and care must be taken to avoid kinking when performing the Roux-en-Y anastomosis. Paraduodenal collections can be drained radiologically, which may convert the collection into an external fistula. Biliary peritonitis requires a laparotomy and peritoneal toilet. In this circumstance it is best to leave a Foley catheter in the duodenum to establish a controlled duodenal fistula. If it is established that there is no distal obstruction, or if any such obstruction is managed, then the fistula will close with time.

The presence of septic collections along with a radical vascular dissection may lead to catastrophic secondary haemorrhage from the exposed or divided blood vessels. This situation may be very difficult to manage, whether or not reoperation or interventional radiology is employed.

Frederick Eugene Basil Foley, 1891–1966, urologist, St Paul Ramsey Medical Center, St Paul, MN, USA.

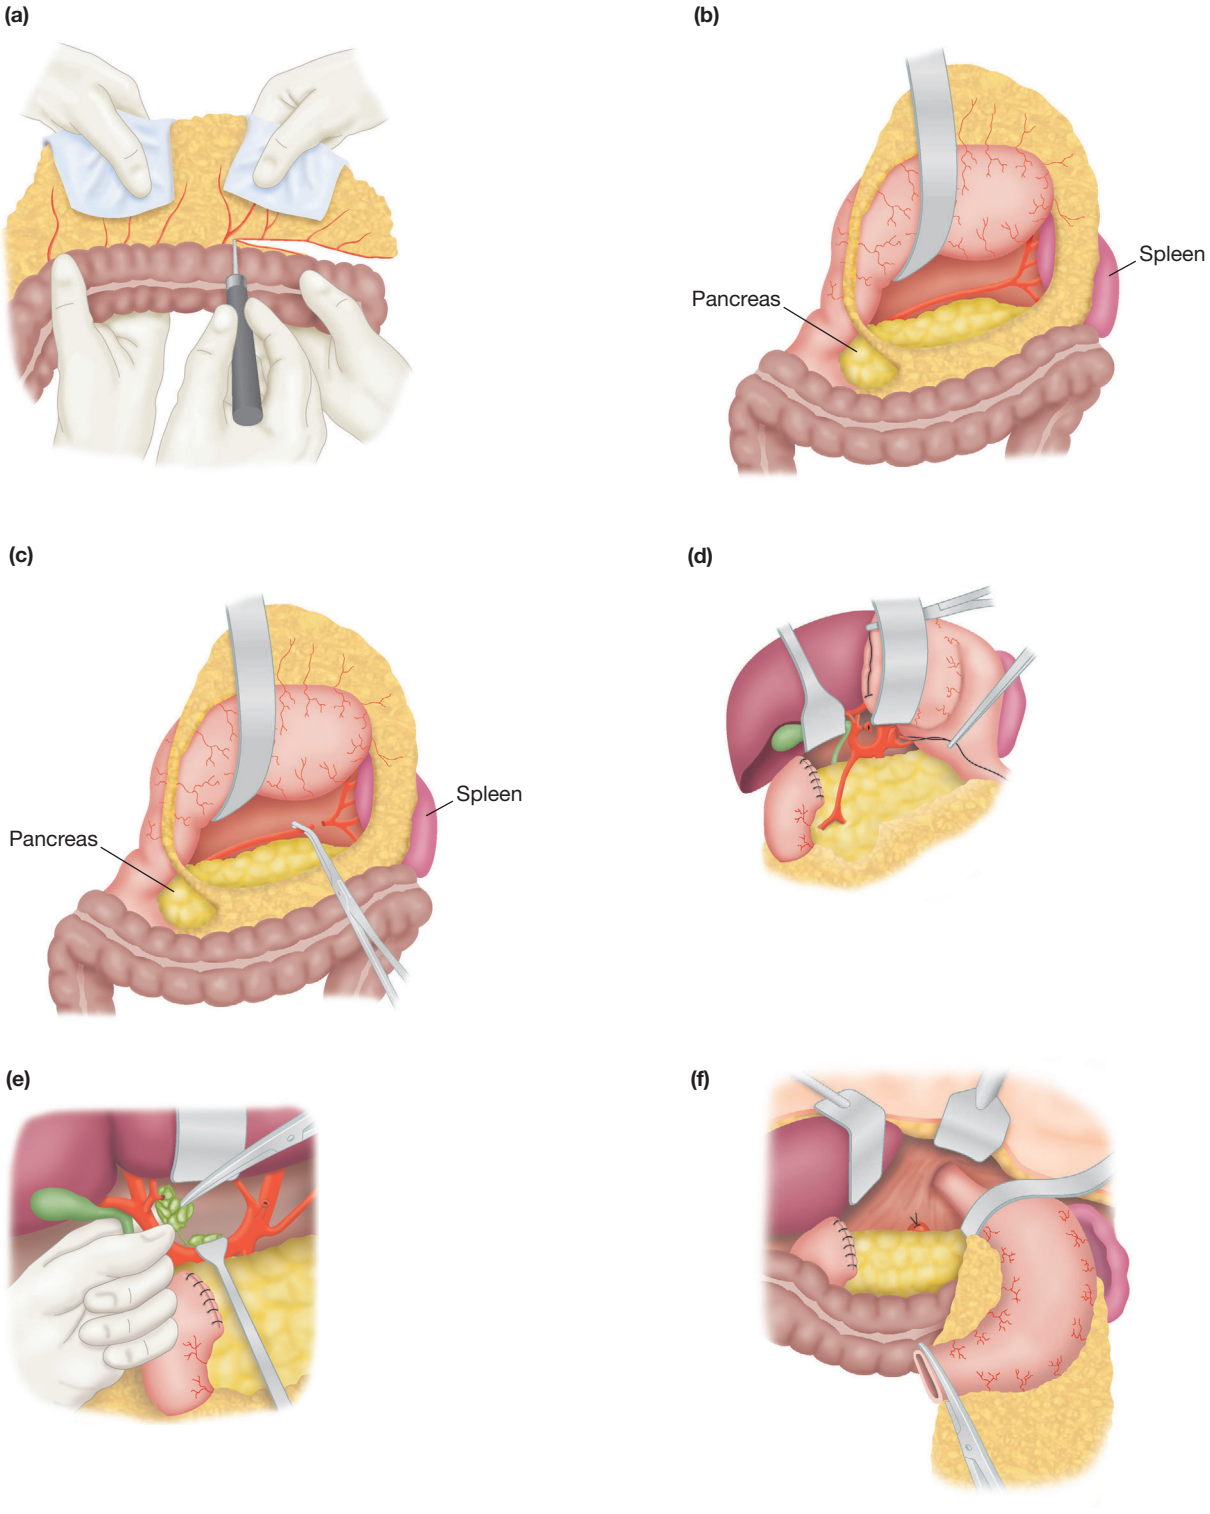

Figure 67.30 Radical total gastrectomy: **(a)** dissection of omentum off the transverse colon; **(b)** exposure of the lesser sac; **(c)** splenectomy; **(d)** division and oversewing of the duodenum; **(e)** dissection of the left gastric artery nodes (group 17); **(f)** mobilisation of the oesophagus.

Long-term complications of surgery

There is very little functional difference between patients who have a total gastrectomy and those who have a subtotal gastrectomy. Patients need to be given detailed nutritional advice, the substance of which is to eat small meals and often, while the jejunum or small gastric remnant adapts. Nutritional deficiencies may occur and loss of the parietal mass leads to vitamin B_{12} deficiency that requires replacement routinely.

TABLE 67.7 The lymph node stations (see ***Figure 67.30***) that need to be removed in a D1 (N1 nodes removed) or a D2 (N2 nodes removed) resection.

		Site of cancer			
Lymph node number		Antrum	Middle	Cardia	Cardia and oesophagus
1	Right cardia	N2	N1	N1	N1
2	Left cardia		N1	N1	N1
3	Lesser curve	N1	N1	N1	N1
4sa	Short gastric	N1	N1	N1	N1
4sb	Left gastroepiploic	N1	N1	N1	N1
4d	Right gastroepiploic	N1	N1	N2	N2
5	Suprapyloric	N1	N1	N2	N2
6	Infrapyloric	N1	N1	N2	N2
7	Left gastric artery	N2	N2	N2	N2
8a	Anterior hepatic artery	N2	N2	N2	N2
9	Coeliac artery	N2	N2	N2	N2
10	Splenic hilum		N2	N2	N2
11	Splenic artery		N2	N2	N2
19	Infradiaphragmatic				N2
20	Oesophageal hiatus			N2	N1
110	Lower oesophagus				N2
111	Supradiaphragmatic				N2

The nodes in stations 12–18 are not routinely removed in a D1 or D2 gastrectomy.

Outlook after surgical treatment

The outlook after surgical treatment varies considerably between the West and Japan. In Japan, approximately 75% of patients will have a curative resection and, of these, the overall 5-year survival rate is 50–70%. In contrast, in the West most series show that only 25–50% of patients undergoing surgery will have a curative operation and the 5-year survival rate in such patients is only about 25–30%, although in some series it approaches Japanese levels. A combination of differences in staging and a higher standard of surgery in Japan probably accounts for the differences. Staging is clearly crucial when survival figures are being compared and, therefore, stage for stage the outcome seems better in patients who are adequately staged pathologically. This phenomenon is termed 'stage migration'.

Other treatment modalities

Because of the failure of radical surgery to cure advanced gastric cancer, there has been an interest in the use of radiotherapy and chemotherapy.

Palliative radiotherapy

The routine use of radiotherapy is controversial as the results of clinical trials are inconclusive. There are a number of radiosensitive tissues in the region of the gastric bed, which limits the dose that can be given. Radiotherapy has a role in the palliative treatment of painful bony metastases.

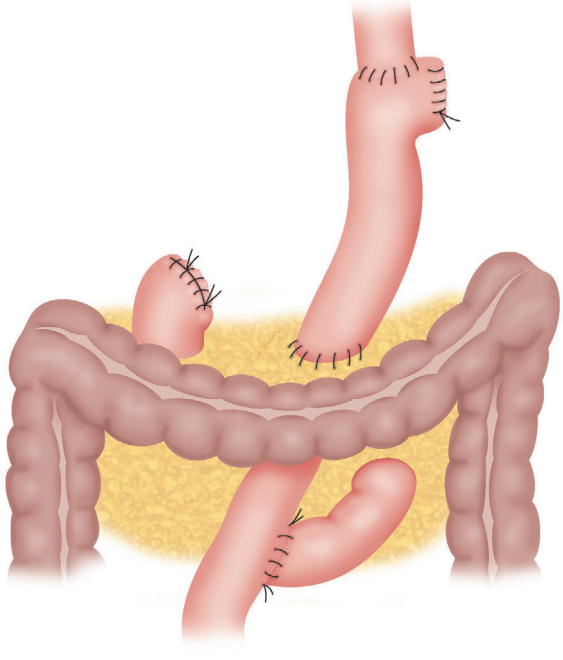

Figure 67.31 Oesophagojejunostomy Roux-en-Y.

Palliative chemotherapy

There are a number of regimes, but the best results are currently obtained using either platinum-containing triplet combinations or FLOT. Second-line treatment using combinations that

include docetaxel are increasingly being used. Chemotherapy for advanced disease is palliative. Newer biological agents such as trastuzumab (Herceptin) offer potential advantages to survival in the minority of patients (<20%) with *HER2*-positive gastric cancer. However, the absolute survival advantages are small (~4 months) and the cost of treatment is high. Nevertheless trastuzumab has been approved for use in metastatic *HER2*-positive gastric cancer in the UK and European Union.

Pattern of relapse following surgical treatment

The most common site of relapse following radical gastrectomy is the gastric bed, representing inadequate extirpation of the primary tumour. Widespread nodal intraperitoneal metastases, distant nodal metastases and liver metastases are all common. Dissemination to the lung and bones usually only occurs after liver metastases are already established.

GASTROINTESTINAL STROMAL TUMOURS

Gastrointestinal stromal tumours (GISTs) may arise in any part of the gastrointestinal tract but 50% will be found in the stomach. Previously named leiomyoma and leiomyosarcoma, the term GIST is now used, recognising the distinct phenotype. They are tumours of mesenchymal origin and are observed equally commonly in males and females. The tumours are universally associated with a mutation in the tyrosine kinase *c-kit* oncogene. These tumours are sensitive to the tyrosine kinase antagonist imatinib, and an 80% objective response rate can be observed. Tumours with mutations in exon 11 of *c-kit* are particularly sensitive to this drug. The biological behaviour of these tumours is unpredictable but size and mitotic index are the best predictors of metastasis. Peritoneal and liver metastases are most common but spread to lymph nodes is extremely rare.

The incidence of the condition is uncertain as small stromal tumours of the stomach are probably quite common and remain unnoticed. Clinically obvious tumours are considerably less common than gastric cancer. GISTs constitute 1–3% of all gastrointestinal neoplasia.

Many GISTs are noticed incidentally at endoscopy or diagnosed if the overlying mucosa ulcerates with bleeding and anaemia (***Figure 67.32***). Because the mucosa overlying the tumour is normal, endoscopic biopsy can be uninformative unless the tumour has ulcerated. Targeted biopsy by endoscopic ultrasonography is more helpful. Larger tumours present with non-specific gastric symptoms, and, in many instances, they may be thought to be gastric cancer initially (***Figure 67.33***).

As the biological behaviour is difficult to predict, the best guide is to consider the size of the tumour. Tumours over 5 cm in diameter should be considered to have metastatic potential. If easily resectable surgery is the primary mode of treatment. Smaller tumours can be treated by wedge excision although the appropriate management of asymptomatic diminutive tumours found incidentally at endoscopy is unclear. Larger tumours may require a gastrectomy or duodenectomy, but lymphadenectomy is not required. Larger tumours that require multivisceral resection may be better treated with 3–6 months of imatinib prior to operation as this will usually radically reduce the size and vascularity of the tumours. Adjuvant imatinib for resected tumours of high malignant potential should probably be continued indefinitely.

The prognosis of advanced metastatic GISTs has been dramatically improved with imatinib chemotherapy but resection of metastases has an important role.

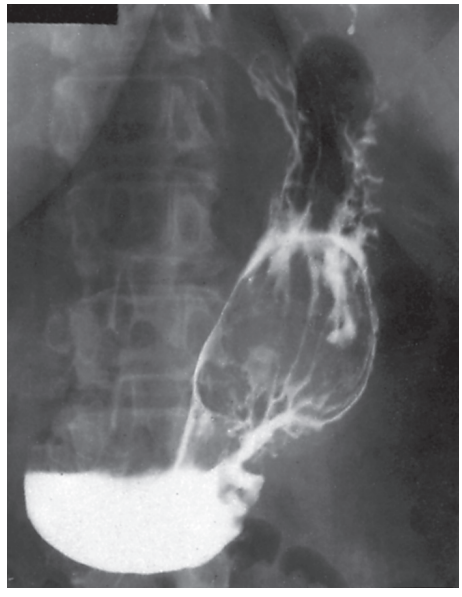

Figure 67.32 Gastrointestinal stomal tumour (GIST) on the greater curve of the stomach with ulceration.

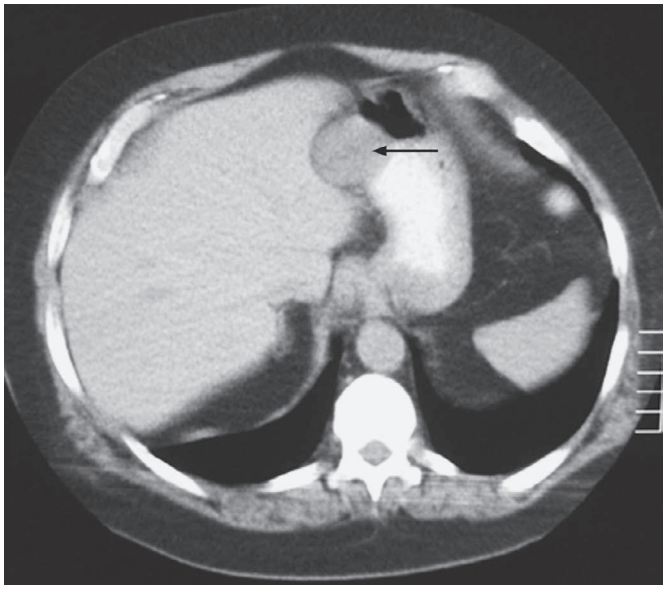

Figure 67.33 Computed tomography scan of the upper abdomen showing a 3.5-cm gastrointestinal stromal tumour arising from the gastric wall.

GASTRIC LYMPHOMA

Unlike gastric carcinoma, the incidence of lymphoma seems to be increasing. It is most common in the sixth decade and presentation is similar to that of gastric cancer. Acute presentation with haematemesis, perforation or obstruction is uncommon. Primary gastric lymphoma accounts for approximately 5% of all gastric neoplasms. It is important to distinguish primary gastric lymphoma from the more common involvement of the stomach in a diffuse lymphoma.

Primary gastric lymphomas are B-cell derived, the tumour arising from mucosa-associated lymphoid tissue (MALT). Primary gastric lymphoma remains in the stomach for a prolonged period before involving lymph nodes. At an early stage, the disease takes the form of a diffuse mucosal thickening, which may ulcerate. Diagnosis is made as a result of the endoscopic biopsy and seldom on the basis of the endoscopic features alone, which are not specific.

Following diagnosis, adequate staging is necessary, primarily to establish whether the lesion is a primary gastric lymphoma or part of a more generalised process. CT scans of the chest and abdomen and bone marrow aspirate are required.

Although the treatment of primary gastric lymphoma is somewhat controversial, it seems most appropriate to use surgery alone for localised disease. Chemotherapy is appropriate for patients with systemic disease. Lymphocytes are not found to any degree in normal gastric mucosa but are found in association with *Helicobacter* infection. Early gastric lymphomas may regress and disappear when the *Helicobacter* infection is treated. Patients with gastric involvement of a diffuse lymphoma are treated with chemotherapy, sometimes with dramatic and rapid responses. The two common surgical complications are bleeding and perforation. Both may follow the chemotherapy when there is rapid regression and normally require gastrectomy.

DUODENAL TUMOURS

Benign duodenal tumours

Duodenal villous adenomas occur principally in the periampullary region. Although generally uncommon, they are often found in patients with FAP. The appearances are similar to those adenomas arising in the colon and, as they have malignant potential, they should be locally excised with histologically clear margins.

Duodenal adenocarcinoma

Most duodenal tumours originate in the periampullary region and commonly arise in pre-existing villous adenomas. Patients present with anaemia due to ulceration of the tumour or obstruction. Direct involvement in the ampulla leads to obstructive jaundice. Histologically, the lesion is an adenocarcinoma. Metastases are commonly to regional lymph nodes and the liver. At presentation, about 70% of patients have resectable disease with an expected 5-year survival rate of approximately 20%. Poor prognostic features include regional lymph node metastases, transmural involvement and perineural invasion. Curative surgical treatment will normally involve a pancreaticoduodenectomy (Whipple's procedure). Patients with FAP, which is due to a mutation in the *APC* gene on chromosome 5, are predisposed to periampullary cancer, which is one of the most common causes of death in patients who have had their colon removed. Other duodenal malignancies include GISTs (see ***Gastrointestinal stromal tumours***) and neuroendocrine tumours.

Summary box 67.7

Duodenal tumours

- Duodenal villous adenomas are commonly found around the ampulla of Vater and are premalignant
- The duodenum is the most common site for adenocarcinoma of the small intestine
- Regular endoscopic screening is advisable in patients with FAP
- Pancreatic cancer is the most common cause of duodenal obstruction

Neuroendocrine tumours

A number of neuroendocrine neoplasms occur in the duodenum. It is a common site for primary gastrinoma (Zollinger–Ellison syndrome). Non-functioning neuroendocrine tumours (usually called carcinoid tumours) also occur but uncommonly in comparison with the ileum.

Zollinger–Ellison syndrome

This syndrome is mentioned here because the gastrin-producing endocrine tumour is often found in the duodenal loop, although it also occurs in the pancreas, especially the head. It is a cause of persistent peptic ulceration. Before the development of potent gastric antisecretory agents, the condition was recognised by sometimes fulminant peptic ulceration that did not respond to gastric surgery short of total gastrectomy. The advent of PPIs such as omeprazole has rendered this extreme endocrine condition fully controllable, but also less easily recognised.

Gastrinomas may be either sporadic or associated with the autosomal dominantly inherited multiple endocrine neoplasia (MEN) type I (in which a parathyroid adenoma is almost invariable). The tumours are most commonly found in the 'gastrinoma triangle', which is defined by the junction of the cystic duct and common bile duct superiorly, the junction of the second and third parts of the duodenum inferiorly and the junction of the neck and body of the pancreas medially (essentially the superior mesenteric artery). Many are found in the duodenal loop, presumably arising in the G cells found in Brunner's glands. It is extremely important that the duodenal wall is carefully inspected endoscopically and at operation.

Abraham Vater, 1684–1751, Professor of Anatomy and Biology, Wittenberg, Germany.
Allen Oldfather Whipple, 1881–1963, surgeon, Columbia-Presbyterian Medical Center, New York, NY, USA.

Very often all that can be detected is a small nodule that projects into the medial wall of the duodenum.

Even malignant sporadic gastrinomas may have a very indolent course. The palliative resection of liver metastases may be beneficial and, as for other gut endocrine tumours, liver transplantation is practised in some centres with reasonable long-term results. However, a minority of tumours found to the left of the superior mesenteric artery (outside the 'triangle') seem to have a worse prognosis, with more having liver metastases at presentation. In MEN type I, the tumours may be multiple and the condition is incurable. Even in this situation, surgical treatment should be employed to remove any obvious tumours and associated lymphatic metastases, as good palliation may be achieved (see ***Chapter 57***).

DUODENAL OBSTRUCTION

Duodenal obstruction in adults is usually due to malignancy, and cancer of the pancreas is the most common cause. Treatment is usually by gastroenterostomy, but duodenal stenting is increasingly being used. In patients having a surgical biliary bypass for pancreatic cancer, gastric drainage may be necessary.

A variety of other malignancies can cause duodenal obstruction, including metastases from colorectal and gastric cancer. Primary duodenal cancer is much less common as a cause of obstruction than these other malignancies.

Annular pancreas may rarely cause duodenal obstruction. Obstruction usually follows an attack of pancreatitis, and, on occasions, the obstruction may be mistaken for malignancy.

Arteriomesenteric compression is an ill-defined condition in which it is proposed that the fourth part of the duodenum is compressed between the superior mesenteric artery and the vertebral column; when it is convincingly demonstrated and causing weight loss, duodenojejunostomy may be performed.

OTHER GASTRIC CONDITIONS

Acute gastric dilatation

This condition usually occurs in association with pyloroduodenal disorders or following abdominal surgery. The stomach dilates enormously. The patient may be dehydrated and have electrolyte disturbances. Failure to treat can result in a sudden vomit with aspiration into the lungs. Treatment is nasogastric suction with a large-bore tube, fluid replacement and treatment of the underlying condition.

Trichobezoar and phytobezoar

Trichobezoar (hair balls) (***Figure 67.34***) are unusual and are virtually exclusively found in young psychiatric patients. It is caused by the ingestion of hair, which remains undigested in the stomach. The hair ball can lead to ulceration and gastrointestinal bleeding, perforation or obstruction. The diagnosis is made easily at endoscopy. Treatment consists of removal of the bezoar, which may require open surgical treatment. Phytobezoars are made of vegetable matter and are found principally in patients who have gastric stasis, usually following gastric surgery.

Figure 67.34 Trichobezoar of the stomach in a girl aged 15 years.

Foreign bodies in the stomach

A variety of ingested foreign bodies reach the stomach, and very often these can be seen on a plain radiograph. If possible, they should be removed endoscopically but, if not, most can be left to pass normally. Even objects such as needles, with which there is understandable anxiety, will seldom cause harm. In general, an object that leaves the stomach will pass spontaneously. In contrast, attempted removal at laparotomy can be very difficult as the object may be much more difficult to find than might be expected. Most adults who swallow foreign bodies have psychiatric problems and may appear to relish the attention associated with serial laparotomies. The treatment should therefore be expectant, and intervention reserved for patients with symptoms in whom the foreign body is failing to progress.

Volvulus of the stomach

Rotation of the stomach usually occurs around the axis and between its two fixed points, i.e. the cardia and the pylorus. In theory, rotation can occur in the horizontal (organoaxial) or vertical (mesenteroaxial) direction, but the former is more common. Volvulus is usually associated with a large diaphragmatic defect around the oesophagus (paraoesophageal herniation) (***Figure 67.35***). Commonly the transverse colon moves upwards to lie under the left diaphragm, taking the stomach with it. The stomach and colon may both enter the chest through the eventration of the diaphragm. The condition is commonly chronic, the patient presenting with difficulty in eating. An acute presentation with ischaemia may occur. Endoscopically, it can be extremely difficult to identify the anatomy, and this is one situation in which the contrast radiograph is superior.

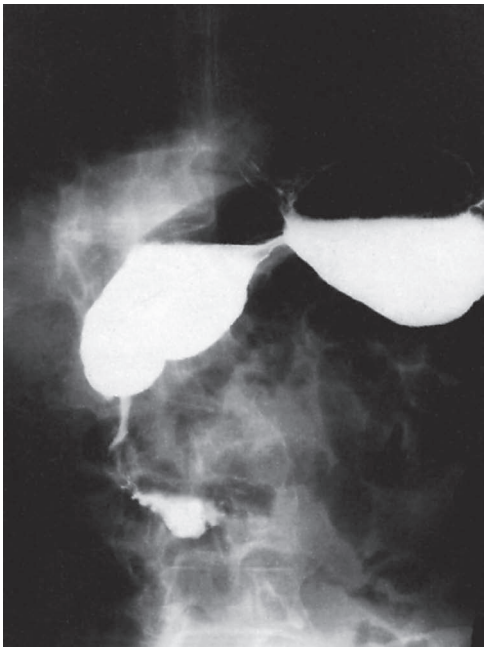

Figure 67.35 Barium meal showing organoaxial volvulus of the stomach associated with eventration of the diaphragm.

Treatment

If symptomatic, surgical treatment is required increasingly by a laparoscopic approach. If there is a hernia, the sac and its contents (usually the stomach) should be reduced. The defect in the diaphragm should be closed, if necessary, with a mesh. It is advisable to separate the stomach from the transverse colon and to perform an anterior gastropexy to fix the stomach to the anterior abdominal wall.

PART 11 | Abdominal

CHAPTER
68 Bariatric and metabolic surgery

Learning objectives

To know and understand:

- How to treat obesity as a disease
- Rationale for surgery and the concept of metabolic surgery
- Eligibility and NICE guidelines
- Multidisciplinary assessment and multimodal treatment
- The common operations and how they work
- How to assess and treat perioperative complications
- Follow-up, nutritional supplements and biochemical monitoring

INTRODUCTION

Obesity is becoming the plague of the twenty-first century. With overweight becoming the norm in most Western countries and developing countries, two-thirds of adults suffer from overweight or obesity (***Table 68.1***). Every clinician and definitely every surgeon faces the condition and its associated diseases, such as type 2 diabetes, as part of their practice. According to the World Health Organization (WHO), overweight and obesity are defined as abnormal or excessive fat accumulation that may impair health. For adults, WHO defines overweight as a body mass index (BMI) of 25 kg/m^2 or more and obesity as a BMI of 30 kg/m^2 or more. Severe obesity increases the risk of cancer, is associated with multiple other diseases, affects quality of life and reduces life expectancy by 5–20 years. Severe and complex obesity is a phrase commonly used for patients with BMI ≥35 kg/m^2 and obesity-related disease, or BMI ≥40 kg/m^2 by itself (***Table 68.2***).

Overweight and obesity can be considered normal physiological responses to the current food environment. Few people with obesity have a single identifiable genetic or hormonal basis. *MC4R* deficiency represents the most common genetic form of severe obesity, with heterozygous mutations in *MC4R* detected in up to 5% of patients with severe, early-onset obesity. Surgeons encounter the challenge of obesity on a daily basis as it affects the treatment of nearly every abdominal pathology in terms of approach and outcomes.

Obesity is a heterogeneous disease and the response of individuals seeking treatment to different therapeutic modalities is variable. Currently there are no available robust tools to predict this response. Therefore a trial of options is required. The principles of therapeutic interventions for all other diseases are applicable, including escalation of treatment, cessation of modalities that are not effective and addition of therapy when the response is insufficient or transient. Lifestyle modifications, supervised interventions, pharmacotherapy, bariatric surgery and bariatric surgery combined with pharmacotherapy are available interventions. It is important to stress that the response is a biological phenomenon and not a volitional one.

TABLE 68.1 Definitions of overweight and obesity.[a,b]

Adult weight status	BMI (kg/m^2)
Normal	18.5–24.9
Overweight	25.0–29.9
Class 1 obesity	30.0–34.9
Class 2 obesity	35.0–39.9
Class 3 obesity	≥40.0

Body mass index (BMI) = weight (kg)/height (m)^2
[a]Obesity for children is defined as BMI at or above the 95th centile.
[b]'Super-obesity' is a term commonly used to describe BMI ≥49.9 kg/m^2.

TABLE 68.2 Conditions that are associated with severe and complex obesity.

Type 2 diabetes
Hypertension
Dyslipidaemia
Obstructive sleep apnoea
Arthritis and functional impairment
Gastro-oesophageal reflux disease
Non-alcoholic fatty liver disease/non-alcoholic steatohepatosis
Polycystic ovary syndrome
Clinical depression
Various cancers, in particular endometrial cancer

Bariatric surgery comes from the Greek 'baros' (meaning weight/pressure) and 'iatric' (the medicine or surgery thereof).

Bariatric surgery is the branch of surgery involving manipulation of the stomach and/or small bowel to achieve weight loss and control of obesity-related disease.

RATIONALE

Bariatric surgery leads to weight loss of 25–35% of body weight (usually at least 15 kg) after 1 year, and sustained weight loss maintenance at 15–25% after 20 years. Additional benefits are that most or all of the obesity-related diseases improve as weight is lost and even independently of weight loss. Quality of life improves. A number of randomised controlled trials (RCTs) have reported on the outcomes of bariatric surgery versus intensive lifestyle interventions, and all favour surgery. The longest follow-up in an RCT is 5 years. However, the non-randomised Swedish Obese Subjects (SOS) study has now shown sustained weight loss and improvement in obesity-related disease up to 20 years after surgery. In this study 2010 patients who chose to have surgery were compared with 2037 controls who did not.

When the SOS study was conceived in 1987 all surgery was done by laparotomy and it was considered unethical to attempt to randomise patients between best medical therapy and bariatric surgery. All had best medical care throughout and follow-up was better than 99%. The SOS study was among the first to demonstrate that bariatric surgery also leads to survival benefit. The primary end point was overall mortality and a significant difference was found at a mean follow-up of 10 years. Many other studies have now found similarly, including one of nearly 8000 operated patients from Utah.

The Utah study was the first large study to show improved survival after gastric bypass surgery compared with matched population controls. The SOS study also reported a lower incidence of both microvascular and macrovascular complications at 15 years of follow-up in the surgical group. The Swedish registry (SOREG) data indicate lower mortality within only 3–4 years after surgery in patients with type 2 diabetes. Both the SOS and Utah studies have shown that bariatric surgery also effectively reduces cancer risk in large patient cohorts.

Rationale for surgery

Owing to the tendency for basal metabolic rate to decrease with dietary calorie restriction most people will regain all their weight, returning to the previous homeostatic set point. Bariatric surgery appears to alter this mechanism and 'reset' this point, with 15–25% weight loss maintenance for up to 20 years. Despite the fact that bariatric surgery leads to long-term survival benefit and improves obesity-related disease and quality of life, it is available to only a fraction of the individuals who could potentially benefit. This is largely because of inequalities in healthcare prioritisation, misconceptions and obesity stigma. Person-first language should always be used ('patient with obesity' or 'patient with diabetes') to avoid categorising patients as the disease, to reduce stigma.

Summary box 68.1

Rationale for surgery

- Because of the tendency for basal metabolic rate to decrease with dieting, most people will regain all their weight, returning to the previous homeostatic set point
- Bariatric surgery appears to alter this mechanism and 'reset' this point, with 15–25% weight loss maintenance for up to 20 years
- Bariatric surgery leads to long-term survival benefit and improves obesity-related disease and quality of life

METABOLIC SURGERY

The phrases 'metabolic' or 'diabetes' surgery are increasingly being used in conjunction with, or instead of, 'bariatric surgery' owing to the highly effective way that surgery improves the metabolic syndrome, with weight loss being a welcome additional effect. Type 2 diabetes is part of the 'metabolic syndrome', which includes high blood pressure, dyslipidaemia and polycystic ovary syndrome.

Control of type 2 diabetes improves with weight loss owing to an improvement in insulin resistance. Remarkably, diabetes control appears to improve after several types of bariatric surgery *before* meaningful weight loss occurs. Some of the effects on glucose metabolism can be attributed to caloric restriction, but changes in gut hormones levels, particularly glucagon-like-peptide 1 (GLP-1), have provoked much interest. GLP-1 is an incretin, a gut hormone that stimulates the beta cells in the pancreas to restore the normal first-phase insulin response after eating. Bile acids are also involved in this.

Although type 2 diabetes is a chronic disease and bariatric surgeons in the early 2000s initially claimed to 'cure' it, the emphasis has now changed to improving glycaemic control by lowering glycated haemoglobin (HbA1c) and improving insulin resistance, with the ultimate goal of reducing cardiovascular risk and improving survival. The term diabetes 'remission' is now commonly used by bariatric surgeons and endocrinologists, and is defined as patients being off all medication with normal glucose homeostasis. In the SOS study, patients with diabetes went into remission after surgery, and in patients without diabetes there was a decreased incidence of patients developing diabetes.

Summary box 68.2

Metabolic surgery

- The term **metabolic surgery** refers to the marked effects of surgery on diabetes and the metabolic syndrome, which may have a more important impact than weight loss itself
- Improvement in type 2 diabetes may be additional to weight loss
- Surgery is very cost-effective

COST-EFFECTIVENESS

A 2009 Health Technology Assessment report in the UK showed bariatric surgery to be cost-effective compared with non-surgical options. The incremental cost-effectiveness ratio (ICER) compared with no surgery was between £2000 and

£4000 per quality-adjusted life year (QALY) gained for patients with BMI ≥40 kg/m^2 over 20 years. For patients with BMI between 30 and <40 kg/m^2 the ICER was £1367 per QALY gained. Regarding maximum willingness to pay, compared with non-surgical interventions, if a decision-maker is willing to pay £20 000 for an additional QALY, then the probability of surgery being cost-effective over a 20-year time horizon was reported as 100%. The ICERs are similar to the cost-effectiveness of stopping smoking and routine statin therapy for the primary prevention of cardiovascular disease. In practice it means that the cost of the operation is recouped within 1–2 years after surgery from reduced medication costs. All the cost-effectiveness studies assess direct or indirect healthcare costs but not the additional benefits of surgery. Thus, return to paid work, coming off state benefits, improved functional capacity and quality of life are 'add-ons' that incur no cost. A systematic review including studies up to 2018 confirmed that bariatric surgery is cost saving over a lifetime. Medication costs for obesity-related comorbidities are substantially reduced after bariatric surgery in the shorter term.

ELIGIBILITY

Eligibility criteria were first proposed by the US National Institutes of Health in 1991, when the obesity epidemic was first recognised. All bariatric surgery was done by open laparotomy, and the safety profile was very different. The National Institute for Health and Care Excellence (NICE) in the UK recommends consideration of bariatric surgery for people with severe obesity in whom all non-surgical measures have been tried with no adequate weight loss achieved or maintained. Commitment to long-term follow-up and behaviour change are also advised. After a review of recent RCTs, NICE updated its guidance and lowered the BMI threshold to 30 kg/m^2 for recent-onset type 2 diabetes (***Table 68.3***). The criteria according to the International Federation for the Surgery of Obesity and Metabolic Disorders (IFSO) Asia Pacific chapter for Asian patients include lower BMI thresholds because of the susceptibility of Asian populations to type 2 diabetes at a lower BMI.

TABLE 68.3 Summary of updates to National Institute for Health and Care Excellence (NICE) guidance on bariatric surgery, 2014 (CG189).

Bariatric surgery is a treatment option for anyone with BMI ≥40 kg/m^2
Offer an expedited assessment for people with BMI ≥35 kg/m^2 with onset of type 2 diabetes in past 10 years
Consider an assessment for people with BMI of 30–34.9 kg/m^2 with onset of type 2 diabetes within 10 years
Consider an assessment for people of Asian origin with onset of type 2 diabetes at a lower BMI than other populations
Bariatric surgery is the option of choice for adults with BMI >50 kg/m^2 when other interventions have not been effective
People fitting the above criteria are also required to be receiving or to receive assessment in a specialist weight management service before referral to a surgical team

BMI, body mass index.

TABLE 68.4 National Institute for Health and Care Excellence (NICE)-accredited guidance on the make-up of the medical and surgical bariatric multidisciplinary team.

Bariatric physician in primary (can be the general practitioner) or secondary care (usually a diabetologist)
Dietician
Specialist nurse
Appropriately trained mental health professional
Bariatric surgeon
Anaesthetist
Radiologist
± Exercise therapists
Other secondary care specialties, e.g. respiratory/sleep medicine, cardiology

NICE estimated that about 80% of people fulfilling the eligibility criteria would have no medical or psychological reason why they would not be fit for surgery. An estimate is that perhaps 10% of these might want it, if bariatric/metabolic surgery were to be promoted or recommended by physicians to patients.

PRINCIPLES OF SETTING UP A BARIATRIC/METABOLIC SURGERY SERVICE

As for gastrointestinal cancer surgery where a number of different specialists routinely work together, it is now agreed that 'bariatric physicians/internists', dieticians, mental health professionals and nurse practitioners should be part of the team assessing and managing long-term care after bariatric surgery (***Table 68.4***). The perioperative risk of surgery is low; however, outcomes can be improved further with appropriate multidisciplinary team (MDT) work-up. Using risk scores such as the Edmonton Obesity Staging System (EOSS) and the Obesity Surgery–Mortality Risk Score (OS-MRS) can help the team discuss with patients the likely prognosis without surgery, and the risk of complications. The OS-MRS scores one point for each of: age 45 or more; BMI 50 kg/m^2 or more; male gender (owing to central obesity); hypertension (owing to central obesity); and increased deep vein thrombosis (DVT)/pulmonary embolism (PE) risk. The more points that are present, the greater the risk. Swedish registry data indicate that obstructive sleep apnoea (OSA) is a risk factor for anastomotic leak. Therefore OSA should be actively investigated as treatment with continuous positive airway pressure might reduce risk. Poorly controlled diabetes must also be considered a risk factor, as it is for all other operations.

Better surgical results are likely in high-volume surgical units. IFSO and the American Society for Metabolic and Bariatric Surgery (ASMBS) recommended 100–125 cases per year, and there should be at least two surgeons each performing 50 or more cases. Surgeons early in the learning curve (about 100 for gastric bypass) need to be mentored before independent practice. Irrespective of the technical expertise of each surgeon, higher volumes usually mean that there are sufficient

MDT members available to provide support and follow-up. Each unit should have expertise in a variety of surgical procedures, including revisions.

It is routine to put patients on a 'liver shrinkage diet' for at least 2 weeks before surgery, especially when there is central obesity, as this is associated with a large liver that can make surgery impossible. Male patients, especially those with central obesity, a very dense/hard abdomen, OSA/diabetes and BMI >50 kg/m^2, may need more, supervised, mandatory weight loss to make surgery safe.

Although not stipulated in any national guidance, every successful bariatric unit depends on active patient support groups and preoperative education sessions, which are best run by bariatric nurses and dieticians. These are invaluable in preparing patients for surgery, and it is difficult to conceive how a programme can run without them. Also, the ward and outpatient environment must be suitably equipped for patients with severe obesity.

Summary box 68.3

Multidisciplinary assessment

- Every patient should be assessed and managed by a coherent and well-functioning team of healthcare professionals with varied backgrounds and expertise
- Improved outcomes are usually achieved in high-volume specialised units
- Data collection and submission to national registries are recommended to provide quality assurance and long-term outcomes

Laparoscopic surgery and enhanced recovery

Bariatric surgery has been transformed by its amenability to laparoscopic techniques, including intracorporeal suturing and modern laparoscopic stapling devices. Probably equally important is the adoption of enhanced recovery after surgery (ERAS) protocols, with preoperative education, avoidance of catheters, central venous and arterial lines and early mobilisation. Free access to fluids is routine immediately after surgery and, because of the relative lack of pain, patients can mobilise straightaway. It is usual for gastric bypass and sleeve gastrectomy patients to go home on postoperative day 2 or 3. Gastric banding patients can be treated as day cases or can go home within 24 hours. The main cause of death after surgery is DVT/PE rather than anastomotic leakage or bleeding; appropriate prophylaxis is usually used for at least a week.

Randomised controlled trial evidence for the different types of surgery

Some evidence suggests that weight loss is more with a Roux-en-Y gastric bypass than sleeve gastrectomy. However, bariatric surgery needs more RCTs comparing different procedures with long-term follow-up. One of the challenges is keeping the research question relevant given the rapidity with which surgeons adopt different techniques. Long-term, large-scale, pragmatic RCTs with good follow-up are needed to inform practice. The By-Band-Sleeve study is an ongoing pragmatic, multicentre, three-arm RCT in the UK assessing weight loss and quality of life at 3 years between gastric bypass, gastric banding and sleeve gastrectomy in 1341 patients; it is expected to report in 2023.

Summary box 68.4

Evidence for the different operations

- Usually the operation choice is guided by patient, surgeon and unit preference
- Well-conducted RCTs comparing the different operations, with comprehensive follow-up, are needed
- Bariatric surgeons and bariatric surgical units should be recording their outcomes, ideally in a registry

The common operations

According to the IFSO Global Registry, in 2018 sleeve gastrectomy constituted 46%, gastric bypass 38%, one-anastomosis gastric bypass procedures 7.6% and gastric banding 5% of procedures. Other procedures include the biliopancreatic diversion (BPD) procedure and its duodenal switch variant (BPD/DS). The variety of procedures usually reflects surgeons' expertise and surgeons' and patients' preferences, as there are no RCTs beyond 5 years comparing different operations. Sleeve gastrectomy is now the most common operation and has gained rapid popularity at the expense of gastric banding and to a lesser extent gastric bypass. Some clinical outcomes are shown (***Table 68.5***). The mechanism of action of most weight-loss procedures remains incompletely understood.

TABLE 68.5 Malabsorption, per cent excess weight loss (% EWL)[a] and diabetes remission after bariatric surgery.

	Protein/ calorie malabsorption	3-year % EWL	3-year % diabetes remission
Sleeve gastrectomy	No	50–60%	50%
Gastric bypass	No	50–60%	50%
OAGB	Yes	60–80%	80%
Gastric band	No	40–50%	20%
BPD/DS, SADI-S	Yes	70–80%	80%

BPD, biliopancreatic diversion; DS, duodenal switch; OAGB, one-anastomosis gastric bypass; SADI-S, single-anastomosis duodenoileal bypass with sleeve gastrectomy.

[a] %EWL refers to the excess weight lost above a notional upper normal body mass index of 25 kg/m^2. Per cent weight loss is another way of measuring weight change, preferred by physicians.

César Roux, 1857–1934, surgeon, Lausanne, Switzerland.

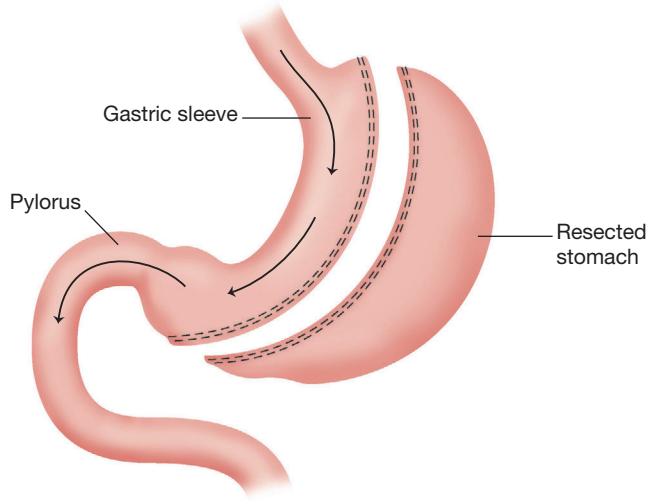

Figure 68.1 Sleeve gastrectomy. (Adapted from Griffin SM, Raimes SA, Shenfine J. *Oesophagogastric surgery*, 5th edn. London: Saunders Elsevier, 2013.)

Reduced appetite and early satiety are common features that are potentially explained by changes in levels of gut hormones such as peptide YY (PYY) and GLP-1 and how these interact with the brain.

Sleeve gastrectomy

Sleeve gastrectomy (***Figure 68.1***) is less challenging to perform than gastric bypass. It evolved from the magenstrasse and mill operation, in which the divided fundus (the 'mill') was left in continuity with the lesser curve-based tube (the 'main street'). Initially, it was done as the first step of a duodenal switch operation; however, it was found to be effective on its own without the switch (see ***Biliopancreatic diversion/duodenal switch***).

The lesser curve-based gastric tube is constructed over a size 32–36Fr bougie, although some surgeons advocate use of larger sizes to reduce the risk of staple line leakage. Linear stapling devices are used. There is variation in the techniques employed between how wide the staplers should be and whether reinforcement strips should be used. The Achilles heel of the sleeve is the risk of a staple line leak at the angle of His, which can take months to heal owing to the high-pressure system in the stomach with an intact pylorus. Another concern in the long term is symptomatic reflux and *de novo* Barrett's oesophagus (see ***Chapter 66***). A proportion of patients will need revisional surgery in future for weight regain.

The mechanism of action is still being investigated. The initial belief that sleeve gastrectomy acts as a restrictive procedure has been challenged by studies which that show gastric emptying is accelerated rather than delayed after sleeve gastrectomy. A change in satiety gut hormones and bile salt metabolism, similar to those described after gastric bypass, may explain some of the phenomena observed.

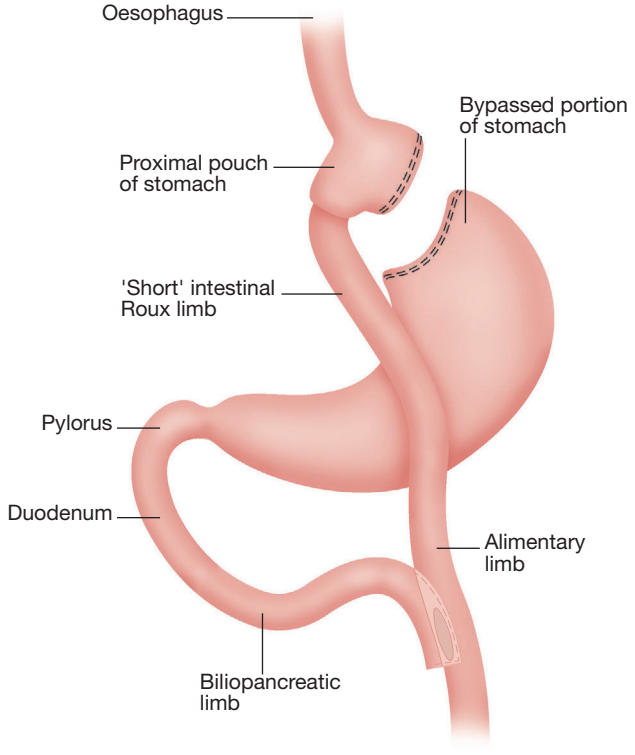

Figure 68.2 Gastric bypass showing a short vertical lesser curve-based gastric pouch with a Roux-en-Y jejunojejunostomy reconstruction. (Adapted from Griffin SM, Raimes SA, Shenfine J. *Oesophagogastric surgery*, 5th edn. London: Saunders Elsevier, 2013.)

Roux-en-Y gastric bypass

Despite the variety in laparoscopic techniques described and the lack of standardisation, most agree that Roux-en-Y gastric bypass (***Figure 68.2***) should include a short vertical lesser curvature-based gastric pouch. The techniques available for construction of the pouch-jejunostomy are linear stapler with suture closure of the defect, circular stapler and entirely hand sewn. It is routine to perform a leak test. The Roux limb can be retro- or antecolic. There is no standard length of the biliary and Roux limbs; however, the biliary limb is usually kept short to reduce vitamin and mineral deficiencies and the Roux limb length is varied between 100 and 150 cm. There are no consistent data regarding the effect of different limb lengths on weight loss. Bowel continuity is restored by a 'Y' jejunojejunostomy, which is either stapled with suture closure of the defect or stapled in its entirety.

It is now recognised that the mechanism of action is complex. Patients lose weight, at least in part, because they eat less owing to a change in appetite, which is facilitated by a change in satiety gut hormones. Other mechanisms such as changes in energy expenditure and change in food preferences may also play a role.

Wilhelm His, 1831–1904, Professor of Anatomy, Leipzig, Germany.
Norman Rupert Barrett, 1903–1979, surgeon, St Thomas' Hospital, London, UK.

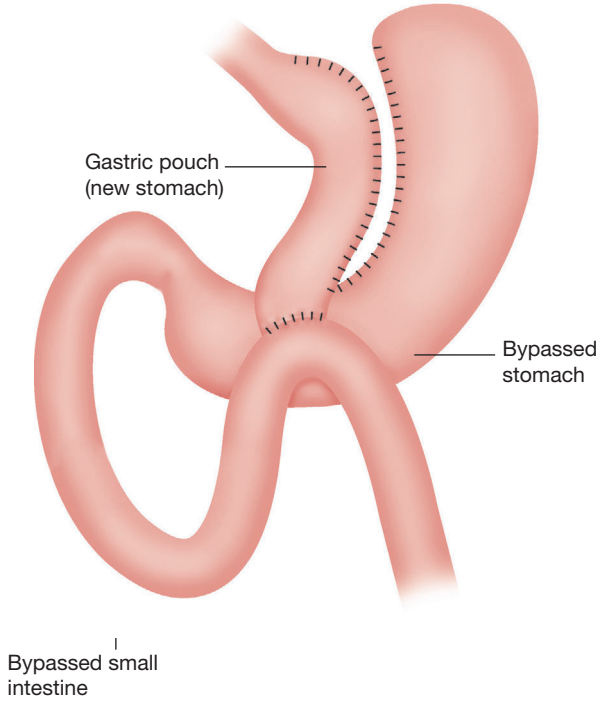

Figure 68.3 Gastric bypass showing a longer vertical lesser curve-based gastric pouch with gastrojejunostomy reconstruction (one-anastomosis gastric bypass).

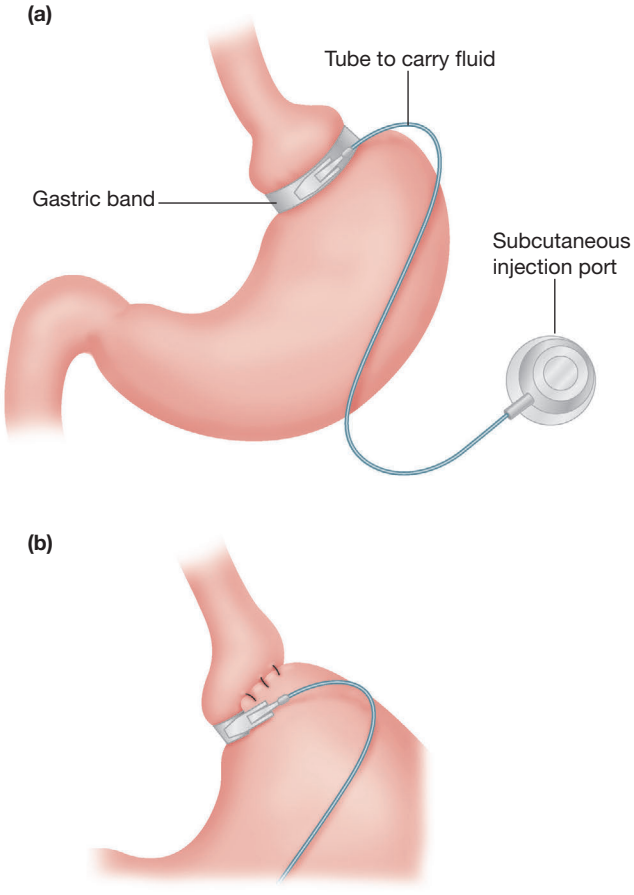

Figure 68.4 Adjustable gastric band. Gastric band surgery showing **(a)** a small 'virtual' pouch of stomach below the gastro-oesophageal junction and **(b)** gastrogastric tunnelling sutures. (Adapted from Griffin SM, Raimes SA, Shenfine J. *Oesophagogastric surgery*, 5th edn. London: Saunders Elsevier, 2013.)

One-anastomosis gastric bypass

One-anastomosis gastric bypass (OAGB) (***Figure 68.3***), previously known as a mini-gastric bypass, was first described by Rutledge. The objective was to develop a technique that is technically less demanding with only one anastomosis (antecolic loop gastrojejunostomy without a Roux-en-Y configuration) and a longer gastric pouch than for standard gastric bypass. Similar weight loss outcomes have been reported but there is concern regarding symptomatic biliary reflux causing gastritis or oesophagitis, marginal ulcers and the management of anastomotic leaks owing to a potentially high volume of biliary and pancreatic secretions. With the Roux-en-Y historically being the standard in surgery of the stomach for ulcer disease and cancer, there is further concern owing to possibly increased risk of Barrett's oesophagus and gastric or oesophageal cancer associated with biliary reflux. These outcomes will need long-term investigation.

Gastric banding

Although use of adjustable gastric banding (***Figure 68.4***) is declining, it did boost the popularity of bariatric surgery because of perioperative safety, lack of nutritional complications and relative ease and availability. The pars flaccida technique (through the window of the lesser omentum) is now standard practice with a band placed just below the oesophagogastric junction, making a small 'virtual' gastric pouch. The band is sutured into place anteriorly with gastrogastric tunnelling sutures to reduce slippage. The access port is routinely sutured to the rectus sheath in the upper abdomen for ease of access by a non-coring, Huber needle for band adjustments.

The operation appears to work by reducing hunger, probably vagally mediated. The initial surgical placement is only the beginning of the treatment. Specialist nurses, physicians and surgeons do 'band consultations' to assess eating habits and then perform an adjustment with injection or aspiration of saline if indicated. The objective is to reach the so-called 'sweet spot' of optimal appetite control. Follow-up should be monthly to begin with as needed during the first year, with full MDT support to help patients get the best use out of their bands. Lack of appropriate follow-up is why results in the literature vary so much, with a consequent high band removal rate.

Biliopancreatic diversion/duodenal switch

BPD, described by Scopinaro, produces greater weight loss than other procedures but is associated with a higher

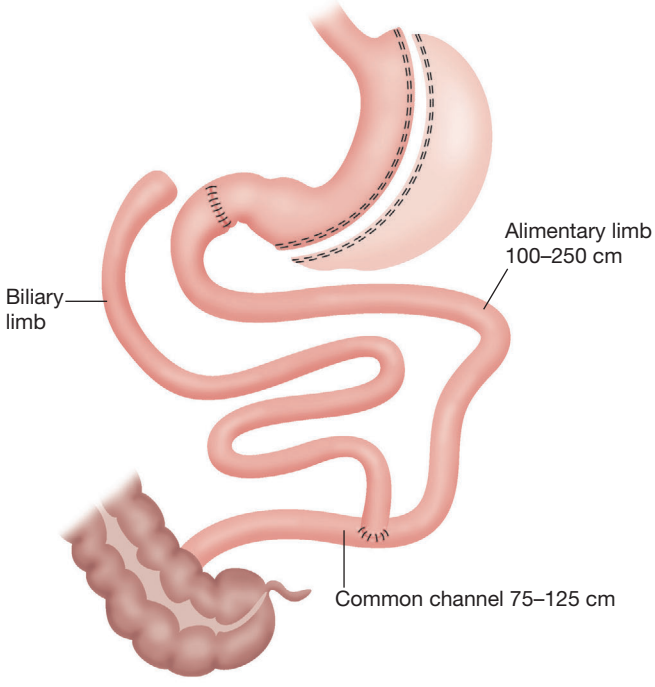

Figure 68.5 Biliopancreatic diversion with duodenal switch variant (BPD/DS).

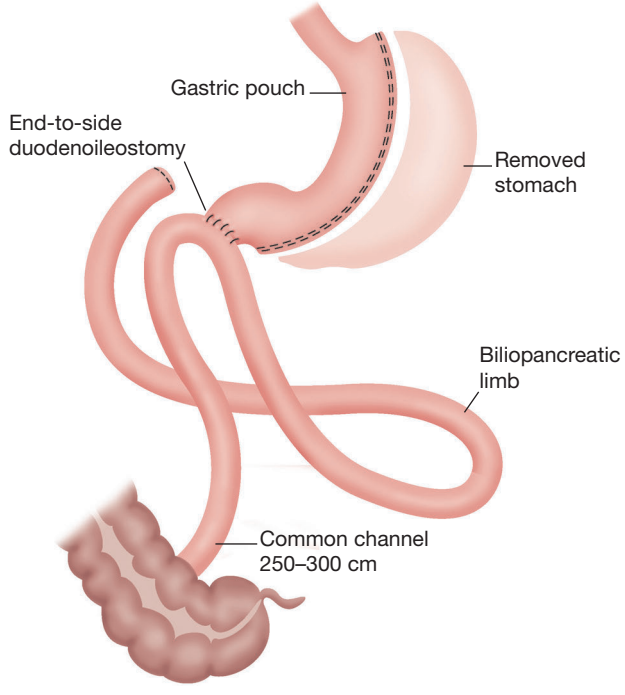

Figure 68.6 Single-anastomosis duodenoileal bypass with sleeve gastrectomy (SADI-S).

nutritional complication rate. The mechanism of action appears to be mainly malabsorption of calories. BPD/DS is the version mainly performed (***Figure 68.5***). A sleeve gastrectomy is followed by division of the duodenum just distally to the pylorus. The ileum is divided with a linear stapler, followed by a duodenoileostomy and ileoileostomy with the objective of creating a common channel of 75–125 cm and an alimentary channel of 100–250 cm. The long remaining biliary limb is not measured.

BPD/DS is increasingly seen as a definitive procedure, particularly after significant weight regain following sleeve gastrectomy. A high-protein diet and regular vitamin and mineral supplements with lifelong monitoring and patient commitment, to avoid malnutrition, is essential postoperatively. Only a few centres offer these procedures.

Single-anastomosis duodenoileal bypass with sleeve gastrectomy

Single-anastomosis duodenoileal bypass with sleeve gastrectomy (SADI-S) is a novel procedure based on the BPD/DS. A sleeve gastrectomy is followed by an end-to-side duodenoileal anastomosis (***Figure 68.6***). The length of the common channel–alimentary limb is 250–300 cm. Potential advantages include the preservation of the pylorus, elimination of one anastomosis compared with the duodenal switch and reducing operating time and risk of perioperative complications.

Complications

The common complications are shown in ***Table 68.6***. In sleeve gastrectomy, a staple line leak at the angle of His usually presents any time *after* discharge up to 30 days, and patients can also deteriorate rapidly with sepsis. Urgent computed tomography (CT) scanning and relaparoscopy is indicated, with source control by drainage the major goal. Patients are typically in hospital for months and need multiple reinterventions, including any of: endoscopic interventions (stenting, endoscopic vacuum therapy), making a controlled fistula, conversion to gastric bypass and fistula enterostomy. Long-term nutritional support is needed as patients are severely catabolic after complications from both bypass and sleeve surgery.

Anastomotic leakage, bleeding and closed loop obstruction after Roux-en-Y or one-anastomosis gastric bypass can be life-threatening. If a bypass patient is not well after 24 hours urgent consideration should be given to oral contrast X-ray swallow or CT scanning and/or relaparoscopy. Other than a feeling of 'impending doom' patients may have few overt features of sepsis and abdominal examination can be very misleading. Deterioration after an anastomotic leak can be very rapid and there is no time for delay.

Very few patients with gastric bands develop early intra-abdominal complications. Unfortunately a large number of patients have their bands removed later on if there is inadequate follow-up, a late complication or the patient is unable to tolerate the device.

The incidence of late complications is difficult to estimate as so many patients are lost to follow-up. Internal hernias develop as weight is lost and hernia spaces open up after gastric bypass. CT scanning has a high rate of false negatives for internal hernia, so anyone presenting with severe, cramping abdominal pain 2–3 years after surgery needs to be

TABLE 68.6 Estimated early surgical complication rates, operative mortality after sleeve gastrectomy, Roux-en-Y or one-anastomosis gastric bypass, and gastric banding, and late complications.

	Early	Mortality	Late
Sleeve gastrectomy	Leak at angle of His (1–2%)	0.1%	Gastro-oesophageal reflux
	Intra-abdominal bleed (2–3%)		Barrett's oesophagus
	DVT/PE (<1%)		Weight regain
Gastric bypass	Anastomotic leak (<1%)	0.1%	Internal hernia
	Intra-abdominal bleed (2–3%)		Chronic abdominal pain
	Unspecified obstruction (1–2%)		Malnutrition if long limb bypass
	DVT/PE (<1%)		Anastomotic ulcer/stricture
			Weight regain
Gastric band	Access port infection (1%)	0.05–0.1%	Band infection
	DVT/PE (<0.1%)		Tubing leak
			Slippage
			Erosion into stomach
			Band intolerance
			Failure to lose weight/weight regain

high priority for investigation by laparoscopy. Closure of the internal hernia spaces is now standard of care in Roux-en-Y gastric bypass.

Summary box 68.5

Acute complications

- Anastomotic leak and staple line dehiscence can be rapidly fatal and require emergency laparoscopy
- Internal hernias developing after surgery are very difficult to diagnose other than by prompt laparoscopy; they require a high index of suspicion

Outcomes reported

There is wide variation in how surgeons report the results of surgery, which means that it is often difficult to compare studies. There is a need to standardise clinician-reported outcomes and patient-reported outcome measures (PROMs) into an agreed core outcome set that includes risk stratification. Obvious PROMs include quality of life.

Follow-up and a shared care model of chronic disease

Shared care arrangements with surgeons/physicians and primary care need to be in place so that diabetes and hypertension medications and dosage can be appropriately reduced as weight is lost. Every patient with diabetes needs at least an annual review.

Although sleeve gastrectomy, short-limb forms of gastric bypass and gastric banding do not cause protein-calorie malabsorption, bariatric surgery can cause severe vitamin and mineral deficiencies, amplifying pre-existing deficiencies caused by obesity. All patients should have lifelong routine metabolic and nutritional monitoring (***Table 68.7***). Patients need regular multivitamins/trace element supplements (***Table 68.8***). The minimum frequency of assessment is 3–6 monthly in the first postoperative year, 6–12 monthly in the second year and at least annually thereafter. Folic acid supplementation should be considered in all sexually active women of childbearing age because of the risk of neural tube defects. This is especially important as fertility often improves after surgery. The MDT also needs to support the small number of patients who develop severe mental health issues after surgery as there is a slightly increased risk of suicide after gastric bypass.

TABLE 68.7 Summary of British Obesity and Metabolic Surgery Society (BOMSS) biochemical guidance after bariatric surgery.

Blood tests all patients should have at baseline
Full blood count, including haemoglobin, ferritin, folate and vitamin B12 levels, urea and electrolytes, liver function tests, vitamin D, Ca^{2+}, parathormone, HbA1c, lipid profile
Postoperatively
After gastric banding: Annual full blood count, urea and electrolytes, HbA1c, fasting glucose, lipids as appropriate *After sleeve gastrectomy, forms of gastric bypass, BPD/DS, SADI-S:* As for banding + liver function tests, ferritin, folate, vitamin D, Ca^{2+}, parathormone at 3, 6, 12 months then annually; vitamin B12 at 6, 12 months then annually; zinc, copper annually; vitamins A, E, K, selenium if concern (e.g. steatorrhoea, night blindness, unexplained fatigue, anaemia, metabolic bone disease, chronic diarrhoea, heart failure)

BPD, biliopancreatic diversion; DS, duodenal switch; HbA1c, glycated haemoglobin; SADI-S, single-anastomosis duodenoileal bypass with sleeve gastrectomy.

TABLE 68.8 Summary of British Obesity and Metabolic Surgery Society (BOMSS) nutritional and micronutrient guidance after bariatric surgery.

After gastric banding
Multivitamin and mineral supplement, thiamine if vomiting, vitamin D, iron
After sleeve gastrectomy, forms of gastric bypass, BPD/DS, SADI-S
As for banding + selenium, copper, zinc, folic acid, vitamins B12, A, E, K BPD/DS, SADI-S may require higher doses

BPD, biliopancreatic diversion; DS, duodenal switch; SADI-S, single-anastomosis duodenoileal bypass with sleeve gastrectomy.

Summary box 68.6

Shared care model of chronic disease

- Close collaboration between surgeons, physicians and primary care doctors is needed to enable seamless follow-up before and after surgery with a focus on the long-term care of patients
- Patients should be committed to lifelong vitamin and micronutrient monitoring and replacement

FUTURE CHALLENGES

Patients with obesity suffer from widespread prejudice. Understanding that the obesity epidemic currently experienced in different parts of the world is driven by a change in the environment towards becoming 'obesogenic' and not a lack of willpower would be the first step in removing the barriers to more surgery.

All surgeons should contribute their results to national registries so that safety can be monitored and operation trends established. Ideally registries should also link to other national healthcare records, e.g. diabetes databases, so that long-term outcomes data can be collected outside of funded RCTs.

PART 11 | Abdominal

CHAPTER
69 The liver

Learning objectives

To understand:

- The anatomy of the liver
- The signs of acute and chronic liver disease
- The investigation of liver disease
- The management of liver trauma
- The management of liver infections
- The management of benign and cystic liver lesions
- The management of intrahepatic cholangiocarcinoma
- The management of hepatocellular carcinoma
- The management of colorectal liver metastases

INTRODUCTION

The liver is a highly complex organ found only in vertebrates that is responsible for over 500 individual functions. It is located in the right upper quadrant, protected by the ribs, and weighs on average 1.5 kg (970–1860 g). It is wedge shaped in both the coronal and axial planes and is divided by the middle hepatic vein into two lobes, with the larger right lobe generally representing 60% by volume. The parenchyma is covered by a thin capsule (Glisson's capsule) and visceral peritoneum apart from the posterior surface, the 'bare area'. Surgery for hepatic disease evolved slowly because of the complexity of hepatic function and anatomy. Remarkable progress has been made since the first formal resection in 1952 with the advent of cross-sectional imaging, liver transection technology and low central venous pressure anaesthesia. Progress continues with the incorporation of laparoscopic and robotic surgery and training techniques, including virtual reality.

ANATOMY OF THE LIVER

Embryology

Liver development begins at 3–4 weeks' gestation when a hepatic foregut diverticulum buds into the ventral wall of the primitive midgut. This diverticulum is the anlage for the liver, extrahepatic biliary ducts, gallbladder and ventral pancreas, which develop over the next week. The basement membrane surrounding the liver bud is then lost and cords of bipotential hepatoblasts invade the septum transversum and differentiate into hepatocytes and cholangiocytes.

Ligaments and peritoneal reflections

The liver is covered by visceral peritoneum (serosa), with a layer of connective tissue, the Glisson capsule, underneath. At the porta hepatis, the capsule envelops and travels along the portal tracts (triads) into the liver, carrying branches of the hepatic artery, portal vein and bile ducts. The liver is fixed in the right upper quadrant by the hepatic veins and ligaments formed from the peritoneal reflections. Division of the left triangular ligament on the superior surface of the left lobe mobilises the liver from the diaphragm, exposing the left lateral wall of the inferior vena cava (IVC). The right triangular ligament similarly fixes the right lobe to the undersurface of the right hemidiaphragm, and division mobilises the liver sufficiently to allow it to be rotated to the left. Another major supporting structure is the falciform ligament (the remnant of the umbilical vein), which runs cephalad from the umbilicus, enters the liver at the interlobar fissure and passes anteriorly on the surface of the liver, attaching it to the anterior abdominal wall. Dividing the cephalad leaves of the falciform ligament exposes the suprahepatic IVC within a thin fibrous sheath. The final peritoneal reflection is the lesser omentum between the stomach and the liver, which contains the hilar structures in its right free edge.

The blood supply to the liver

The liver is composed of eight segments (***Figure 69.1***), each supplied by terminal branches of the portal vein (80% of the blood flow) and hepatic artery (20%) and drained by bile ducts and hepatic veins. The shape of the segments varies among individuals, but the configuration remains relatively constant.

Francis Glisson, 1597–1697, Regius Professor of Physic, Cambridge, UK, described the capsule of the liver and its blood supply in his book *Anatomia hepatis* (1654).

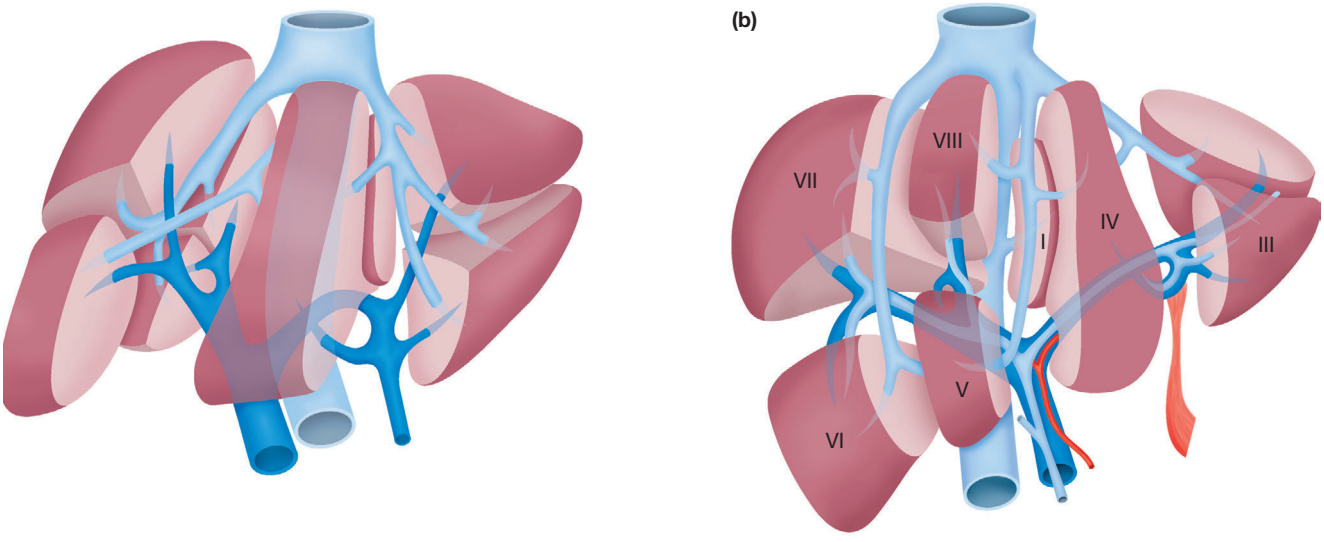

Figure 69.1 The functional division of the liver and of the liver segments according to Couinaud's nomenclature. **(a)** As seen in the patient. **(b)** In the *ex vivo* position.

The arterial blood supply is variable in origin and course but in most individuals is derived from the coeliac trunk, which usually divides into left gastric, common hepatic and splenic arteries.

After supplying the gastroduodenal artery, the hepatic artery branches at a variable level to produce the right and left hepatic arteries, the larger right branch supplying the right lobe. The right lobe may be partly or completely supplied by a right hepatic artery arising directly from the superior mesenteric artery running to the liver on the posterior wall of the bile duct after passing behind the uncinate process and head of the pancreas. Similarly, the left lobe artery may be augmented or replaced by a branch of the left gastric artery running in the lesser omentum from the lesser curve of the stomach.

The hilum of the liver

The porta hepatis is a pronounced transverse fissure on the visceral surface of the liver running between the cephalad end of the fissure for the ligamentum teres and the gallbladder fossa. The neurovascular structures and lymphatics running in the right free edge of the lesser omentum (the hepatoduodenal ligament) enter at this point and the right and left hepatic ducts emerge. There are numerous variations of the hilar structures which are important in the planning and performance of operations on the liver (***Figure 69.2***).

In the most common arrangement, the bile duct runs in the free edge of the hepatoduodenal ligament with the hepatic artery medially and the portal vein posteriorly, each dividing into two branches at the hilum. The right and left hepatic ducts arise from the hepatic parenchyma and form the common hepatic duct. The cystic duct draining the gallbladder enters the ligament at a variable level, joining the common hepatic duct to form the common bile duct (CBD). The right hepatic artery crosses the bile duct anteriorly or posteriorly before giving rise to the cystic artery, and multiple branches predominantly from the right hepatic artery supply the bile duct. The portal vein is formed by the confluence of the splenic and superior mesenteric veins behind the neck of the pancreas, with the left branch having a longer (approximately 2 cm) extrahepatic course. The portal vein often has two large branches to the right lobe, which are usually outside the liver for a short length, before giving a left portal vein branch that runs behind the left hepatic duct.

The venous drainage

The IVC occupies a groove on the posterior surface of the liver that drains into it via three large veins immediately below the diaphragm. The suprahepatic IVC immediately traverses the diaphragm to enter the right atrium, but below the liver there is a short clear segment above the insertion of the renal veins. A variable number of short inferior hepatic veins pass directly from the liver to the anterior wall of the IVC. The right hepatic vein can be exposed fully outside the liver parenchyma, but the middle and left veins usually terminate in a short common trunk before entering the IVC. The right adrenal gland is adjacent to the retrohepatic IVC and drains into it, usually by a single vein.

Segmental anatomy

The liver is divided into functional right and left 'units' along the line between the gallbladder fossa and the middle hepatic vein (Cantlie's line). Understanding the internal anatomy of the liver facilitated safe liver surgery and Couinaud, a French anatomist, described the liver *as being divided into eight segments* (***Figure 69.1***). Each segment can be considered a functional

A **hilum** is a depression or fissure where nerves, vessels or ducts enter a bodily organ.
Sir James Cantlie, 1851–1926, Scottish-born physician who cofounded the Hong Kong College of Medicine for Chinese (now Hong Kong University School of Medicine).

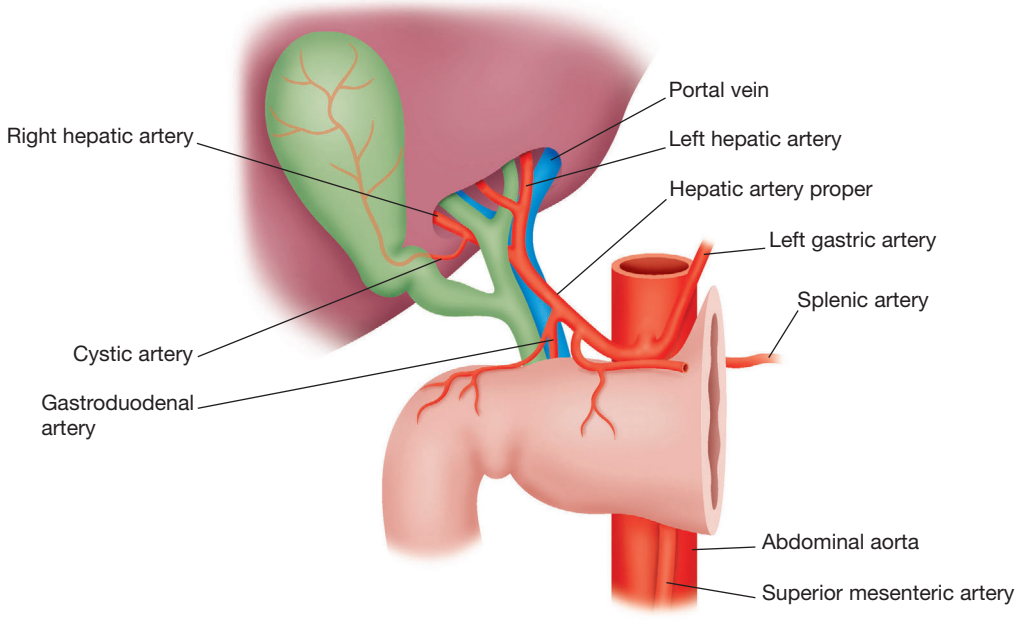

Figure 69.2 Anatomy of the liver hilum.

unit supplied by a branch of the hepatic artery, portal vein and bile duct, and drained by a hepatic vein tributary; this concept facilitates 'anatomical' liver resection. Liver segments V–VIII to the right of Cantlie's line are supplied by the right hepatic artery and the right branch of the portal vein and biliary drainage is via the right hepatic duct. To the left of Cantlie's line segments, I–IV are supplied by the left hepatic artery and left portal vein and drain via the left hepatic duct. Resections of individual segments, the whole of the left or the right hemiliver or combinations are possible.

Microscopic anatomy and structure

The liver comprises approximately 100 000 hexagonal functional units known as lobules with a central vein surrounded by six hepatic portal veins and six hepatic arteries. These vessels are connected by capillary-like tubes called sinusoids, which extend to meet the central vein. Lobules are separated by hepatic sinusoids, which are large-diameter capillaries lined by endothelial cells between rows of plates or cords of hepatocytes. Each sinusoid contains Kupffer cells, a type of macrophage that captures and breaks down effete red blood cells, and hepatocytes, which are cuboidal epithelial cells making up the majority of cells in the liver. Hepatocytes perform most liver functions, including metabolism, storage, digestion and bile production. Tiny bile canaliculi run parallel to the sinusoids on the contralateral side to the hepatocytes and drain bile in the opposite direction to the blood flow via the bile duct tributaries within the portal tracts.

Summary box 69.1

Liver anatomy

- There are two anatomical lobes with a separate blood supply, bile duct and venous drainage
- There is a dual blood supply; 80% portal vein and 20% hepatic artery
- The liver regenerates to 90–100% of its previous volume following resection
- Resection is based on anatomical lines to preserve maximal functioning liver and blood supply

ACUTE AND CHRONIC LIVER DISEASE

Liver blood tests

The liver performs a myriad of biochemical, metabolic and immunological functions. Anhepatic humans survive for 24–48 hours. It is the only organ in the body that regenerates. Awareness of currently available liver blood tests and their significance is essential (***Table 69.1***).

Karl Wilhelm von Kupffer, 1829–1902, Professor of Anatomy at Kiel (1869), Königsberg (1875) and Munich (1880), Germany, described these 'stellate cells' in 1880.

Summary box 69.2

Main functions of the liver

- Maintaining core body temperature
- pH balance and correction of lactic acidosis
- Synthesis of clotting factors
- Glucose metabolism, glycolysis and gluconeogenesis
- Urea formation from protein catabolism
- Bilirubin formation from haemoglobin after breakdown of effete red cells in the spleen
- Drug and hormone metabolism and excretion
- Removal of gut endotoxins and foreign antigens
- Vitamin and mineral storage, including A, D, E, K and B12
- Immunological function as part of the mononuclear phagocyte system
- Albumin production for transport of fatty acids, steroids and waste products
- Angiotensin synthesis
- Body temperature through heat production
- Cytochrome P450 detoxifies contaminants and pollutants, insecticides, food additives and alcohol

Clinical signs

Depending on the severity of liver dysfunction, the aetiology and acute or chronic development, symptoms vary and combinations occur. The most common include jaundice, drowsiness, abdominal pain/swelling, nausea, tremors, vomiting, malaise, confusion and disorientation, bruising, peripheral oedema and foetor hepaticus (strong musty smell to the breath).

Acute liver failure

Causes of acute liver failure

Acute liver failure is the development of sudden, severe hepatic dysfunction from an acute insult associated with the onset of hepatic encephalopathy and coagulation abnormalities. The most widely accepted definition, from the American Association for the Study of Liver Diseases, is:

> ***evidence of coagulation abnormality, usually an international normalized ratio above 1.5, and any degree of mental alteration (encephalopathy) in a patient without pre-existing liver disease and with an illness of less than 26 weeks' duration.***

Treatment of acute liver failure

Acute liver failure is rare in the developed world, with an annual incidence of <10 cases per million and a current mortality of 30–40%. In the early stages, there may be no objective signs, but with severe dysfunction clinical jaundice may be associated with neurological signs of liver failure (hepatic encephalopathy), consisting of a liver flap, drowsiness, confusion and eventually coma.

Liver transplantation is appropriate for some patients, although the short-term results are poor compared with transplantation for chronic liver disease and suitable donor livers are frequently not available in a suitable time frame owing to the precipitate deterioration.

TABLE 69.1 Routinely available blood tests for the assessment of liver function.

Test	Normal range	Significance
Bilirubin	5–17 µmol/L (0.3–1.2 mg/dL)	Bilirubin is synthesised in the liver and excreted in bile. Increased levels may be associated with increased haemoglobin breakdown, hepatocellular dysfunction resulting in impaired bilirubin transport and excretion or mechanical biliary obstruction. In patients with known parenchymal liver disease, progressive elevation of bilirubin in the absence of a secondary complication suggests deterioration in liver function
Alkaline phosphatase (ALP)	30–140 IU/L	The serum ALP is particularly elevated with cholestatic liver disease or biliary obstruction. It is important to note that routine laboratory analysis of ALP is not isoform specific and so ALP from a skeletal source may also lead to elevation, particularly Paget's disease and prostate cancer
Aspartate transaminase (AST)	5–40 IU/L	Although significant liver injury does occur in the presence of normal liver blood tests, levels of the transaminase (AST, ALT and GGT) usually reflect acute hepatocellular damage and GGT is a useful marker of alcohol intake
Alanine transaminase (ALT)	5–40 IU/L	
Gamma-glutamyl transpeptidase (GGT)	10–48 IU/L	
Albumin	35–50 g/L (3.5–5 g/dL)	The synthetic functions of the liver are indicated by the ability to synthesise proteins (albumin level) and clotting factors (PT) and the standard method of monitoring liver function in patients with chronic liver disease is serial measurement of bilirubin, albumin and PT
Total protein	60–85 g/L (6–8.5 g/dL)	
Prothrombin time (PT)	12–16 s	

Chronic liver disease

Liver disease is the third leading cause of premature death in the UK, and since 1970 deaths have increased by 400%. Liver disease is potentially preventable in 90% of cases, and 75% of patients present with late-stage disease. Lethargy and weakness are common features, irrespective of the aetiology, and often precede clinical jaundice. In advanced cirrhosis, glucuronyl conjugation of bilirubin and biliary excretion of conjugated

Sir James Paget, 1814–1899, Surgeon, St Bartholomew's Hospital, London, UK.

Summary box 69.3

Causes of acute liver failure

- Viral hepatitis (hepatitis A, B, C, D, E)
- Drug reactions (halothane, isoniazid–rifampicin, antidepressants, non-steroidal anti-inflammatory drugs [NSAIDs], valproic acid)
- Paracetamol overdose
- Prescription medicines, including antibiotics, NSAIDs, anticonvulsants and statins
- Herbal supplements
- Mushroom poisoning
- Toxins, including carbon tetrachloride in refrigerants, solvents for industrial use and varnishes
- Shock and multiorgan failure
- Autoimmune disease
- Acute Budd–Chiari syndrome
- Rare metabolic disorders, including Wilson's disease
- Cancer
- Fatty liver of pregnancy
- Heat stroke
- Reye's syndrome in children following a viral infection including
- Chickenpox
- Severe acute respiratory syndrome coronavirus (SARS-CoV-2) can cause liver failure in up to 20% of patients with a severe episode

Summary box 69.4

Supportive therapy for acute liver failure

- Fluid balance and electrolytes
- Acid–base balance and blood glucose monitoring
- Nutrition
- Renal function (haemofiltration)
- Respiratory support (ventilation)
- Monitoring and treatment of cerebral oedema
- Treat bacterial and fungal infection
- Extracorporeal liver support devices (principally as a bridge to transplantation)

Summary box 69.5

King's College selection criteria for liver transplantation in acute liver failure: paracetamol (acetaminophen) and non-paracetamol induced

Paracetamol toxicity

Criteria met if arterial pH <7.30

OR/AND

All three of the following present:

- INR >6.5 (PT >100 s)
- Serum creatinine 3.4 mg/dL (301 µmol/L)
- Grade III or IV encephalopathy[a]

Additionally,[b]

- Hyperlactaemia or hyperphosphataemia are strong predictors of poor prognosis for survival without transplantation

Non-paracetamol toxicity

Criteria met if INR >6.5 (PT >100 s)

OR/AND

Three out of five of the following present:

- Age less than 10 or greater than 40
- Aetiology non-A, non-B hepatitis, idiosyncratic drug reactions
- Duration of jaundice before development of encephalopathy >7 days
- PT greater than 50 s (approximate INR >3.5)
- Serum bilirubin >18 mg/dL (300 µmol/L)

INR, international normalised ratio; PT, prothrombin time.

[a]Hepatic encephalopathy grades can be described as:

- Grade 1: inverted sleep pattern, agitation, forgetfulness, irritability, apraxia
- Grade 2: lethargy, time and/or place disorientation, personality change, ataxia
- Grade 3: somnolence to semistupor but responds to verbal stimuli, place disorientation, asterixis, hyperactive reflexes
- Grade 4: coma

[b]The addition of lactate or phosphate thresholds to the criteria may improve sensitivity and negative predictive value.

bilirubin are impaired and jaundice develops. Progressive deterioration in liver function is associated with a hyperdynamic circulation with a high cardiac output, large pulse volume, low blood pressure and flushed warm extremities. Fever is common and may be related to underlying inflammation and cytokine release or bacterial infection due to innate immune dysfunction in acute and chronic liver disease. Skin changes include spider naevi (cutaneous vascular abnormalities that blanch on pressure), palmar erythema and white nails (leukonychia) and endocrine abnormalities produce hypogonadism and gynaecomastia. Hepatic encephalopathy is responsible for the mental derangement with memory impairment, confusion, personality changes, altered sleep patterns and slow, slurred speech. The most useful clinical sign is a flapping tremor when the patient extends their arms while hyperextending the wrist joints. Ascites is a common late feature causing abdominal distension, detected clinically by the demonstration of a fluid thrill or shifting dullness. Protein catabolism produces sarcopenia and wasting, and bruising suggests a coagulopathy.

Summary box 69.6

Features of chronic liver disease

- Lethargy
- Fever
- Jaundice
- Protein catabolism (wasting)
- Coagulopathy (bruising)
- Cardiac (hyperdynamic circulation)
- Neurological (hepatic encephalopathy)
- Portal hypertension
  - Ascites
  - Oesophageal varices
  - Splenomegaly and hypersplenism
- Cutaneous
  - Spider naevi
  - Palmar erythema

SA Kinnier Wilson, 1878–1937, Professor of Neurology, King's College, London, UK.
Ralph Douglas Reye, 1912–1977, pathologist, Royal Alexandra Hospital for Children, Sydney, Australia.

Assessment of chronic liver disease

A number of parameters are required to accurately assess the degree of liver dysfunction, enable predictions about a patient's ability to tolerate surgical or radiological procedures and assess the prognosis following transplantation. Two prognostic models commonly used are the Child–Turcotte–Pugh (CTP) classification (***Table 69.2***) and the Model for End-Stage Liver Disease (MELD) score. The original Child classification was developed to predict mortality following shunt surgery in patients with cirrhosis, with the CTP classification modified to predict mortality after any surgery. The MELD score was devised to predict the short-term prognosis following transjugular intrahepatic portosystemic stent shunt (TIPSS) but has been adopted to prioritise patients on liver transplant waiting lists. In the MELD model survival probability is calculated based on the patient's international normalised ratio (INR), serum bilirubin and creatinine.

TABLE 69.2 Child–Turcotte–Pugh (CTP) classification of hepatocellular function in cirrhosis.

Points	1 point each	2 points each	3 points each
Bilirubin (μmol/L)	<34	34–50	>50
Albumin (g/L)	>35	25–35	<25
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	Grade I or II	Grade III or IV
INR	<1.7	1.7–2.2	>2.2

CTP-A, 5 or 6 points; CTP-B, 7–9 points; CTP-C, 10–15 points.
INR, international normalised ratio.

Operating in the presence of chronic liver disease

Surgical and anaesthetic complications are increased in chronic liver disease, with the risk dependent on the magnitude of the procedure, degree of liver impairment and type of anaesthesia. Overall surgical mortality rates are increased by 10% in CTP-A disease, 30% in CTP-B and 75–80% in CTP-C (***Table 69.2***). MELD scores correlate with operative mortality: 1% increase for each MELD point up to 20 and a further 2% for each point above 20, with rates considerably higher following emergency presentation.

INVESTIGATING LIVER DISEASE

Imaging modalities

Major advances in surgical approaches to the liver required improvements in preoperative imaging. The choice of imaging modality is determined by the likely pathology and locally available equipment and expertise (***Table 69.3***).

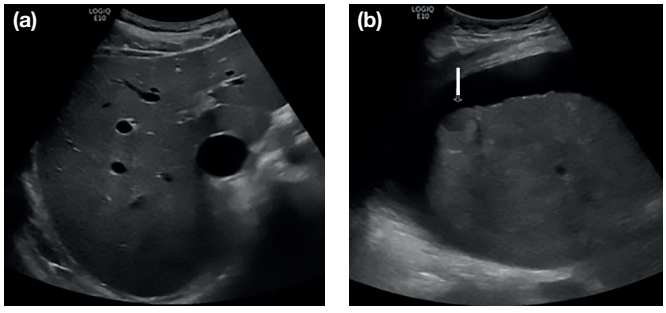

Figure 69.3 Ultrasound scans of the liver. **(a)** Normal liver and **(b)** surveillance for a patient with cirrhosis demonstrating hepatocellular carcinoma (arrow).

Ultrasonography

Ultrasonography (US) is traditionally the first imaging modality for the investigation of jaundice and right upper quadrant pain (***Figure 69.3***). Good quality US can characterise benign cystic lesions but is operator dependent; accurate characterisation of malignant pathologies is not possible. Body habitus and anatomical variations frequently prevent detailed examination, with steatosis reducing liver penetration; US should not be used when malignancy is suspected.

US can reliably identify biliary dilatation but not the aetiology, and overlying air-containing viscera often prevent complete examination. Contrast-enhanced ultrasonography (CEUS), introduced in the early 1990s, uses transient intravascular bubbles to differentiate normal liver parenchyma from solid tumours. CEUS increases US sensitivity and specificity by assessing real-time lesion vascularity with an accuracy for focal liver lesions of 90%.

Computed tomography

Modern spiral computed tomography (CT) technology has increased the accuracy of diagnosis and staging of liver lesions, and contrast-enhanced CT is currently the most widely used and best validated modality. Fine detail of liver lesions with resolutions of 6–8 mm is possible, liver algorithms allow characterisation and density data identify cystic lesions (***Figure 69.4a***). The early arterial phase following intravenous contrast detects small hepatocellular carcinomas (HCCs) owing to their predominantly arterial blood supply. The venous phase demonstrates branches of the intrahepatic portal vein and the hepatic veins. Inflammatory liver lesions often exhibit rim enhancement with intravenous contrast, whereas haemangiomas characteristically show late venous enhancement. CT is extremely accurate when assessing the stage and resectability of liver tumours apart from peritoneal metastases.

Magnetic resonance imaging

Magnetic resonance (MR) of the liver is superior to CT in characterising focal lesions (***Figure 69.4b***). The resolution for small metastases is superior and is further improved by liver-specific

Charles Gardner Child, 1908–1991, surgeon, Michigan, USA. **Child** and **Jeremiah G Turcotte** first proposed the scoring system in 1964. In 1972, **RN Pugh** and colleagues from King's College Hospital, London, UK, modified the scoring system by replacing nutritional status with prothrombin time or international normalised ratio.

TABLE 69.3 Modalities employed for imaging of the liver.

Imaging modality	Principal indication
Ultrasonography	• Standard first-line investigation • CEUS 90% accurate for focal lesions
Spiral CT	• Investigation of malignancy • Cancer surveillance • Anatomical planning for liver surgery
MRI	• Alternative to spiral CT • Characterisation of liver lesions • Liver-specific contrast agents are taken up by hepatocytes, which are absent in malignant lesions, which consequently contrast with the enhanced background liver
MRCP	• First-line, non-invasive cholangiography • Investigation and surveillance of parenchymal liver disease (sclerosing cholangitis, autoimmune cholangitis) for the development of malignancy
ERCP	• Therapeutic procedure only • Imaging the biliary tract when endoscopic intervention is required (stones, strictures, iatrogenic and traumatic injury)
PTC	• Biliary tract imaging when ERCP not possible or failed
EUS	• Generally for examination of the extrahepatic biliary tree and pancreas • Caudate lobe, hilar nodes and liver parenchyma can be assessed
Octreotide scanning	• Form of scintigraphy used to identify and localise NETs and carcinoid tumours • Particularly useful to exclude metastatic disease
HIDA scanning	• Determination of the patency of the intra- and extrahepatic biliary system and investigation of biliary atresia and jaundice following liver transplantation
Angiography	• To detect vascular involvement by tumour • Treatment of vascular pathology (pseudotumours, haemobilia, iatrogenic injuries, trauma)
PET scanning	• To quantify tumour spread • Differentiate benign and malignant pathologies
Laparoscopy ± laparoscopic ultrasonography	• To detect peritoneal and serosal disease, assess the extent of tumours and spread • Ultrasonography to determine the relationship of tumours to vascular structures and biopsy of liver tumours and superficial lesions

CEUS, contrast-enhanced ultrasonography; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasonography; HIDA, hepatobiliary iminodiacetic acid; MRCP, magnetic resonance cholangiopancreatography; MRI, magnetic resonance imaging; NET, neuroendocrine tumour; PET, positron emission tomography; PTC, percutaneous transhepatic cholangiography.

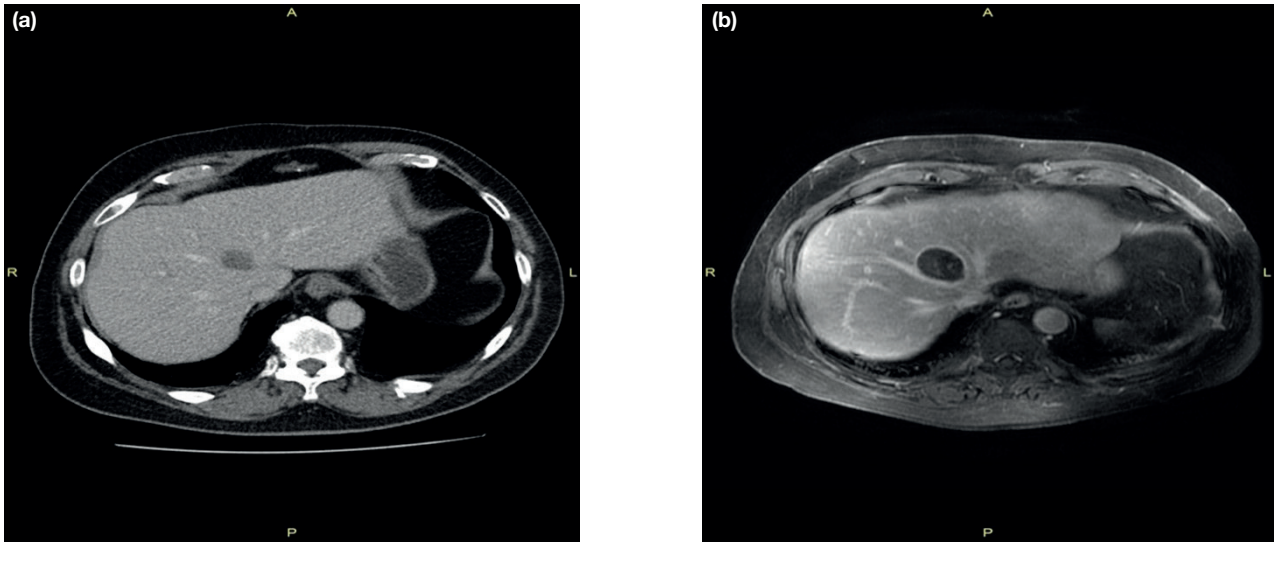

Figure 69.4 Computed tomography (CT) and magnetic resonance imaging (MRI) scans of the same patient following a road traffic accident and fall from a motorcycle. CT scan **(a)** was interpreted as a traumatic haematoma, but the MRI scan **(b)** demonstrated an incidental hepatocellular carcinoma.

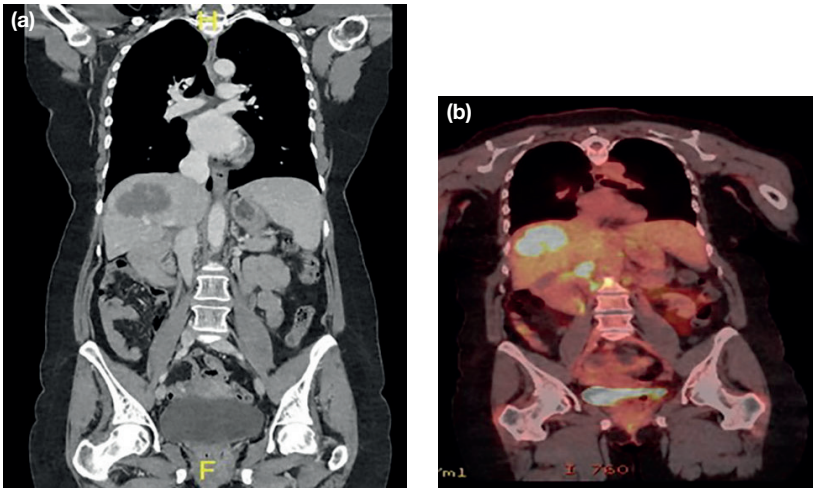

Figure 69.5 Computed tomography scan **(a)** and positron emission tomography scan **(b)** of a patient with a large colorectal metastasis and hilar lymphadenopathy.

contrast agents, particularly in differentiating between small HCCs and regenerative nodules. Magnetic resonance cholangiopancreatography (MRCP) provides excellent, non-invasive imaging of the intra- and extrahepatic biliary tract with an accuracy comparable to direct cholangiography.

Positron emission tomography

Positron emission tomography (PET) scanning is a functional test that demonstrates the metabolic activity of a tissue. A variety of tracers are available depending on the process being investigated. For the investigation of malignancy ^{18}F-2-fluoro-2-deoxy-d-glucose is commonly used, and detection depends on the avid uptake of glucose by malignant cells compared with benign or inflammatory tissue. Deoxyglucose is labelled with the positron emitter fluorine-18 (^{18}F-FDG) which is administered prior to PET imaging. A three-dimensional image of the whole body is obtained, highlighting areas of increased glucose metabolism (***Figure 69.5***). A positive PET scan result does not always indicate malignant disease (inflammation being the most common cause of a false-positive result), and conversely false-negative results occur. A critical mass is required for adequate uptake to be detectable, and resolution is similar to CT and MRI. PET scanning is particularly useful for the detection of metastatic disease and confirmation of lymph node involvement, serving as 'its own control' if some lesions prove to be FDG avid and some are cold.

Angiography

Angiography is almost exclusively employed when therapeutic intervention is considered; occlusion of arteriovenous malformations, embolisation of bleeding sites in the liver and the treatment of liver tumours by transarterial chemoembolisation (TACE).

Octreotide scan

Octreotide scanning is a form of scintigraphy in which radioisotopes attached to drug carriers are taken up by specific tissues or processes (***Figure 69.6***). Octreotide is an octapeptide that pharmacologically mimics somatostatin. When radiolabelled with indium-111 and administered intravenously it is taken up by tumour cells containing somatostatin receptors; emitted gamma radiation is detected by a scintillation camera and a whole-body image constructed. It is particularly useful for the identification of carcinoid and neuroendocrine tumours (NETs) and metastatic disease, with a 75–100% sensitivity for detecting pancreatic NETs.

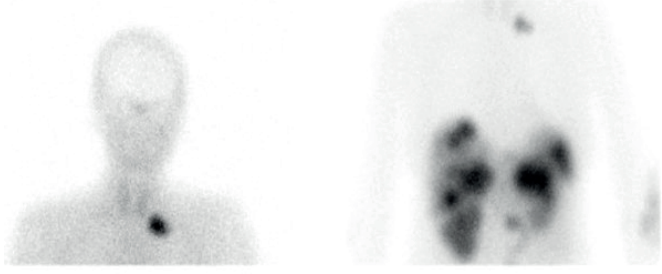

Figure 69.6 Octreotide scan demonstrating liver metastases from a neuroendocrine tumour with additional metastatic disease in mediastinal lymph nodes.

Hepatobiliary iminodiacetic acid

Hepatobiliary iminodiacetic acid (HIDA) labelled with technetium-99m (^{99m}Tc-HIDA) is concentrated by hepatocytes and excreted with bile, visualising intrahepatic uptake, the extrahepatic biliary system and the gallbladder. Under normal circumstances HIDA enters the duodenum within 30 minutes and scintigraphy produces an image together with an activity–time curve. HIDA scanning is useful because biliary excretion occurs despite hyperbilirubinaemia (<85 μmol/L). It is most commonly used to investigate biliary atresia, to investigate jaundice in liver transplant patients and to demonstrate patency of the biliary tract.

Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is performed in patients with obstructive jaundice when a therapeutic endoscopic procedure is indicated (see ***Chapter 9***). It provides definitive views of Klatskin tumours (hilar

Gerald Klatskin, 1910–1986, pathologist, Yale School of Medicine, New Haven, CT, USA.

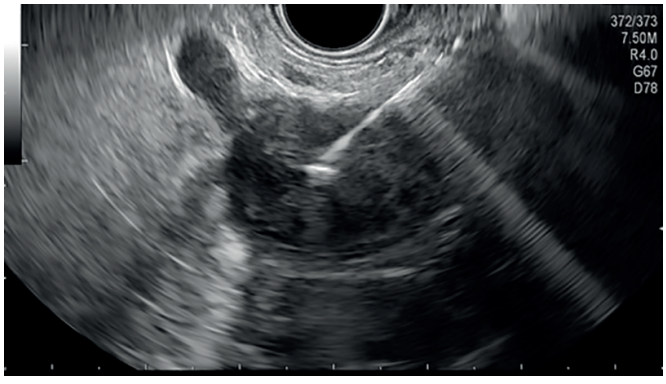

Figure 69.7 Endoscopic ultrasonography demonstrating liver parenchyma and a caudate lobe metastasis being biopsied.

cholangiocarcinoma) and facilitates staging by defining the extent of involvement of intrahepatic ducts. ERCP also provides clear images of the intrahepatic ducts in primary sclerosing cholangitis (PSC) and facilitates stenting and drainage of obstructed, infected segments.

Endoscopic (peroral) cholangiography

Cholangioscopy enables direct visualisation of the bile ducts, either operatively or endoscopically. The original 'mother and baby' ERCP cholangioscopy has been superseded by SpyGlass™ (Boston Scientific) cholangioscopy, which enables a single operator to examine the biliary mucosa. The inclusion of a working channel facilitates visualised biopsies and targeted therapy. Targeted biopsies improve diagnostic yields, with an overall accuracy of 85–95% in patients with indeterminate biliary strictures compared with 55–90% for brush cytology.

Endoscopic ultrasonography

Endoscopic ultrasonography (EUS) is predominantly used to evaluate the extrahepatic biliary tree and pancreas, but linear and radial instruments enable visualisation of hilar lymph nodes and the caudate lobe and assessment of the liver parenchyma (***Figure 69.7***).

Summary box 69.7

Management of liver trauma

- Remember associated injuries
- At-risk groups
  - Stabbing or gunshot to lower chest or upper abdomen
  - Crush injury with multiple rib fractures
  - High-speed road traffic accident
- Resuscitate
  - Airway
  - Breathing
  - Circulation
- Assessment of the injury
  - CT chest and abdomen with contrast
  - Laparotomy if haemodynamically unstable
- Treatment
  - Correct coagulopathy
  - Suture lacerations
  - Resect if major vascular injury
  - Packing if diffuse parenchymal injury

Percutaneous transhepatic cholangiography

Percutaneous transhepatic cholangiography (PTC) is indicated where endoscopic cholangiography has failed or is impossible because of anatomical constraints from previous surgery or malignant involvement of the duodenum. Tumour extent in patients with hilar tumours can be assessed and combined percutaneous/endoscopic or antegrade metal stent placement is facilitated.

Laparoscopy and laparoscopic ultrasonography

Laparoscopy is useful to stage primary hepatopancreatobiliary cancers. Unrecognised peritoneal metastases, superficial liver tumours and peritoneal disease can be identified and biopsied, avoiding an inappropriate laparotomy. Routine biopsy of resectable lesions is contraindicated to avoid tumour seeding.

LIVER TRAUMA

Liver injury due to blunt or penetrating abdominal trauma is second in frequency only to that of the spleen. Blunt injury produces contusion, laceration and avulsion, often associated with splenic, mesenteric or renal injuries. Penetrating injuries, including stab and gunshot wounds, are often associated with chest or pericardial involvement. Blunt injuries are more common and have a higher mortality (***Table 69.4***).

TABLE 69.4 Mortality from liver trauma.

Type of injury	Mortality
Blunt abdominal trauma	Overall mortality 10–30%
Severe and high-velocity injuries	Up to 60%
Injury to main hepatic veins or retrohepatic inferior vena cava	50–100%
Penetrating injuries	12–20%
Penetrating injuries with associated duodenal, pancreatic or chest involvement; multiple stab wounds	20–40%

Diagnosis and grading of liver injury

The liver is an extremely well-vascularised organ and blood loss is the major early complication following injury. A high index of suspicion is essential with any chest or upper abdominal stab wound, especially where significant blood loss is obvious. Severe crushing injuries to the lower chest or upper abdomen frequently result in rib fractures, haemothorax and splenic and/or liver injury. Focused assessment sonography in trauma (FAST) performed by an experienced operator will identify free intraperitoneal fluid. In haemodynamically unstable patients with penetrating wounds a laparotomy and/or thoracotomy is indicated once active resuscitation has commenced. Penetrating injuries are frequently associated with massive, continued blood loss and coagulopathies; transfer to the operating

theatre should occur while blood products are obtained and resuscitation continues. In haemodynamically stable patients, urgent contrast-enhanced CT scan of the chest and abdomen is performed to look for parenchymal injury and concomitant damage to other thoracic or abdominal organs.

The American Association for the Surgery of Trauma liver injury scale was revised in 2018 to incorporate vascular injury such as pseudoaneurysm and arteriovenous fistula. The guidelines recommend dual arterial/portal venous phase imaging (*Table 69.5*).

TABLE 69.5 Grading of liver injuries according to American Association for the Surgery of Trauma.

Grade 1	• Haematoma: subcapsular, <10% surface area • Laceration: capsular tear, <1 cm parenchymal depth
Grade 2	• Haematoma: subcapsular, 10–50% surface area • Haematoma: intraparenchymal, <10 cm diameter • Laceration: capsular tear 1–3 cm parenchymal depth, <10 cm length
Grade 3	• Haematoma: subcapsular, >50% surface area of ruptured subcapsular or parenchymal haematoma • Haematoma: intraparenchymal, >10 cm • Laceration: capsular tear, >3 cm parenchymal depth • Vascular injury with active bleeding contained within liver parenchyma
Grade 4	• Laceration: parenchymal disruption involving 25–75% hepatic lobe or involves 1–3 Couinaud segments • Vascular injury with active bleeding breaching the liver parenchyma into the peritoneum
Grade 5	• Laceration: parenchymal disruption involving >75% of hepatic lobe • Vascular: juxtahepatic venous injuries (retrohepatic vena cava/central major hepatic veins)

Additional points:
- Advance one grade for multiple injuries up to grade III.
- 'Vascular injury' (i.e. pseudoaneurysm or arteriovenous fistula): appears as a focal collection of vascular contrast that decreases in attenuation on delayed images.
- 'Active bleeding': focal or diffuse collection of vascular contrast that increases in size or attenuation on a delayed phase.

Initial management of liver injuries

Penetrating injuries

Modern approaches to liver trauma are based on conservative management where possible. The initial management is maintenance of airway patency, breathing and circulation (ABC), following the principles of advanced trauma life support (ATLS). Peripheral venous access requires two large-bore cannulae and blood is sent for cross-match of 10 units of blood, full blood count, urea and electrolytes, liver function tests, clotting screen, glucose and amylase. Initial volume replacement should be with blood; arterial blood gases should be obtained; and the patient intubated and ventilated if gas exchange is inadequate. Intercostal chest drains are indicated if an associated pneumothorax or haemothorax is suspected. Once resuscitation has commenced, the patient should be transferred to the operating theatre, with further resuscitation performed on the operating table. The necessity for fresh-frozen plasma (FFP) and cryoprecipitate should be discussed with the blood transfusion service immediately the patient arrives in the hospital (often by activation of a major transfusion protocol), as these patients rapidly develop irreversible coagulopathies due to a lack of fibrinogen and clotting factors. Standard coagulation profiles are inadequate to evaluate this acute loss of clotting factors, and products should be given empirically aided by the results of thromboelastography if available (see *Chapter 2*).

Blunt trauma

Enhanced resuscitation, anaesthesia and intensive care have contributed to reduced mortality rates. Optimum results are obtained with specialist teams that include experienced liver surgeons, anaesthetists, endoscopists and interventional radiologists (*Figure 69.8*).

Initial resuscitation and management are as outlined for penetrating injuries. Unstable patients require immediate laparotomy, but the majority of haemodynamically stable patients should be managed non-surgically (management depends on haemodynamic stability not the grade of injury).

Haemodynamic instability and signs of generalised peritonitis mandate surgical intervention. Interventional radiology with embolisation for hepatic arterial bleeding is safe and

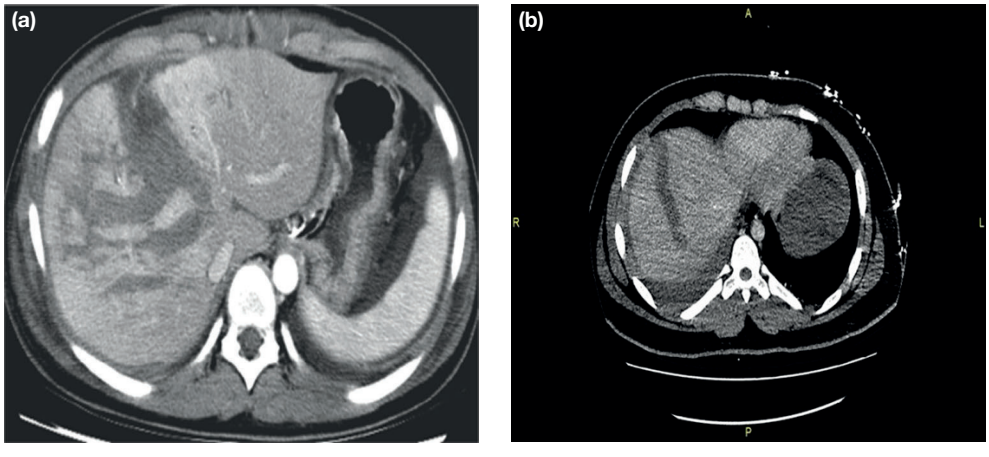

Figure 69.8 Computed tomography scans demonstrating the significant differences between blunt **(a)** and penetrating **(b)** trauma (assault with a kitchen knife).

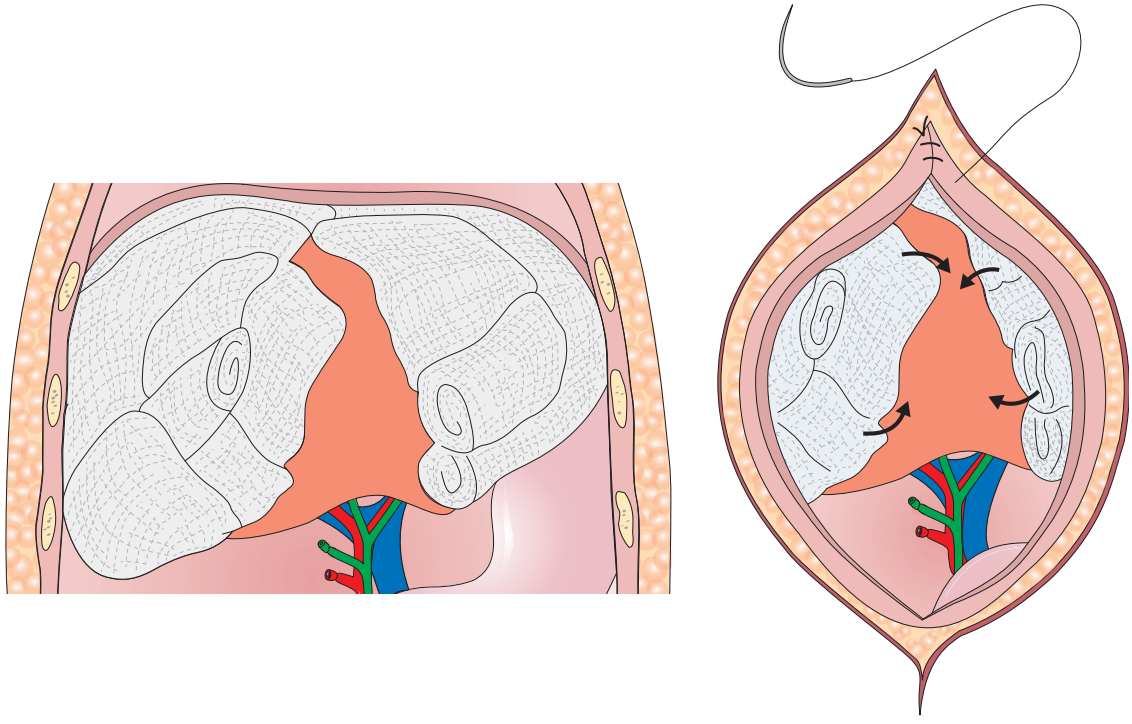

Figure 69.9 Packing the liver to achieve haemostasis. The abdomen can then be closed and the patient transferred to critical care for stabilisation prior to relook laparotomy 24–48 hours later. (Adapted from Poston GJ, D'Angelica M, Adam R (eds). *Surgical management of hepatobiliary and pancreatic disorders*. Boca Raton: CRC Press, 2010.)

effective in stable patients. If conservative management is successful patients are discharged after 8–10 days, advised to avoid abdominal trauma and rescanned after 6–8 weeks. If fever, bleeding or pain occurs prompt readmission is required.

Surgical approaches to liver trauma

When a laparotomy is indicated, especially when CT scanning is not possible, a 'rooftop' incision (see ***Figure 69.19***) with midline extension to the xiphisternum and retraction of the costal margins gives excellent access to the liver and spleen. If a midline incision is made initially a transverse right lateral extension will improve access. Required operative techniques include resectional debridement, hepatotomy with direct suture ligation and perihepatic packing. Anatomical resection, hepatic artery ligation and bypass techniques are possible following transfer of patients to tertiary hepatobiliary centres. Major complications include recurrent haemorrhage, sepsis and bile leak.

Packing or manual pressure intended to compress the parenchyma without causing caval compression is the initial aim (***Figure 69.9***); if additional intra-abdominal bleeding is found the source needs to be identified.

Care should be taken to avoid overzealous packing, which may produce pressure necrosis of the liver parenchyma or abdominal compartment syndrome. Packing is effective for the majority of liver injuries if the liver is packed against the natural contour of the diaphragm. If control is not achieved a Pringle manoeuvre should be performed (***Figure 69.10***). Large abdominal packs should be used to ease their removal, and the abdomen closed to facilitate compression.

Continued bleeding implies damage to the hepatic veins and/or the IVC but exploration of a liver laceration should only be attempted if control is not possible. If insufficient facilities or assistance are available and packing controls the situation, the abdomen should be closed and the patient transferred to a tertiary centre.

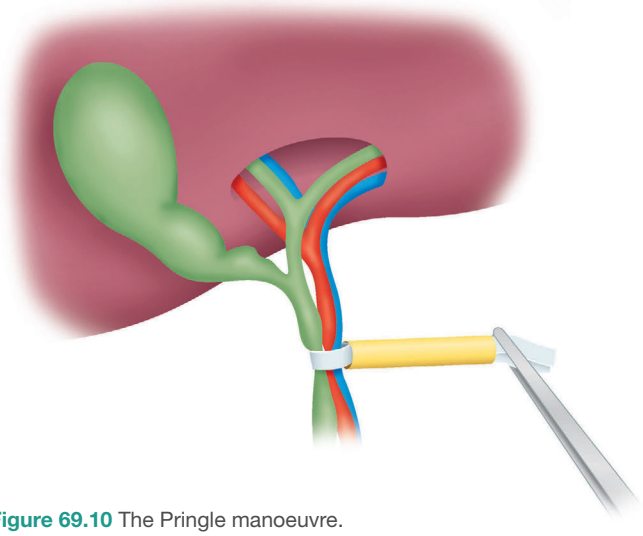

Figure 69.10 The Pringle manoeuvre.

James Hogarth Pringle, 1863–1941, surgeon, The Royal Infirmary, Glasgow, UK.

Crush injuries to the liver may produce large parenchymal haematomas and diffuse capsular lacerations (***Figure 69.8a***). Suturing is ineffective, and perihepatic packing is frequently the only option. Necrotic tissue should be removed but poorly perfused but viable liver left *in situ*. If packing is necessary, this should be removed after 48–72 hours; usually, no further intervention is required. Antibiotic cover is advisable and full reversal of any coagulopathy essential. If a major vascular injury (hepatic vein or vena cava, grade V or VI) is suspected then packing and referral to a specialist centre should be considered as venovenous bypass is often required. Following transfer, a further laparotomy is performed, the liver fully mobilised and, after a Pringle manoeuvre and IVC occlusion above the renal veins and at the level of the diaphragm using atraumatic vascular clamps (with/without venovenous bypass), caval or hepatic vein damage is repaired. Warm ischaemia of the liver is tolerated for up to 45 minutes.

Complications of liver trauma

A subcapsular or intrahepatic haematoma requires no specific intervention and should be allowed to resolve spontaneously. Abscesses may form as a result of secondary infection of an area of parenchymal ischaemia and treatment is systemic antibiotics and US-guided aspiration once liquefaction has occurred. Bile collections require US-guided aspiration with/without drain insertion and biliary fistulae are investigated by endoscopic or percutaneous cholangiography with/without stent insertion for biliary decompression. If a fistula persists liver resection may be required.

Late vascular complications include hepatic artery aneurysms and arteriovenous fistulae (hepatic artery to hepatic vein, producing heart failure; arterioportal, causing portal hypertension) and arteriobiliary fistulae indicated by haemobilia are treated by embolisation. Hepatic insufficiency may occur following extensive liver trauma but usually recovers following supportive treatment if the blood supply and biliary drainage to an adequate liver remnant are preserved (***Figure 69.11***).

Summary box 69.8

Complications of liver trauma

- Intrahepatic haematoma
- Liver abscess
- Bile collection
- Biliary fistula
- Haemobilia
- Ascites
- Biliary strictures
- Intra-abdominal collections
- Hepatic artery aneurysm
- Arteriovenous fistulae
- Arteriobiliary fistulae
- Liver failure

Long-term problems following liver trauma and their management

Late complications are rare, but biliary strictures occur many years after liver trauma and treatment depends on the extent and site of stricturing. A segmental or lobar stricture with atrophy of the corresponding area of liver parenchyma and compensatory contralateral hypertrophy is treated expectantly. A dominant extrahepatic bile duct stricture associated with obstructive jaundice should be treated endoscopically but may require surgical correction with a Roux-en-Y hepatodochojejunostomy.

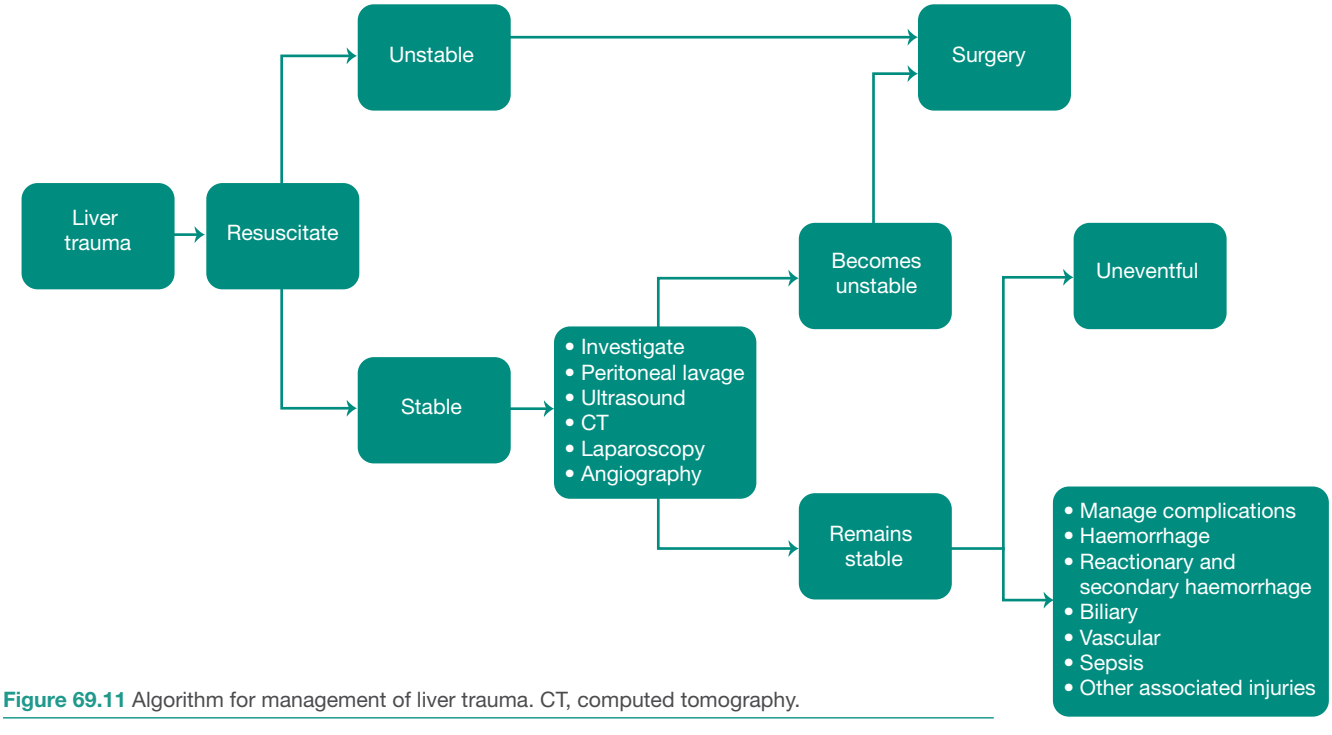

Figure 69.11 Algorithm for management of liver trauma. CT, computed tomography.

César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland. Described the Roux-en-Y loop in 1908.

PORTAL HYPERTENSION

Portal hypertension is most commonly due to liver cirrhosis, although it also occurs with extrahepatic portal vein occlusion, intrahepatic veno-occlusive disease and occlusion of the main hepatic veins (Budd–Chiari syndrome). The condition is common in clinical practice and portal hypertension represents a significant clinical challenge, with patients who have often been ill for long periods repeatedly presenting as emergencies. Many symptoms are intractable, surgery is technically difficult and procedures and timing must be chosen with extreme care. Portal hypertension *per se* produces no symptoms and is generally diagnosed following presentation with decompensated chronic liver disease causing encephalopathy, ascites or variceal bleeding (***Figure 69.12***).

Surgical involvement occurs in four situations:

1. ascites;
2. oesophageal varices;
3. portosystemic shunting for problems not managed by other methods;
4. left-sided portal hypertension and hypersplenism.

Management of variceal bleeding

Resuscitation

Varices are ubiquitous in patients with portal hypertension irrespective of the aetiology and usually present with an acute, large-volume haematemesis associated with a high morbidity and significant mortality. The lower oesophagus is the most common site and the diagnosis should be suspected in a patient known to have cirrhosis, but confirmation of the source is required following initial resuscitation. Variceal haemorrhage is a medical emergency and failure to control variceal bleeding with current medical management occurs in 10–20% of cases.

Patients with massive haemorrhage should be admitted to an intensive therapy unit, venous access obtained through two

Summary box 69.9

Causes of portal hypertension

- Pre-sinusoidal
  - Extrahepatic: portal vein thrombosis, splenic vein thrombosis (pancreatitis, pancreatic tumour), myelofibrosis, arterioportal shunt, tropical splenomegaly
  - Intrahepatic: schistosomiasis, congenital hepatic fibrosis and portal infiltration (sarcoidosis), drugs and toxins, veno-occlusive disease
- Sinusoidal
  - Cirrhosis
- Post-sinusoidal
  - Hepatic vein occlusion (Budd–Chiari syndrome), veno-occlusive disease, congestive cardiac failure

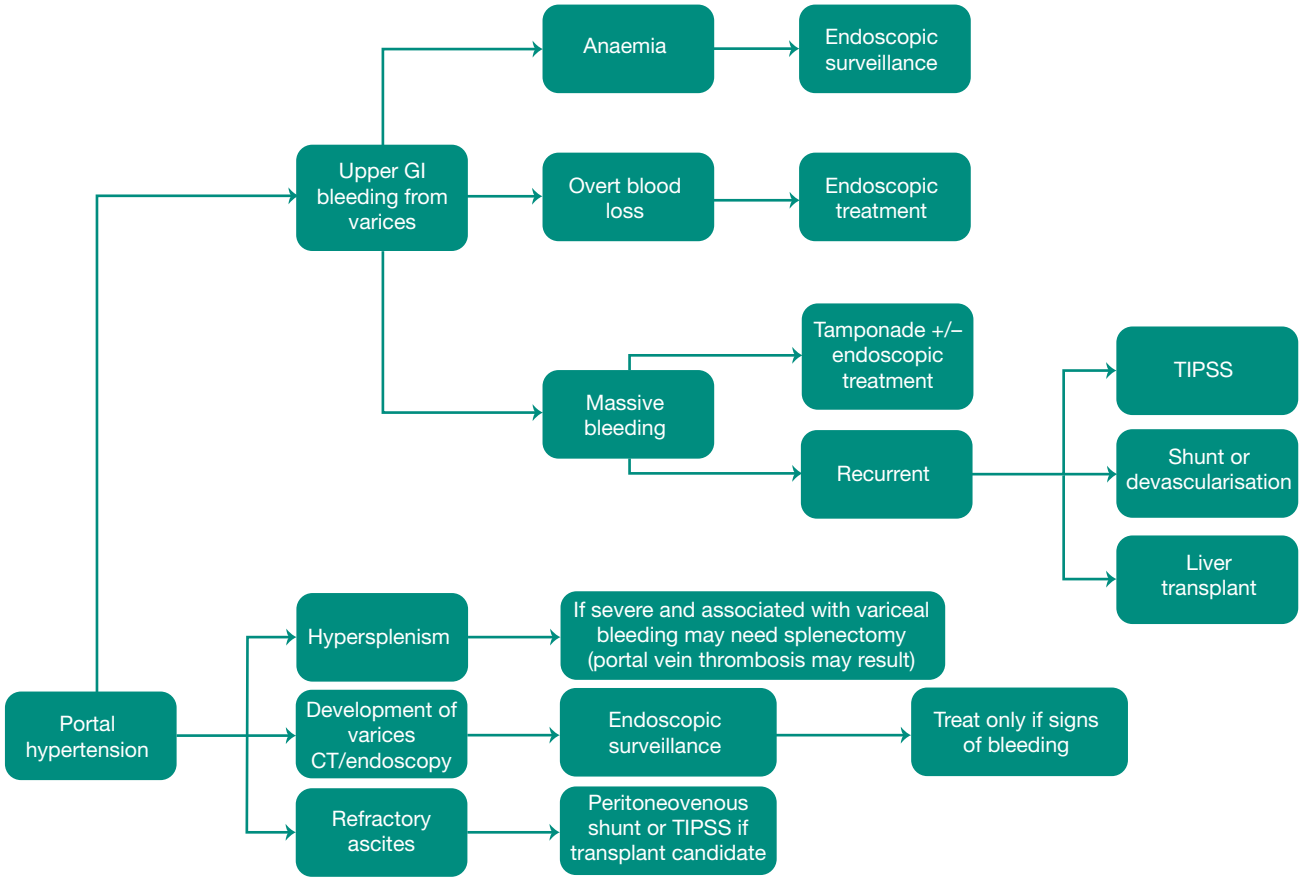

Figure 69.12 Management of complications of portal hypertension. CT, computed tomography; GI, gastrointestinal; TIPSS, transjugular intrahepatic portosystemic stent shunt.

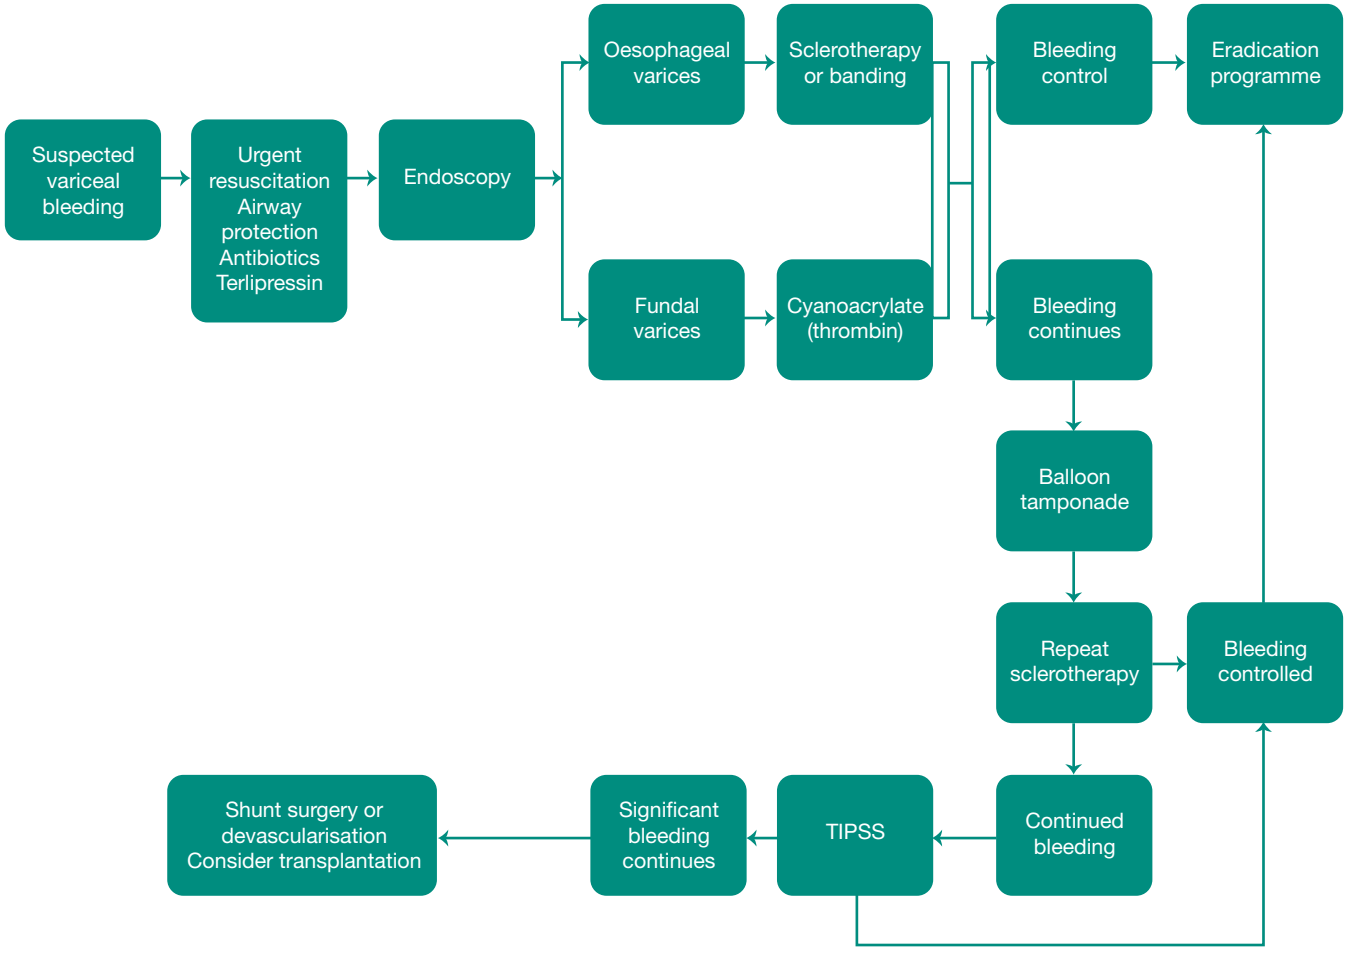

Figure 69.13 The management of variceal bleeding. TIPSS, transjugular intrahepatic portosystemic stent shunt.

large-bore peripheral cannulae and resuscitation commenced, ideally with blood. Liver function tests will reveal underlying liver disease and a coagulation profile will identify any coagulopathy. Hypervolaemia may increase portal pressure and exacerbate bleeding. Ten milligrams of vitamin K are administered intravenously but a coagulopathy requires FFP and activation of a major transfusion protocol. Thrombocytopenia secondary to hypersplenism is treated if the platelet count is $<50 \times 10^9$/L. Treatment protocols include the use of splanchnic vasoconstrictors, such as terlipressin, octreotide and somatostatin, and prophylactic antibiotics. When bleeding continues treatment options are sclerotherapy, banding, balloon tamponade and TIPSS. The use of oesophageal balloons should be avoided, which is usually possible when experienced endoscopists are available. As soon as the patient is haemodynamically stable the diagnosis should be confirmed endoscopically as 30% will have a non-variceal source of bleeding. Variceal bleeding is often associated with hepatic encephalopathy and endotracheal intubation may be required prior to endoscopy to protect the airway and prevent aspiration (***Figure 69.13***).

Balloon tamponade and self-expanding stents

Balloon tamponade is effective for massive or refractory variceal bleeding but is only recommended as a 'bridge' to definitive treatment. If the rate of blood loss prohibits endoscopic evaluation, a Sengstaken–Blakemore tube (originally described in 1950) or a Minnesota tube (addition of an oesophageal aspiration port) can be inserted to provide temporary haemostasis (***Figure 69.14***).

Once inserted, the gastric balloon is inflated with 300 mL of air and retracted to the gastric fundus and the oesophagogastric varices tamponaded by inflation of the oesophageal balloon to 60 mmHg. The two remaining channels allow gastric and oesophageal aspiration, and the position of the tube is confirmed radiologically. A strict protocol for the management of balloon tamponade is important to avoid complications particularly oesophageal pressure necrosis.

Recently, self-expanding covered metal oesophageal stents have also been employed for the emergency treatment of oesophageal varices and results are equivalent to balloon tamponade unless the bleeding site is intragastric.

Robert William Sengstaken Sr, 1923–1978, neurosurgeon, Garden City, New York, NY, USA.

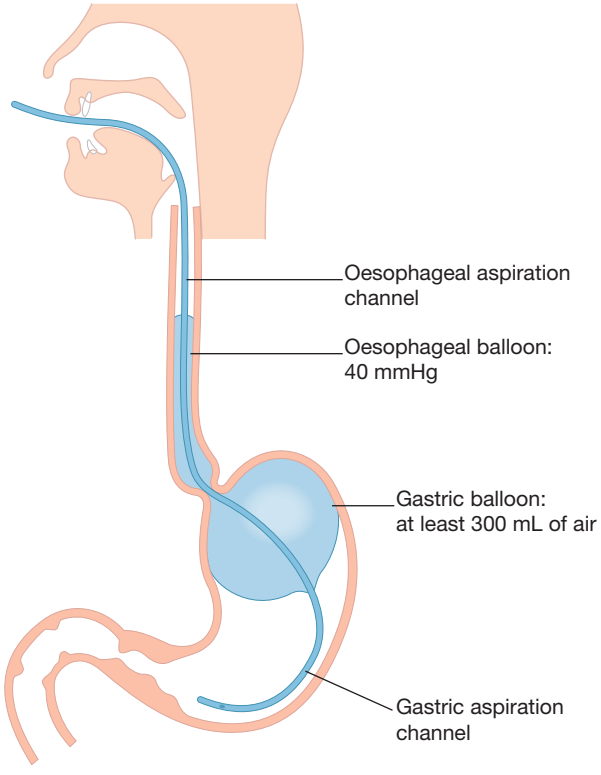

Figure 69.14 Oesophageal and gastric balloon tamponade with a Sengstaken–Blakemore or Minnesota tube. The tube must be carefully managed.

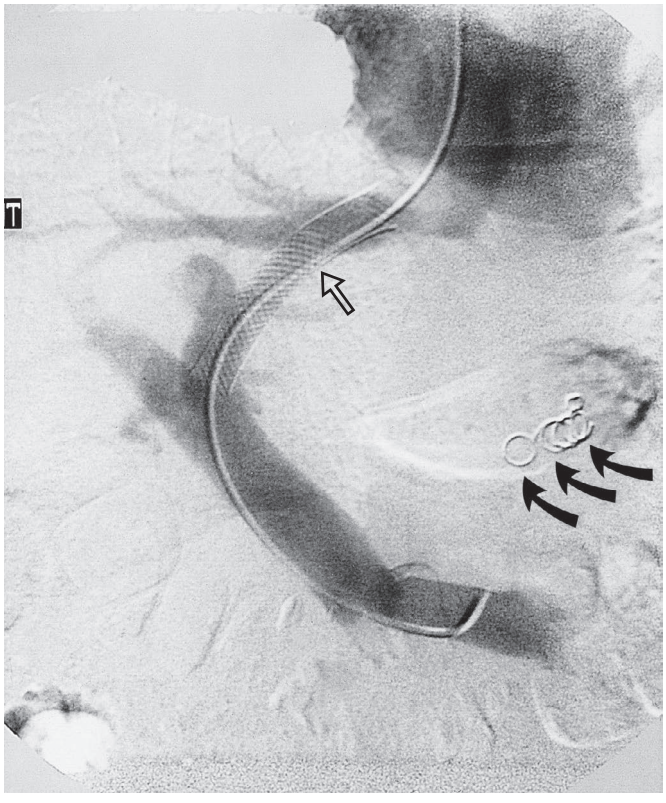

Figure 69.15 An angiogram following insertion of a transjugular intrahepatic portosystemic stent shunt (TIPSS) (open arrow). Contrast in the portal vein flows through the metallic stent and outlines the right hepatic vein. Pressure measurements are taken from within the portal vein before and after insertion. Solid arrows indicate coils placed at the site of previous embolisation.

Endoscopic treatment

The two most commonly used endoscopic techniques are endoscopic band ligation to the base of the varix and injection of a sclerosant into or around the varix. Following resuscitation, endoscopy is performed in a head-down position with good suction available. A double-channel endoscope with a bridge is essential to facilitate suction during injection and provide manoeuvrability of the needle, and power washers dramatically improve visualisation. Some time should be spent assessing the bleeding, confirming it is variceal and obtaining a stable position. When the bleeding varix or varices are identified only the source should be treated. Sclerotherapy or banding both achieve effective control with banding reducing rebleeding; a single treatment is usually sufficient.

Transjugular intrahepatic portosystemic stent shunts

The emergency management of variceal haemorrhage is extremely difficult when pharmacological and endoscopic therapies have failed. Treatment of these patients now relies on TIPSS, a radiological procedure first described in 1969 but not widely available until the development of endovascular stents in 1985. TIPSS has replaced surgical portocaval shunt and is now accepted as the preferred method for treating refractory portal hypertension. A TIPSS is inserted under local anaesthetic, analgesia and sedation using fluoroscopic guidance and ultrasonography. Via the internal jugular vein, superior vena cava and hepatic vein, a guidewire is inserted through the hepatic parenchyma into a branch of the portal vein. The tract is dilated; a metallic stent is then inserted and expanded, forming a portovenous channel (***Figure 69.15***). A satisfactory drop in portal venous pressure is usually associated with good control of the variceal haemorrhage. The main early complication is perforation of the liver capsule, with potentially fatal intraperitoneal haemorrhage. TIPSS occlusion may produce further variceal haemorrhage and occurs more commonly in patients with well-compensated liver disease and good synthetic function. The incidence of post-TIPSS encephalopathy is comparable to that following surgical shunts (40%) and due to portal blood avoiding hepatic detoxification, if severe, flow is reduced by inserting a smaller stent. The main contraindication to TIPSS is portal vein occlusion, and long-term stenosis occurs in 50% of patients at 1 year.

Surgical shunts

The increasing availability of liver transplantation and TIPSS has greatly reduced the indications for surgical portosystemic shunts, which, because of their high morbidity and mortality, are now rarely considered for variceal haemorrhage. The current indication is the failure of medical management in non-cirrhotic patients with extrahepatic portal vein occlusion. Surgical shunts effectively prevent rebleeding from oesophageal

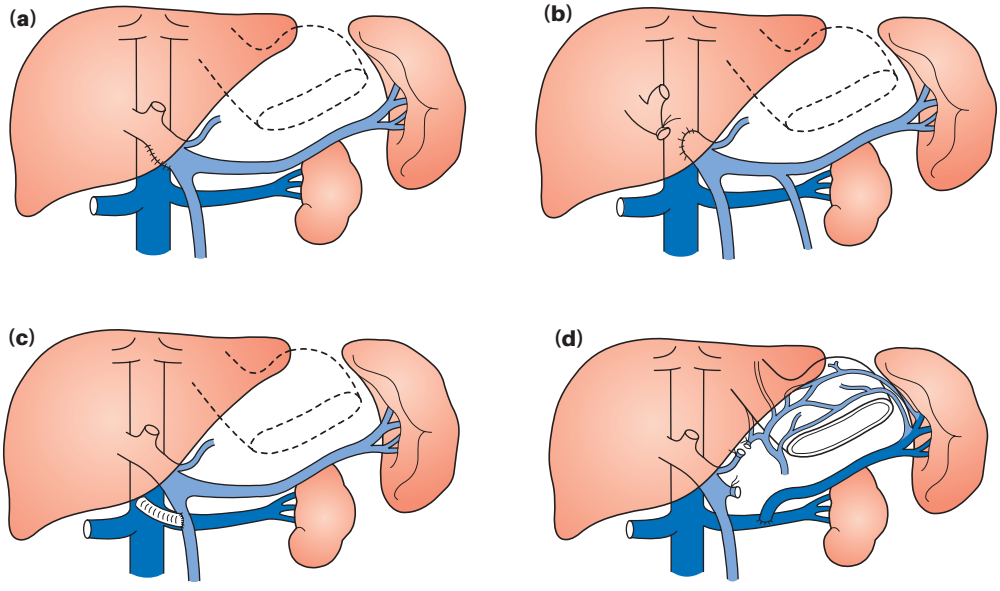

Figure 69.16 Surgical shunts for portal hypertension involve shunting portal blood into the systemic veins. This commonly involves a side-to-side portocaval anastomosis **(a)** or end-to-side portocaval **(b)**, mesocaval 'H graft' **(c)** or splenorenal **(d)** anastomoses.

or gastric varices by reducing portal pressure and are divided into selective, splenorenal and non-selective portocaval. Selective shunts attempt to preserve hepatoportal blood flow while decompressing the left side of the portal circulation, which is responsible for oesophageal and gastric varices (***Figure 69.16***). Selective shunts have a lower incidence of encephalopathy but there is no evidence that prophylactic shunting is beneficial.

Recurrent or refractory variceal bleeding

Sugiura procedure

The Sugiura procedure for oesophageal varices combines splenectomy with oesophagogastric devascularisation, permanently interrupting the intraoesophageal portacaval shunt while preserving perioesophageal varices. The surgery is performed on the stomach wall and all venous tributaries are divided as for highly selective vagotomy except on both the lesser and greater curves. The upper half of the stomach and 8–10 cm of oesophagus are cleared (less than originally described but avoiding entering the chest). After devascularisation with careful preservation of the collateral channels and the vagus, a large oesophageal stapler is introduced into the lower oesophagus, which is transected just above the cardia.

Liver transplantation

Liver transplantation is the only therapy that treats portal hypertension and the underlying liver disease and may ultimately be required in patents with variceal bleeding. Previous surgical shunts increase the complexity and morbidity of orthotopic liver transplantation and TIPSS should be the preferred management (see ***Chapter 89***).

Summary box 69.10

Management of bleeding oesophageal varices

- Blood transfusion
- Correct coagulopathy
- Oesophageal balloon tamponade (Sengstaken–Blakemore or Minnesota tube)
- Drug therapy (terlipressin)
- Endoscopic sclerotherapy or banding
- Assess portal vein patency (Doppler ultrasonography or CT)
- TIPSS
- Surgery
- Portosystemic shunts
- Splenectomy and gastric devascularisation
- Sugiura procedure

Ascites

Accumulation of ascites is a common feature of advanced liver disease irrespective of the aetiology. Development is usually insidious and fluid accumulation is associated with abdominal discomfort and a dragging sensation. CT will confirm the aetiology of the ascites and demonstrate the irregular, shrunken cirrhotic liver, associated portal hypertension and splenomegaly. Intravenous contrast will demonstrate abdominal varices and assess patency of the portal vein. Portal vein occlusion is a common finding and in non-cirrhotic patients malignancy is usually responsible. The protein content and amylase levels will exclude pancreatic ascites and determine the serum–ascites albumin gradient (SAAG), with a high gradient (>1.1 g/dL) indicating portal hypertension. Cytology may confirm the presence of malignant cells, and microscopy and culture will

Mitsuo Sugiura, 1925–1988, surgeon, University of Juntendo, Tokyo, Japan.

exclude primary bacterial and tuberculous peritonitis (see ***Chapter 65***).

Summary box 69.11

Determining the cause of ascites

- Imaging, ultrasonography or CT
  - Irregular cirrhotic liver
  - Portal vein patency
  - Splenomegaly of cirrhosis
- Aspiration
  - Culture and microscopy
  - Protein content
  - Cytology
  - Amylase level

Management of ascites in chronic liver disease

The initial treatment is to restrict salt intake and commence diuretics (spironolactone or frusemide), together with advice on avoiding precipitating factors, including alcohol intake, infection and causes of hypoproteinaemia. Patients on diuretics require regular biochemical monitoring.

Summary box 69.12

Treatment of ascites in chronic liver disease

- Salt restriction
- Diuretics
- Abdominal paracentesis
- Peritoneovenous shunts
- TIPSS
- Liver transplantation

CHRONIC LIVER DISEASE

Several rare chronic liver conditions are important because they require a specific investigation plan and treatment and may imitate more common clinical conditions (***Table 69.6***).

TABLE 69.6 Important chronic liver conditions.

Condition	Common presentations
Primary sclerosing cholangitis	Abnormal LFTs, pruritus or jaundice
Primary biliary cirrhosis	Malaise, lethargy, pruritus, abnormal LFTs
Budd–Chiari syndrome	Ascites, pain, abdominal distension
Caroli's disease	Abdominal pain, sepsis, biliary obstruction
Simple liver cysts	Coincidental finding, pain, palpable mass
Polycystic liver disease	Hepatomegaly, pain

LFT, liver function test.

Primary sclerosing cholangitis

PSC is a chronic cholestatic liver disease of unknown aetiology, although a genetic predisposition is likely owing to its association with ulcerative colitis. It produces diffuse, progressive inflammation and fibrosis with structuring of the intra- and extrahepatic biliary tree and mainly affects young men in their thirties. The exact worldwide prevalence is unclear, but it appears to affect 1.5/100 000 men and 0.5/100 000 women.

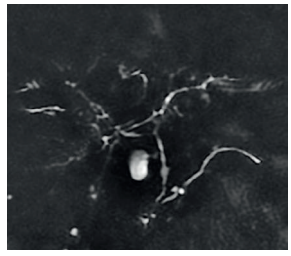

Figure 69.17 Typical appearance of primary sclerosing cholangitis with a 'beaded' appearance of the intrahepatic ducts and diffuse widespread strictures. The intrahepatic ducts usually do not dilate owing to the pathological process involving the whole of the biliary tract.

In patients with PSC and ulcerative colitis, the condition usually progresses even following colectomy. The diagnosis is principally based on the finding of irregular, narrowed bile ducts at cholangiography involving both the intra- and extrahepatic biliary tree (***Figure 69.17***), but if the radiological appearances are equivocal a liver biopsy is required. There is no specific treatment and patients usually progress inexorably with progressive cholestasis and fatal liver failure. Isolated areas of intrahepatic sclerosing cholangitis can occasionally be resected but diffuse disease usually requires liver transplantation. There is a strong predisposition to cholangiocarcinoma and gallbladder cancer, which should be considered when a new or dominant stricture is demonstrated on cholangiography or when gallbladder 'polyps' are identified.

The difficulty in the clinical setting is distinguishing sclerosing cholangitis from a malignant process, particularly multifocal cholangiocarcinoma. Imaging cannot reliably differentiate between inflammatory and malignant strictures and rarely demonstrates a mass lesion even in patients with advanced cholangiocarcinoma. Diagnosis often requires biliary brush cytology or direct endoscopic inspection (SpyGlass™). Serum cancer antigen (CA) 19-9 levels may be increased but the sensitivity of CA 19-9 in detecting cholangiocarcinoma in PSC is only 60%. Temporary relief of obstructive jaundice owing to a dominant bile duct stricture can be achieved by biliary stenting, although there is considerable risk of cholangitis. Patients with good liver function, no dominant strictures and negative biliary cytology are monitored for disease progression. Liver transplantation produces excellent results if performed before the development of malignancy.

Primary biliary cirrhosis

As with PSC, patients with primary biliary cirrhosis often present insidiously with malaise, lethargy and pruritus or abnormal liver function tests prior to becoming clinically jaundice. The condition is largely confined to females and the diagnosis is suggested by circulating anti-smooth muscle antibodies with/without liver biopsy. As the condition progresses liver function deteriorates, and portal hypertension, ascites and variceal

bleeding may occur. The definitive treatment is liver transplantation when a normal lifestyle is not possible.

Non-alcoholic steatohepatitis, non-alcoholic fatty liver disease and chemotherapy-associated hepatitis

Non-alcoholic steatohepatitis (NASH) is the inflammatory subtype of non-alcoholic fatty liver disease (NAFLD) and is associated with disease progression, the development of cirrhosis and frequently the need for liver transplantation. NAFLD is now recognised as the most prevalent chronic liver disease worldwide and this is expected to increase 60% by 2030. Presently the prevalence of NAFLD is 25% and NASH 1.5–6%, with an estimated 20% of patients with NASH developing cirrhosis.

Some drugs may induce hepatotoxic lesions, such as steatosis or steatohepatitis found in NAFLD. Among these drugs there are some antitumoral molecules, such as methotrexate, 5-fluorouracil, irinotecan, tamoxifen and l-asparaginase. The hepatotoxic phenotype developed from treatment with such drugs is known as chemotherapy-associated, chemotherapy-induced acute steatohepatitis or chemotherapy-associated hepatitis (CASH). The parenchymal consequences of CASH are important surgically and must be considered when predicting future liver remnant (FLR) function.

Budd–Chiari syndrome

The Budd–Chiari syndrome affects 1/1 000 000 adults and is a collective term for conditions that impede hepatic venous outflow at any level from the small hepatic veins to the junction of the IVC with the right atrium. Cardiac and pericardial diseases and sinusoidal obstruction syndrome are excluded from this definition. It principally affects young women, who present the classic triad of abdominal pain, ascites and hepatomegaly. A hypercoagulable condition such as antithrombin 3, protein C or protein S deficiency is identified in 75% of patients, extrinsic compression in 25% and rarely congenital or acquired IVC webs.

The liver becomes acutely congested, with impaired liver function and portal hypertension; ascites and oesophageal varices develop. Fulminant hepatic failure may result from acute thrombosis but in the majority of cases abdominal discomfort and ascites are the main presenting features. If chronic, the liver progresses to established cirrhosis. Colour and pulsed Doppler ultrasonography and CT scanning together with detailed haematological studies will usually identify the cause. The diagnosis should be suspected in patients with ascites where a CT scan demonstrates a large, congested liver or cirrhosis with gross enlargement of the caudate lobe resulting from preservation and hypertrophy of the segment due to direct venous drainage to the IVC. Further IVC compression or occlusion and portal vein thrombosis are common consequences of caudate lobe hypertrophy.

Treatment of Budd–Chiari syndrome depends on the stage of disease at presentation and the specific findings in each patient. Fulminant liver failure, established cirrhosis and complications of portal hypertension may require liver transplantation. If the liver parenchyma is relatively normal TIPSS or a side-to-side portocaval shunt should be considered and IVC compression relieved by the insertion of a retrohepatic expandable metallic stent. With effective Budd–Chiari syndrome treatment prognosis depends on whether it is possible to treat the underlying pathology. Patients usually require lifelong anticoagulation.

Caroli's disease

Caroli's disease is a rare congenital dilatation of the intrahepatic biliary tree with an incidence of <1/100 000. It is often complicated by intrahepatic stone formation and presentation is usually with abdominal pain or sepsis. Imaging is diagnostic with ultrasonography or CT demonstrating intrahepatic biliary lakes containing stones which predispose to potentially life-threatening biliary sepsis. Acute infective episodes are treated with antibiotics and obstructed and infected bile ducts may be drained radiologically, endoscopically or surgically. Ductal dilatation is usually diffuse but if segmental may be treated by resection of the affected part. Cholangiocarcinoma is more common than for other forms of biliary ectasia and treatment by liver transplantation is described.

INFECTIVE CONDITIONS OF THE LIVER

Ascending cholangitis

Ascending cholangitis is a potentially life-threatening emergency associated with infection of the biliary tree and usually associated with obstruction. It presents with clinical jaundice, rigors and a tender right upper quadrant (Charcot's triad). The most common bacteria linked to ascending cholangitis are gram-negative bacilli: *Escherichia coli* (25–50%), *Klebsiella* (15–20%) and *Enterobacter* (5–10%). The diagnosis is confirmed by the finding of dilated bile ducts on ultrasonography, an obstructive picture of liver function tests and organisms identified from blood cultures. Delay in appropriate treatment may result in multiorgan failure secondary to sepsis and broad-spectrum antibiotics, rehydration, and endoscopic or percutaneous transhepatic drainage are urgently required. Biliary stone disease is a common predisposing factor although strictures, pancreatitis, pancreatic tumours and parasites may also be responsible. If an obstructive cause is identified it must be urgently treated by ERCP, sphincterotomy (± stent) or percutaneous drainage.

Liver abscess

Microbial contamination of the liver leading to a liver abscess continues to occur at a fairly constant rate of approximately 1/5000 hospital admissions. The incidence of causative organisms varies and reflects changes in aetiology and geographical distribution. Bacterial, parasitic and fungal organisms can cause liver abscess but, worldwide, bacteria remain the most common; although infection is usually polymicrobial *Klebsiella, Escherichia coli* and the *Streptococcus milleri* group are the usual organisms identified.

There is an increased incidence in the elderly, those with diabetes and the immunosuppressed and presentation is usually with anorexia, fever, malaise and right upper quadrant discomfort. The overall mortality has declined because of improved imaging and effective antimicrobial therapy and the outcome is increasingly dependent on the underlying cause and the presence of comorbidities.

Biliary tract pathology is the most common source (35%), followed by portal spread from the gastrointestinal tract, including diverticulitis and appendicitis (20%). Other unusual aetiologies include contiguous spread from subphrenic or intra-abdominal collections, bacteraemia secondary to trauma or infected cysts and necrotic tumours following chemotherapy. The cause is not identified in 10% of cases and a number of liver abscesses become recurrent (12–38% depending on whether the responsible organism is identified and whether the patient has diabetes). The diagnosis is suggested by the finding of a multiloculated cystic mass on ultrasonography or CT scan (***Figure 69.18***) and is confirmed by aspiration.

Treatment of liver abscesses initially requires identification of the source, if possible, aspiration of the lesion for microbiology and culture (repeated aspirations may be required) and treatment with appropriate antibiotics. Simple cysts containing debris, hydatid cysts, necrotic tumours and non-infected haematomas (after unrecognised or occasional trivial trauma) can all be mistaken for abscesses. Antibiotic treatment using a combination of two or more antibiotics is recommended. Metronidazole and clindamycin provide wide anaerobic coverage and excellent penetration into the abscess cavity. Third-generation cephalosporins and aminoglycosides are very effective against most Gram-negative organisms.

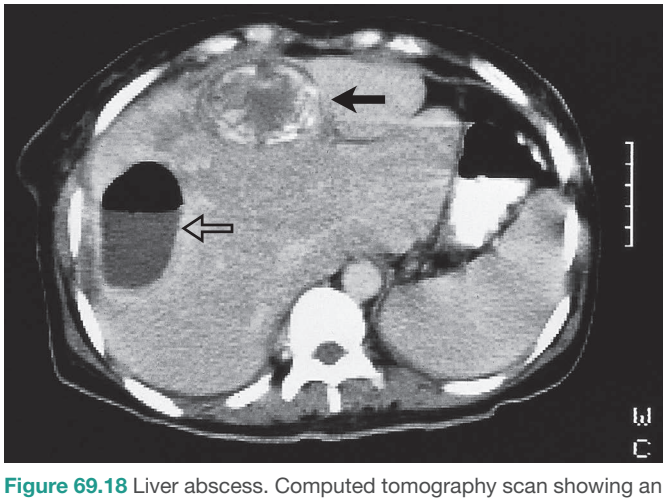

Figure 69.18 Liver abscess. Computed tomography scan showing an air–fluid level and rim enhancement (open arrow). The second lesion seen is a haemangioma (closed arrow).

Recurrent or refractory abscesses

Recurrent abscesses usually occur when the initial lesion was large, abscesses were multiple or there is continued communication with the biliary tract. It can be difficult to confirm whether a liver abscess is recurrent or new, but it is important as treatment differs. Recurrent lesions which were aspirated and treated with antibiotics can be re-aspirated, but a drain is often required. Refractory lesions should have microbiology repeated and a drain inserted, and recurrences are rare if left until resolution is complete. If unsuccessful occasionally surgery is required, and laparoscopy which allows a full examination of the peritoneal cavity (especially valuable when the source has not been identified) has replaced laparotomy.

Parasitic diseases of the liver

The liver is frequently affected by parasitic infections, which, owing to the worldwide prevalence of these organisms, are responsible for considerable morbidity and mortality (see ***Chapter 6***).

Hydatid disease

Human echinococcosis (hydatidosis, hydatid disease) is a parasitic disease caused by the larval stages of cestodes (tapeworms) of the genus *Echinococcus*. Medical treatment and diagnosis are discussed in ***Chapter 6***. Surgical intervention is occasionally required when medical management fails, and options range from liver resection or local excision of the cysts to deroofing with evacuation of the contents. Contamination of the peritoneal cavity at the time of surgery with active hydatid daughters should be avoided by continuing drug therapy with albendazole and adding preoperative praziquantel. This should be combined with packing of the peritoneal cavity with 20% hypertonic saline-soaked packs and instilling 20% hypertonic saline into the cyst before it is opened. A biliary communication should be actively sought and sutured. Infection and

Summary box 69.13

Infections of the liver

- Pyogenic liver abscesses 1/5000 admissions
- Worldwide billions of people have parasitic infections
- Parasitic infections cause live abscess and biliary tract damage
- Biliary tract involvement predisposes to cholangiocarcinoma
- Parasitic infections mimic pyogenic abscesses
- Obstructive jaundice from calcified flukes or involvement of the biliary tract

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czechoslovakia, Zurich, Switzerland, and the Rush Medical College, Chicago, IL, USA.

bile leaks can be reduced by packing the space with pedicled greater omentum (an omentoplasty). Calcified cysts may be dead; however, if doubt exists as to whether a suspected cyst is active, it can be followed on ultrasonography as active cysts gradually enlarge and become more superficial.

LIVER TUMOURS

Liver resection continues to evolve, and the safety has been established with a mortality of 1–2% and a 5-year survival following resection of colorectal metastases of 50%. Early surgical approaches involved a formal left or right hepatectomy and the presence of bilobar disease or more than three or four metastases were considered inoperable. Advances in surgery and anaesthesia, including combinations of staged procedures, portal vein embolisation (PVE), ablation and local resections, increased the number of potentially curative procedures. Concurrent progress in oncology has increased the ability of chemotherapy to 'downstage' disease sufficiently to operable lesions that would have been formerly considered inoperable.

Surgical approaches to resection of liver tumours

Parenchyma-preserving resections that achieve adequate oncological clearance have emerged from an understanding of oncological principles and the impact of chemotherapy on hepatic function. Such resections preserve functioning liver volume, improving postoperative recovery, reducing morbidity and facilitating re-do surgery for recurrent metastases. Limited extrahepatic disease is also no longer an absolute contraindication and pulmonary and adrenal metastases and contiguous portal vein lymph nodes are increasingly resected.

Mobilisation of the liver

Incision

A roof top incision is performed 2–3 cm below the costal margin (***Figure 69.19***) with a vertical extension (Mercedes-Benz) if required. Fixed retraction under the ribs provides adequate access and thoracoabdominal incisions are no longer required. If doubt exists about operability a small right subcostal incision is used initially, and a thorough examination performed, including the caudate lobe. Intraoperative ultrasonography (IUS) is the standard of care for hepatobiliary surgery and is used with bimanual palpation to assess the extent of the tumour(s). IUS detects only an additional 10% compared with palpation alone.

The hepatic pedicle

Hilar dissection

Having determined that tumour does not directly involve the hilar structures a standard cholecystectomy is performed. The CBD is identified in the free edge of the lesser omentum, facilitated by following the cystic duct to its junction, dissected free and slung. The tissue in the right free border of the hepatoduodenal ligament is dissected and removed by ligation and division to avoid lymphatic leaks and the portal vein identified and slung. Developing the plane anterior to the vein allows the bile duct and artery to be mobilised forwards and the bifurcation of the vein to be identified (the branch to the side to be retained must be clearly identified). At this point anterior tissue (the hilar plate) should be freed from the base of the liver, lowering the structures that bifurcate. The artery and duct are separated at the bifurcation and slung just below it. The vascular anatomy is then confirmed, and the possibility of a replaced right hepatic artery arising from the superior mesenteric artery and lying posterior to the bile duct (25% of people) and an accessory left hepatic artery from the left gastric artery in the lesser omentum (25% of people) considered. Hilar arterial and biliary anatomy in the hepatoduodenal ligament and at the hilum is so variable that careful dissection is required even if the pattern appears to be one of the recognised variants. A standard approach is important in the event of unexpected intraoperative findings. The approach to the hilum allows different conditions and pathologies to be approached with confidence, including formal resections (metastases and primary liver tumours), hilar cholangiocarcinoma, bile duct injuries and penetrating trauma.

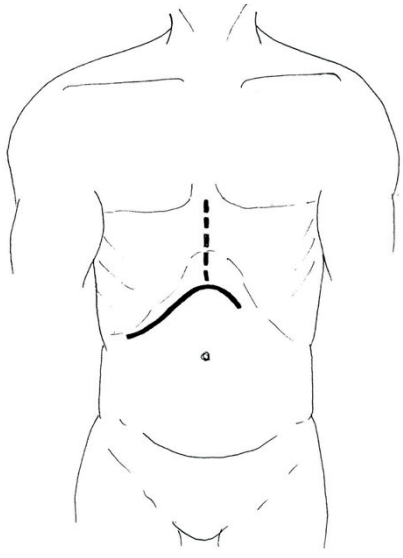

Figure 69.19 Access for liver surgery. Rooftop incision with optional vertical extension.

Methods of parenchymal transection

An array of techniques and technologies have been developed to aid parenchymal dissection by facilitating identification of vascular and biliary structures to enable accurate diathermy, ligation or clipping. They also allow safe resection with adequate clearance of centrally placed tumours near the confluence of the hepatic veins and the IVC or the inflow sheaths. Safe transection with minimal blood loss and an adequate tumour clearance can be achieved using a crushing clamp, cavitating

The Mercedes-Benz sign takes its name from the insignia displayed on the bonnet of a Mercedes-Benz car.

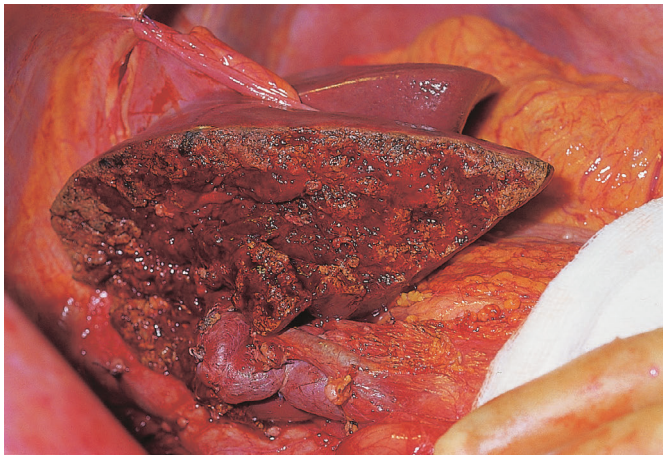

Figure 69.20 Hepatectomy post resection. Cut surface of the residual liver following a right hepatectomy in which segments V–VIII have been removed. On the lower edge, the portal vein and bile duct can be seen.

ultrasonic suction and aspiration (CUSA), harmonic scalpel or radiofrequency ablation (RFA) and is a matter of personal preference with no evidence that any method is superior (***Figure 69.20***). Hepatic veins and the Glissonian sheath are now routinely stapled with an endoscopic vascular stapler.

The parenchyma is divided after diathermy of the liver capsule along the plane of demarcation 5 mm into the devascularised liver. As the parenchyma is divided, vessels and bile ducts are diathermised, clipped or ligated depending on their size. The hepatic veins can be divided outside the liver at the time of mobilisation or parenchymal dissection continued until they are encountered, when they are ligated or stapled then divided.

Resection options

Segmental resections

Hepatic resection traditionally involved the formal removal of the right (segments V–VIII) or left (segments II–IV with/without I) hemiliver to ensure the largest possible clearance. Although anatomical resection remains the treatment of choice for patients with HCC, a parenchyma-sparing non-anatomical approach involving multiple segmentectomies and/or metastectomies is now the standard of care for colorectal liver metastasis (***Figure 69.21***).

Staged procedures

Extensive resection of the liver in two stages was first described in 1965. The aim is to 'clear' one lobe of the liver of all known disease followed 4–6 weeks later by a formal major resection to clear all residual disease. Staged resections are usually only possible if the left side can be cleared first by local resections, something that is usually not possible on the right because of the need to remove as little normal parenchyma as possible to avoid stimulating too much regeneration. The stimulus for regeneration following resection of too much liver may accelerate growth of the tumour, which despite chemotherapy may become inoperable.

ALPPS procedure for extended liver resections

'ALPPS' stands for Associating Liver Partition and Portal vein Ligation for Staged hepatectomy and was first described in 2011. It is the most recent modification of techniques developed to facilitate two-stage hepatectomies for resection of widespread or extensive liver tumours and employs the remarkable capacity of the liver to regenerate. ALPPS involves two stages. Initially the right portal vein is ligated and, depending on the distribution of the tumour within the liver, transection is performed as for a formal hemihepatectomy or left lateral segmentectomy (*in situ* splitting). In contrast to a classical hepatectomy, the liver containing the tumour(s) is left *in situ* and remains vascularised by the right hepatic artery and the biliary and systemic venous drainage, represented by the right bile duct and hepatic veins, preserved. The second stage of the procedure is performed 1–2 weeks after the first stage following CT demonstration of adequate hypertrophy; the involved liver is resected after division of the right hepatic artery, bile duct and hepatic vein. Initially ALPPS was associated with significant morbidity and mortality but modifications of the technique, particularly a reduction in the amount of liver transected, improved results.

Portal vein embolisation

Preoperative PVE induces hypertrophy of one side of the liver prior to a planned resection of the other side. The procedure

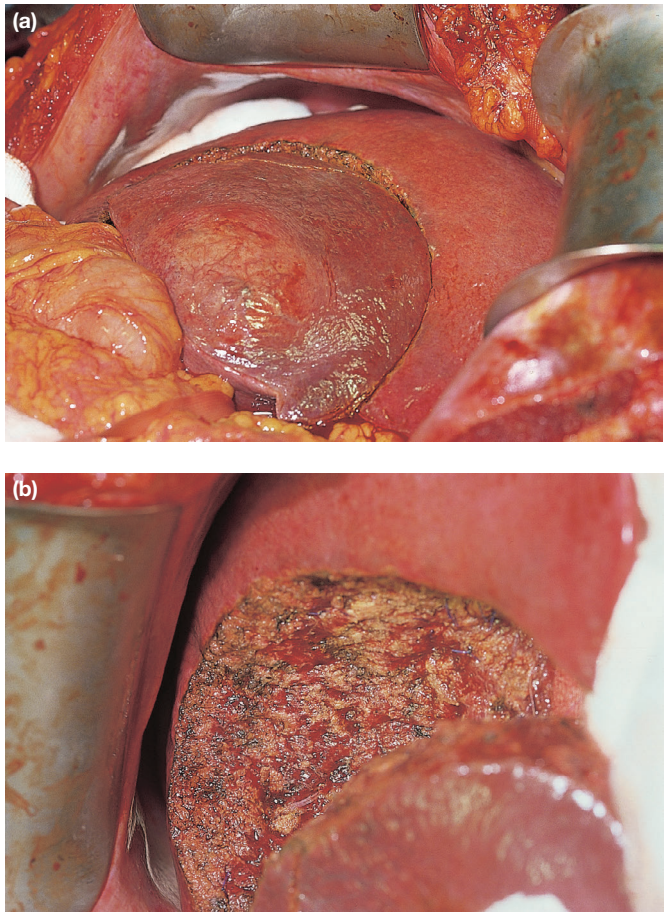

Figure 69.21 (a, b) Segmental resection. Removal of a primary liver tumour by resection of liver segment VI in a patient with well-compensated liver cirrhosis.

is frequently used for HCC and colorectal liver metastases and was first described by Makuuchi in 1984 before an extended hepatectomy for bile duct carcinoma. Several techniques for PVE have been reported, including intraoperative ligation, transileocolic PVE and the percutaneous transhepatic ipsilateral or contralateral PVE techniques. The underlying principle is to block the portal venous blood flow to the liver segments that require resection. This induces atrophy of the ipsilateral liver segments and compensatory hypertrophy of the contralateral liver segments, resulting in an increase in the size of the proposed FLR. In addition to the different techniques, different embolisation materials are used, including polyvinyl alcohol particles, coils, gelatin sponge, *n*-butyl cyanoacrylate and lipiodol, or fibrin glue. Indications for PVE depend on the ratio of the proposed FLR to total estimated liver volume (TELV) and the condition of the liver. There is no clear consensus about the volume required for adequate postresection liver function but an FLR/TELV ratio of at least 25% is recommended with a normal liver and 40% in the presence of cirrhosis. Patients who have received extensive chemotherapy with an FLR/TELV ratio less than 30% should also receive PVE prior to resection.

Laparoscopic liver resections

The development of laparoscopic liver resection (LLR) following its first performance in the USA in 1991 for a benign tumour on the edge of the liver has been one of the most impressive in the field of hepatobiliary surgery. Technical innovation has made LLR a safe and effective procedure with significantly improved postoperative recovery. The potential advantages of LLR mean that it is gradually replacing conventional open liver resection. Indications have expanded from local resections to include major liver resection, isolated resection of the caudate lobe, living donor liver resection and ALPPS. For some procedures such as laparoscopic local resection and left lateral segmentectomy LLR is the approach of choice and formal hepatectomies are now routinely performed laparoscopically in high-volume centres.

Robotic surgery

With the safe and effective development of laparoscopic liver surgery, robotic surgery, which obviates some of the technical issues, was welcomed and the first robotic liver resection was performed in 2007 for a 2.4-cm HCC. Indications for robotic surgery will expand but are presently limited by cost, time constraints, the lengthy learning curve, the lack of haptic feedback and the availability of dedicated instruments for parenchymal transection (see ***Chapter 10***).

Blood loss and transfusion

The reduction of blood loss during liver surgery has developed such that resection is often possible without blood transfusion. Better understanding of the segmental anatomy of the liver and patient selection, low central venous pressure anaesthesia and the routine availability of thromboelastography has facilitated better control of the coagulation cascade and significantly reduced bleeding in patients with liver disease and underlying coagulopathies.

The Pringle manoeuvre can reduce blood loss during parenchymal transection and improves the effectiveness of other techniques used to treat oozing from the resected surface of the remnant liver. These include the topical application of fibrin glue or fibrin-impregnated collagen fleece and non-contact electrosurgical technique such as argon plasma coagulation.

Ablation for liver tumours

Ablative therapies destroy tumour by the direct application of energy or toxic substances to discrete lesions. The basic technique for RFA was described in 1891 by d'Arsonval, who first demonstrated that heat was produced when radiofrequency waves passed through tissue. Ablation techniques now include RFA, microwave ablation, cryoablation, laser ablation, irreversible electroporation (IRE) and alcohol injection, all of which can be performed percutaneously, laparoscopically or at open surgery. There is wide variation in overall survival and local recurrence rates following ablation and surgery remains the gold standard treatment for resectable disease. Despite these concerns, ablation still has a role as an adjunct to resection and for combined approaches. Patients with small-volume resectable lesions who are not sufficiently fit to undergo liver resection should be considered for ablation, as should those with liver metastases where predicted FLR precludes resection.

RFA and microwave ablation, which rely on the generation of heat, are the most widely used techniques. Increasing lesion size exponentially increases impedance, limiting the size of the effective ablation zone and increasing the risk of local recurrence. Microwave ablation has been designed to overcome these issues with higher intratumoral temperatures, larger tumour ablation volumes and faster ablation times. Newer microwave technologies include the use of cooled applicators and multiple antennae, such that tumours adjacent to large vascular structures can be effectively treated. Local recurrence after RFA and microwave ablation is 5–15%.

Benign tumours

A number of pathologies produce focal liver lesions, and the three most common benign hepatic tumours are haemangiomas, focal nodular hyperplasia (FNH) and hepatic adenomas. These lesions are common and often discovered incidentally on cross-sectional imaging. The main clinical challenge is confirming the benign nature non-invasively where possible.

Hepatic adenoma

Adenomas are benign liver tumours seen almost exclusively in women aged between 25 and 50 years. These well-defined and vascular lesions are classically associated with use of the oral

Masatoshi Makuuchi, b. 1946, surgeon, Koto Hospital, Tokyo, Japan. In 1990 described preoperative portal embolisation to increase the safety of major hepatectomy for hilar bile duct carcinoma.

Jacques-Arsène d'Arsonval, 1851–1940, physician and physicist, Collège de France, Paris, France.

contraceptive pill and are generally solitary. The majority are found incidentally on imaging, although up to one-third may present with pain because of rupture or bleeding. Adenomas are recognised as having malignant potential, with up to 10% developing into HCC. The risk of rupture and malignancy means that surgical excision is generally recommended if >5 cm in size, although some lesions may regress after discontinuation of the oral contraceptive pill.

Focal nodular hyperplasia

FNH is an unusual but not uncommon benign condition of unknown aetiology, in which there is a focal overgrowth of functioning liver tissue supported by fibrous stroma. Patients are usually middle-aged women, and there is no association with underlying liver disease. Ultrasonography shows a solid tumour mass. Contrast CT or MRI may show central scarring and a hypervascular lesion. FNH contains both hepatocytes and Kupffer cells. MRI using liver-specific contrast agents may be useful in determining the hepatocellular origin of FNH and allowing differentiation of FNH from metastatic cancer. FNH does not have any malignant potential and, once the diagnosis is confirmed, does not require any treatment or follow-up.

Haemangiomas

These are the most common benign liver lesions, and the reported incidence has increased with the widespread availability of diagnostic ultrasonography. They consist of an abnormal plexus of vessels, and their nature is usually apparent on ultrasonography. If diagnostic uncertainty exists, CT scanning with delayed contrast enhancement shows the characteristic appearance of slow contrast enhancement owing to small vessel uptake in the haemangioma. Often, haemangiomas are multiple. Lesions found incidentally require radiological confirmation of their nature and no further treatment. Diagnosis is usually incidental, and surgical resection is only recommended if patients are significantly symptomatic or significant diagnostic uncertainty remains after multimodal imaging.

Biopsy of liver lesions

Liver biopsy is generally considered a safe procedure but is not without risk of mechanical complications, which although minor (pain and subcapsular or intrahepatic haematoma) occur in 6–25% of patients. Significant complications, including bile leak, sepsis, pancreatitis, local infections or pneumothorax, occur in 0.25% and haemobilia in 0.05% of cases. Mortality specifically related to liver biopsy is mainly caused by haemorrhage and varies from 0.1% to 0.3%.

Lesions found within the liver that are likely to be malignant will need resection; if surgery is possible then FNA or true cut biopsy should not be performed. Biopsy of malignant liver lesions results in poorer long-term survival following resection and confers no diagnostic advantage over non-invasive imaging and tumour markers. Needle tract seeding also occurs (1000–100 000 cells/tract) or peritoneal spread, particularly with HCC.

Summary box 69.14

Benign liver lesions

- May present with symptoms or be found incidentally on imaging for another condition
- Significant symptoms (pain or pressure effects) justify surgery
- If imaging is equivocal biopsy may be necessary to exclude a primary or metastatic lesion
- If observation for 3–6 months demonstrates a stable lesion malignancy is unlikely

Cystic lesions

Simple liver cysts

Simple cysts of the liver are usually asymptomatic and were thought to be uncommon before the routine use of ultrasonography. The exact prevalence and incidence are not known but they are estimated to occur in 5% of the population with 10–15% presenting because of symptoms. Fortunately, their appearance on ultrasonography and MRI scanning generally allows them to be dismissed; confusion usually only occurs when CT scanning was the initial investigation. Cysts are more common in females (1.5:1) and are larger in patients over 50 years of age. The situation is different for very large symptomatic or complex cysts, which are 10 times more common in women, and huge cysts requiring treatment in men are rare. Most cysts only cause problems and require treatment when they increase in size or become complex or infected. Prior to treatment it is important to exclude other causes, particularly parasitic infections.

Polycystic liver disease

Multiple liver cysts are frequently associated with adult polycystic kidney disease (PKD) but may occur alone. PLD is a term for a heterogeneous group of patients; it is an inherited disorder estimated to affect around 1 in 100 000 people and 10% have cerebral aneurysms. It is characterised by the progressive growth of cysts of various sizes that are widely and randomly distributed throughout the liver. In many patients the cysts are asymptomatic but when extensive they produce mechanical symptoms from stretching of the liver capsule, pressure effects on the stomach when the left side is involved and gross abdominal distension related to the large increase in the size of the liver. Cysts can become infected, but this normally follows ill-advised aspiration of what is felt to be a symptomatic cyst. Biliary obstruction occurs as a result of distortion or compression and must be treated endoscopically as there is no surgical option. Surgical treatment is usually employed for bulk reduction or a mechanical problem and, when planning surgery, it is important to remember that biliary radicals and vessels run between cysts and are difficult to differentiate from the wall.

Hepatic cystadenomas and cystadenocarcinomas

The prevalence of hepatic cystadenomas is low, with fewer than 200 cases reported. Of the two types, cystadenomas with mesenchymal (ovarian-like) stroma occur only in females and

cystadenomas without mesenchymal stroma predominate in men.

Cystadenomas are often multilocular, septated, non-calcified and surrounded by compressed liver tissue. Upper abdominal pain and an abdominal mass can occur, but patients are usually asymptomatic. Cystadenomas are slow growing but have malignant potential and must be distinguished from simple hepatic cysts, polycystic liver disease, hydatid cysts and complex non-neoplastic cystic lesions. Serum and cyst fluid CA 19-9 levels may be elevated in cases of cystadenoma with mesenchymal stroma, but serum carcinoembryonic antigen (CEA) is unhelpful although it may be raised in cyst fluid. Cyst fluid cytology is unreliable.

Ultrasonography may demonstrate an anechoic mass with internal septations. CT scanning generally demonstrates the multilocular nature with internal septations. In the contrast phase, the wall of the cyst enhances and nodules may be seen. MRI also demonstrates septations and a hyperintense signal on T2-weighted images. The risk of recurrence and the potential for malignant transformation mandates complete anatomical resection. If the lesions are technically irresectable or cannot be separated from major venous or arterial structures liver transplantation may be required. Biliary cystadenocarcinomas account for 0.4% of malignant epithelial hepatic lesions.

Malignant liver tumours

Neuroendocrine/carcinoid tumours

Carcinoids are the most common NETs affecting men and women equally. The overall incidence is steadily increasing, estimated at 1.5–1.9 clinical cases per 100 000 population, although in autopsy series this reaches 650/100 000 population. Primary carcinoid tumours in the liver are rare and hepatic lesions are almost invariably metastases from small bowel or colon. Approximately 20% of small intestine carcinoids develop metastases and 30% of these patients develop carcinoid syndrome.

If the primary has been resected, liver metastases can be observed unless carcinoid syndrome develops. Hepatic carcinoid disease that is resectable should be treated but this must be preceded by a thin-slice CT scan and laparoscopy with intraoperative ultrasonography if doubt remains to exclude small-volume disease. Carcinoid syndrome is a difficult clinical problem, especially when pharmacological approaches are ineffective; in these patients, debulking should be considered. Some patients will develop a small number of lesions of similar sizes that can often be resected with curative intent. A significant proportion will develop recurrence(s), but this may take 18–36 months and further surgery is often possible. When lesions are numerous and of different generations (sizes) there are no surgical options and ablative, transarterial embolisation or targeted treatment with somatostatin analogues should be considered.

Hepatocellular carcinoma

HCC is a malignant tumour arising from hepatocytes and is the most common primary liver cancer. There is a steadily rising global burden. In 2016 there were 1 million incident cases of liver cancer globally and 829 000 deaths. It ranks as the fifth most common cause of cancer in men and the seventh in women, representing a third of all cancer-related deaths. HCC is the leading cause of death in patients with cirrhosis, affecting three times more men than women.

There is wide variation in geographical incidence. More than 80% of cases occur in Asia and sub-Saharan Africa, with an incidence of 99/100 000 compared with 5/100 000 in Europe. Geographical variation reflects the incidence of aetiological factors. Chronic hepatitis B virus (HBV) infection accounts for >50% of cases worldwide and HBV vaccination programmes reduce the incidence in high-risk areas. Hepatitis C virus (HCV) increases the risk of HCC 17-fold by promoting end-stage liver disease. Aflatoxin contamination of rice in some parts of the world is probably responsible for seasonal variations. Lifetime alcohol exposure remains an intractable risk factor and correlates with the incidence of HCC. Obesity and diabetes mellitus are additional independent risk factors.

Cancer-related causes are fatal in 60% of patients and 40% die of underlying parenchymal disease. HCC is typically diagnosed at a late stage and prognosis even in developed countries is limited with median survivals following diagnosis of 6–20 months and overall survival of less than 50% at 2 years and 10% at 5 years, with worse results in developing countries.

Staging of hepatocellular carcinoma

Clinical staging systems for HCC are designed to guide management. The Barcelona Clinic Liver Group (BCLC) staging system, initially designed to define both prognosis and optimal treatment for patients with HCC, is the most commonly used (***Figure 69.22***). As patients with HCC usually have underlying liver disease that has a marked impact on prognosis, the BCLC system was designed to reflect underlying liver function and performance status together with tumour characteristics. Underlying liver function is assessed using the CTP system.

Treatment of hepatocellular carcinoma

Surgical resection for hepatocellular carcinoma

Only 20–40% of patients with HCC are candidates for surgery, but with surveillance programmes in at-risk patients, improved imaging and advances in perioperative management resection is increasingly possible. Selecting suitable patients remains controversial and although tumour size, vascular invasion and multifocal disease are poor prognostic indicators they are not absolute contraindications. Multinodular lesions may represent multiple discrete lesions occurring independently against a background of procarcinogenic parenchymal damage or aggressive tumour biology with intrahepatic metastases. Oncological contraindications include extrahepatic metastasis, multiple/bilobar tumours, main bile duct involvement and tumour thrombus in the main portal vein/vena cava.

Preoperative evaluation of patients with hepatocellular carcinoma

Achieving good outcomes for patients undergoing surgical resection requires accurate assessment of tumour stage, comorbidities and liver function. This is particularly important

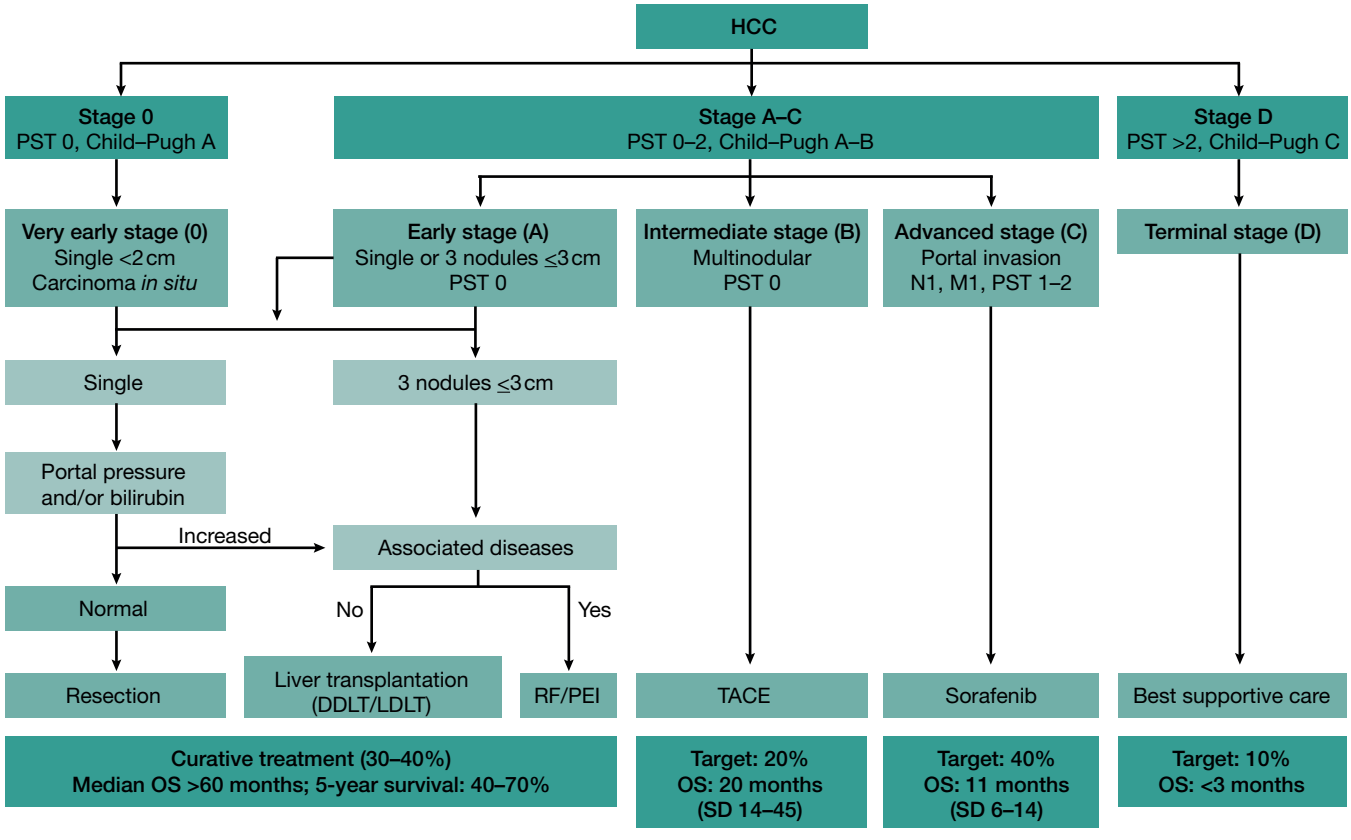

Figure 69.22 The Barcelona Clinic Liver Group staging system for the management of hepatocellular carcinoma (HCC). Patients with asymptomatic early tumours (stage 0–A) are candidates for curative therapies (resection, transplantation or local ablation). Asymptomatic patients with multinodular HCC (stage B) are suitable for chemoembolisation (TACE), whereas patients with advanced symptomatic tumours and/or an invasive tumoral pattern (stage C) are candidates for sorafenib. End-stage disease (stage D) includes patients with grim prognosis who should be treated by best supportive care. DDLT, deceased donor liver transplantation; LDLT, living donor liver transplantation; OS, overall survival; PEI, percutaneous ethanol injection; PST, ECOG performance status; RF, radiofrequency ablation; SD, standard deviation; TACE, transcatheter arterial chemoembolisation. (Reproduced with permission from Villanueva A. Medical therapies for hepatocellular carcinoma: a critical view of the evidence. *Nat Rev Gastroenterol Hepatol* 2013; **10**: 34–42.)

when planning larger resections, where the function of the FLR becomes critical. Postoperative morbidity and mortality increase with higher CTP scores, and major liver resection is usually only possible in patients with CTP-A disease. Minor liver resection may be considered in those with CTP-B disease but remains a high-risk procedure, and CTP-C patients are not candidates for liver resection. If inadequate FLR is the only contraindication preoperative radiological PVE should be performed.

Preoperative imaging for hepatocellular carcinoma

Imaging is a critical part of the preoperative assessment of HCC and accurate tumour staging and anatomical assessment is essential to determine technical and oncological resectability and exclude metastatic disease. Triple-phase CT chest/abdomen/pelvis and MRI of the liver is the standard of care, although MRI and CT have limited sensitivity and specificity for lesions <1 cm (improved with liver-specific contrast agents). FDG-PET does not appear to confer any benefit over standard imaging.

Surgical principles for hepatocellular carcinoma

Surgical resection is a compromise requiring resection of the tumour while preserving sufficient functional parenchyma. HCC spreads within the liver by direct invasion of portal and hepatic venous systems. Anatomical resections that include removal of the entire venous drainage of a tumour, including occult micrometastases, is the optimal approach. There are clear long-term survival benefits for anatomical versus non-anatomical resections, with anatomical resection now considered the standard of care when underlying liver function allows. Improvements in patient selection and surgical technique have reduced the 30-day mortality to <5%.

Disease recurrence after resection

Intrahepatic recurrence occurs in 80% of cases within 5 years and neoadjuvant or adjuvant options do not reduce the risk. Intrahepatic recurrence is thought to result from missed micrometastases or the development of new lesions and the most effective approach to reducing intrahepatic recurrence is liver transplantation.

Liver transplantation

Liver transplantation that definitively treats the tumour and underlying cirrhosis represents an attractive option, but organ shortages mandate careful selection of patients and early experience with transplantation was disappointing. Transplantation for HCC, first described by Mazzaferro in 1996 for patients with tumours ≤5 cm or up to three nodules ≤3 cm, achieved 4-year overall survivals of 75% and recurrence-free survivals of 83%. These inclusion criteria were adopted as the Milan criteria, with angioinvasion and extrahepatic involvement as additional exclusion criteria, and are now universally accepted. Liver transplantation criteria, however, continue to evolve and 'expanded' criteria remain debated. Locoregional therapies such as ablation may downstage HCC from beyond to within the Milan criteria and following a period of observation these patients may be considered as candidates for transplantation.

Intrahepatic cholangiocarcinoma

Cholangiocarcinomas develop in the bile duct and demonstrate considerable variation in origin, behaviour and pathophysiology. Twenty per cent of cholangiocarcinomas are intrahepatic (ICC), representing 5–30% of primary liver tumours, which is second only to HCC. They are rare in the West with an incidence of 0.5–2/100 000, although the incidence is increasing and is significantly higher in South East Asia, where *Clonorchis sinensis* infection is endemic, and in Thailand the rate is 60/100 000. There are three morphological subtypes – infiltrating periductal (***Figure 69.23a***), mass-forming (***Figure 69.23b***) and intraductal – and ICC is now considered to have multiple cellular origins. Ultrasonography will confirm intrahepatic biliary obstruction and MRCP is preferred for diagnosis. ERCP will delineate tumour extent and with brush cytology or SpyGlass™ can achieve pathological confirmation of malignancy.

ICC was originally staged with HCC but is now classified separately. Prognostic pathological features include vascular invasion, tumour multiplicity, local extension, periductal infiltration and lymph node metastasis. CT scanning is the best staging modality to identify distant metastases and confirm that the lesion is primary and not metastatic. Angiography is sometimes required preoperatively to assess vascular involvement. The sensitivity and specificity of PET-CT for diagnosis of cholangiocarcinoma varies by location, being higher for intrahepatic (>90%) than for extrahepatic (60%) tumours, although detection rates for distant metastases approach 100%.

ICC is an aggressive tumour and, even when confined to the liver, only 30% of patients are suitable for resection at the time of presentation. If surgical resection is considered, biopsy should be avoided; in borderline cases diagnostic laparoscopy and intraoperative ultrasonography will exclude additional hepatic or peritoneal disease. Lymph node status (porta hepatis, common hepatic artery and the gastroduodenal ligament) remains an important prognostic factor and should be sampled. One-year survival rates have improved to 25%, although 5-year survival of 3% remains unchanged. Unfortunately, conventional chemotherapy offers limited survival benefit for unresectable or metastatic disease.

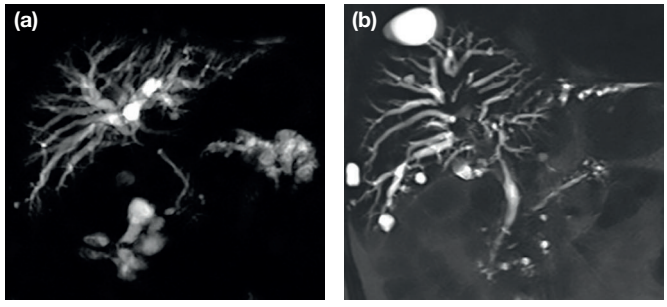

Figure 69.23 Hilar cholangiocarcinoma (Klatskin tumour) demonstrating tight stricture and intrahepatic dilatation of intrahepatic ducts due to infiltrating tumour **(a)** and an apparent space-occupying lesion due to the mass-forming variety **(b)**.

Colorectal liver metastases

Worldwide colorectal cancer (CRC) is the third most common solid organ malignancy and the fourth most common cause of cancer-related deaths. Up to 70% of patients with CRC develop synchronous (15–25%) or metachronous (20–45%) liver metastases. Thirty years ago, metastatic CRC was associated with a 5-year survival of less than 3%; however, liver resection in selected patients with liver-only metastatic disease demonstrated 5-year survivals of 50%, so the potential benefits were recognised. Despite recent advances in chemotherapeutic agents, resection remains the only potentially curative option, but only 20% of patients will be candidates at presentation. A further 20–30% will become operable following chemotherapy, the 5-year overall survival rate following resection is 50% and tumour recurs in 65% with the recurrent disease limited to the liver in 40%.

Defining resectability for colorectal liver metastases

Previously, patients with synchronous metastases, a rectal primary, multiple diffuse metastases, metastases larger than 5 cm, disease-free intervals of less than 1 year from the diagnosis of primary disease or a high serum CEA were considered irresectable and suitable only for palliative treatment. Modern surgical techniques and chemotherapy regimes now mean that resection with curative intent is defined as the ability to successfully remove all residual disease from the liver with clear surgical margins, leaving adequate disease-free viable liver. Technical contraindications to resection are related to the anatomical location of metastases, principally the involvement of major vascular or biliary structures.

An R0 resection with a negative surgical margin of 1 cm is considered the gold standard, but with effective modern chemotherapy patients with an R1 resection (≥1-mm margin

Vincenzo Mazzaferro, b. 1957, surgeon, Istituto Nazionale dei Tumori, Milan, Italy.

microscopically negative), which occurs in 10–30% of patients, have similar survivals to those with R0 resections. An FLR of 25% of preoperative volume is considered sufficient to prevent postoperative hepatic failure (see ***Portal vein embolisation***). Historically, extrahepatic metastatic disease was considered a contraindication to liver surgery, but long-term survival is now possible in selected patients. Survival after lung resection for colorectal metastases is similar to that seen after liver resection (40–50%) with low morbidity and mortality.

Staging and selection of patients for liver surgery

A specialist multidisciplinary team should coordinate the staging of patients with colorectal liver metastases and the treatment plan. Routine staging involves triple-phase CT chest/abdomen/pelvis, contrast MRI scan of the liver, whole-body PET-CT to identify metastatic disease with/without laparoscopy and intraoperative ultrasonography.

Chemotherapy for colorectal liver metastases

Despite new chemotherapeutic agents and locoregional therapies (embolisation, percutaneous ablation, hepatic artery-directed infusion chemotherapy, internal radiation) the role of adjuvant and neoadjuvant chemotherapy remains unclear. The traditional approach was to resect an operable colonic primary followed by routine postoperative chemotherapy or holding chemotherapy 'in reserve' in case of metastases. Neoadjuvant chemotherapy is now recommended by some groups for the majority of patients even if the liver disease is resectable. The aim is to reduce lesion size and improve resectability while treating occult disease and revealing the tumour biology where progression despite chemotherapy signifies a poor prognosis.

A major development with advanced disease was the recognition that a subgroup of patients may become resectable after systemic chemotherapy. Although resectability rates after chemotherapy for initially irresectable disease vary, when successful 5-year survivals of 35–50% are similar to disease resectable at presentation. Chemotherapy with 5-fluorouracil and folinic acid produces a response rate of approximately 30% but combination with oxaliplatin increases this to 50–60%. Combination chemotherapy with monoclonal antibodies that recognise vascular endothelial growth factor receptor (VEGFR) or epidermal growth factor receptor (EGFR) provide additional benefit (see also ***Chapters 12 and 77***).

Synchronous colon and liver resection

Synchronous resectable liver metastases are frequently identified at the time of diagnosis. Treatment options include sequential, delayed and simultaneous resection strategies. Resection of the colonic primary followed by chemotherapy, restaging and resection of the liver disease, if appropriate, is the standard approach. It is occasionally possible with low-volume, accessible liver disease to perform synchronous liver and colonic resections, but this is contraindicated when both procedures represent a major undertaking per se.

Liver-first approach

The traditional surgical strategy for resectable synchronous colorectal liver metastases (CRLMs) is colonic resection followed by chemotherapy and a delayed liver resection. This may allow progression of the liver disease and render the CRLM unresectable, which is a particular concern in patients who develop postoperative complications following their colon resection that delay or prevent chemotherapy. The liver-first approach or reverse strategy is a downstaging regimen consisting of systemic chemotherapy, chemoradiotherapy and/or biological agents, followed by resection of the CRLM prior to removal of the colonic primary. The approach is valuable in the subset of patients in whom failure to respond to systemic treatment potentially renders CRLMs non-resectable.

Follow-up

Optimal follow-up remains controversial, and protocols vary. Close observation will identify patients who may benefit from further surgery and at least a yearly scan should be performed for the first 5 years. Tumour markers are measured if initially elevated and patients seen if symptoms develop. Recurrence within 12 months has a poor prognosis.

Re-do surgery

Close follow-up identifies recurrent isolated liver metastases and if CT and PET exclude additional disease repeat resection is appropriate when possible. The operative approach must take into account the consequences of previous surgery and hypertrophy following a major resection. Left lobe resections may produce a more inferiorly based and medially shifted portal triad, making the origin of the right hepatic pedicle deeper and more medial than expected, and a right hepatectomy will often rotate the hilum more anteriorly.

Non-colorectal, non-neuroendocrine metastases

Although metastases from non-CRCs do not spread via the portal circulation and are rarely confined to the liver, with the low mortality associated with liver resection palliative or potentially curative surgery for metastases from renal, breast, gastric and lung metastases together with deposits from melanoma, sarcoma and a range of rarer tumours is reported.

Management of metastatic gastrointestinal stromal cell tumours

Gastrointestinal stromal tumours (GISTs) are non-epithelial tumours originating in interstitial Cajal cells of the autonomic nervous system, which metastasise in 20–25% of patients. Management has changed with the effective chemotherapy

imatinib mesylate, which often produces dramatic responses. The primary bowel tumour should be removed if possible and the liver assessed to identify potentially resectable disease. If metastases respond to postoperative imatinib, surveillance is recommended; however, when metastases escape imatinib control debulking has no role and surgical resection is performed only if extirpation of all disease is possible.

PART 11 | Abdominal

CHAPTER
70 The spleen

Learning objectives

To understand:

- The function of the spleen
- The common pathologies involving the spleen
- The principles and potential complications of splenectomy
- The potential advantages of laparoscopic splenectomy
- The benefits of splenic conservation
- The importance of prophylaxis against infection following splenectomy

EMBRYOLOGY, ANATOMY AND PHYSIOLOGY

Embryology

Fetal splenic tissue develops from condensations of mesoderm in the dorsal mesogastrium. This peritoneal fold attaches the dorsal body wall to the fusiform swelling in the foregut that develops into the stomach. This condensation divides the mesogastrium into two parts, one between the fetal splenic tissue and the stomach to form the gastrosplenic ligament and the other between it and the left kidney to form the lienorenal ligament.

Anatomy

The weight of the normal adult spleen is 75–250 g and it measures up to 10 × 7 × 3 cm. It lies in the left hypochondrium between the gastric fundus and the left hemidiaphragm, with its long axis lying along the 10th rib. The spleen is connected to the stomach and kidney by a double fold of peritoneum that originates from the stomach as a part of the greater omentum. The gastrosplenic (gastrolienal) ligament is anterior to the splenic hilum and connects the spleen to the greater curvature of the stomach. The splenorenal (lienorenal) ligament lies posterior to the splenic hilum and connects the hilum of the spleen to the left kidney. The splenic vessels and the tail of the pancreas lie within this ligament (***Figure 70.1***). The hilum of the spleen sits in the angle between the stomach and the kidney and is in contact with the tail of the pancreas. The concave visceral surface lies in contact with these structures, and the lower pole extends no further than the midaxillary line. There is a notch on the inferolateral border, and this may be palpated only when the spleen is enlarged. The tortuous splenic artery arises from the coeliac axis and runs along the upper border of the body and tail of the pancreas, to which it gives small branches. The short gastric and left gastroepiploic branches pass between the layers of the gastrosplenic ligament. These arteries are divided whenever the greater curvature of the stomach has to be excised. The main splenic artery generally divides into superior and inferior branches, which, in turn, subdivide into several segmental branches. The splenic vein is formed from several tributaries that drain the hilum and runs behind the pancreas, receiving several small tributaries from the pancreas before joining the superior mesenteric vein at the neck of the pancreas to form the portal vein (***Figure 70.2***).

The splenic pulp is invested by an external serous and internal fibroelastic coat, which is reflected inwards at the hilum onto the vessels to form vascular sheaths. The lymphatic drainage comprises efferent vessels in the white pulp that run with the arterioles and emerge from nodes at the hilum. These nodes and lymphatics drain via retropancreatic nodes to the coeliac nodes.

Physiology

The splenic parenchyma consists of white and red pulp that is surrounded by serosa and a collagenous capsule with smooth muscle fibres. These penetrate the parenchyma as trabeculae of dense connective tissue fibres rich in collagen and elastic tissue. These, with the reticular framework, support the cells of the spleen and surround the vessels in the splenic pulp. The white pulp comprises a central trabecular artery surrounded by nodules with germinal centres and periarterial lymphatic sheaths that provide a framework filled with lymphocytes and macrophages. Arteries from the central artery and the peripheral 'penicillar' arteries pass into the marginal zone that lies at the edge of the white pulp. Plasma-rich blood that has passed through the central lymphatic nodules is filtered as it passes through the sinuses within the marginal zone, and particles are phagocytosed.

Immunoglobulins produced in the lymphatic nodules enter the circulation through the sinuses in the marginal zone,

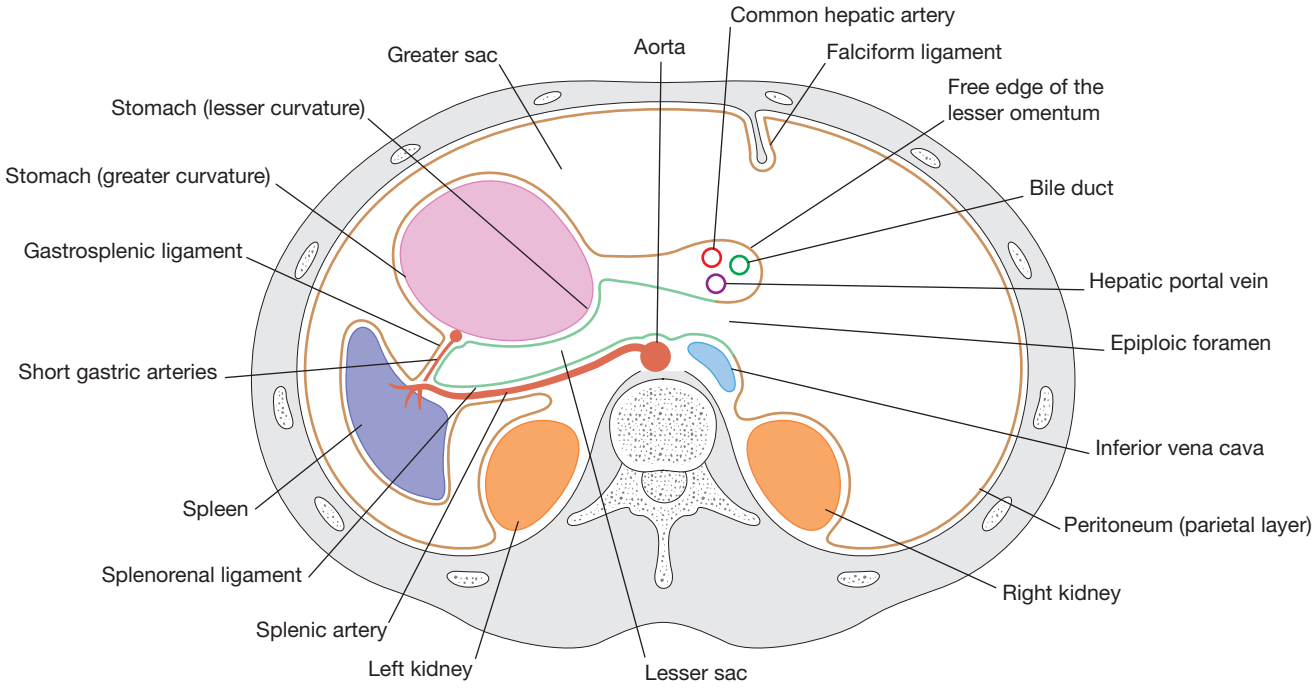

Figure 70.1 Transverse section (craniocaudal view) showing the important ligaments of the spleen containing the blood vessels (courtesy of Dr Tusharindra Lal, Chennai, India).

beyond which lies the red pulp, which consists of cords and sinuses. Cell-concentrated blood passes in the trabecular artery through the centre of the white pulp to the red pulp cords. Red cells must elongate and become thinner to pass from the cords to the sinuses, a process that removes abnormally shaped cells from the circulation (***Figure 70.3***). As 90% of the blood passing through the spleen moves through an open circulation in which blood flows from arteries to cords, and thence sinuses, splenic pulp pressure reflects the pressure throughout the portal system. The remaining 10% of the blood flow through the spleen bypasses the cords and sinuses by direct arteriovenous communications. The overall flow rate of blood is about 300 mL/min.

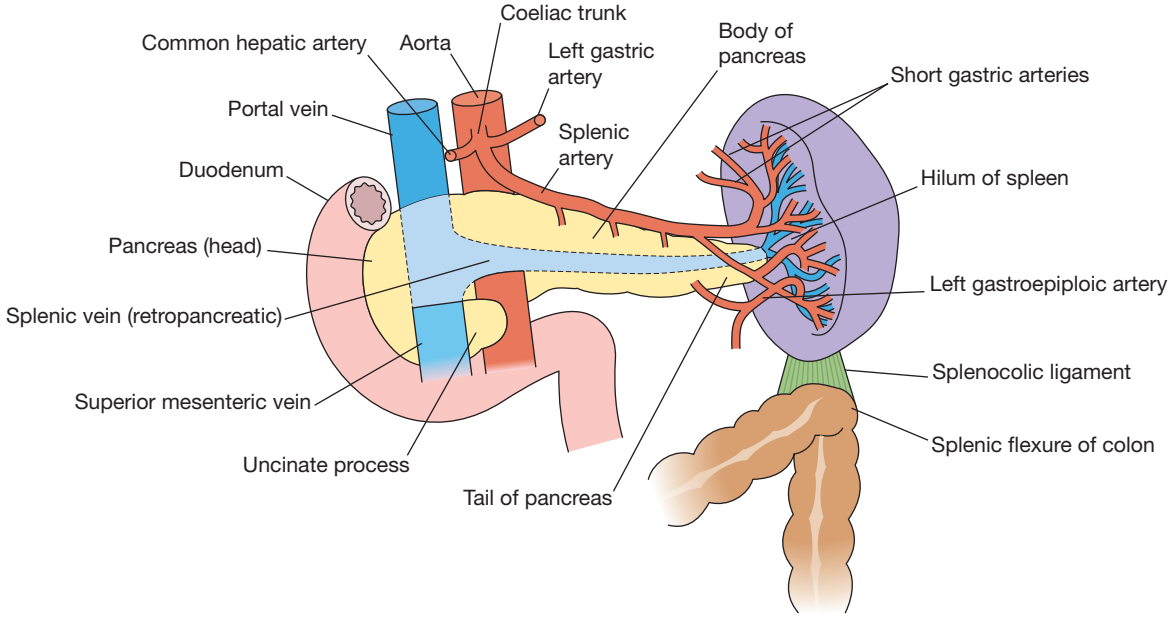

Figure 70.2 Schematic representation showing relations at the hilum of the spleen with the blood supply and venous drainage. Note the avascular splenocolic ligament that needs to be divided carefully to free the inferior pole of the spleen from the splenic flexure (courtesy of Dr Tusharindra Lal, Chennai, India).

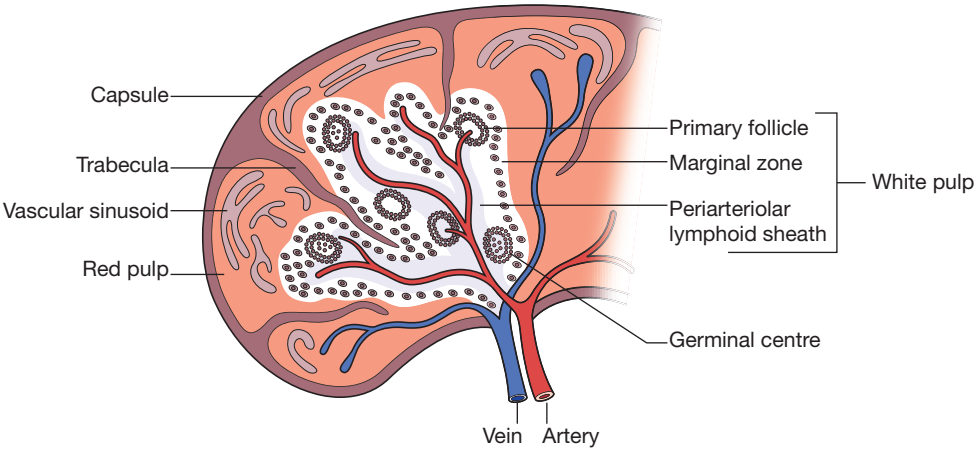

Figure 70.3 Functional anatomy of the spleen. Blood from a central trabecular artery passes through the white pulp into the surrounding red pulp and hence to the vascular cords and sinuses that drain into the trabecular vein.

FUNCTIONS OF THE SPLEEN

Although the spleen was previously thought to be dispensable, it is now recognised that an incidental splenectomy during the course of another operative procedure increases the risk of complications and death. The surgeon should therefore normally endeavour to preserve the spleen to maintain the following functions.

- **Immune function**. The spleen contains 70.5% and 10–15% of the body's total T and B lymphocyte population, respectively. It processes foreign antigens and is the major site of specific immunoglobulin (Ig) M production. The non-specific opsonins, properdin and tuftsin, are synthesised. These antibodies are of B- and T-cell origin and bind to the specific receptors on the surface of macrophages and leukocytes, stimulating their phagocytic, bactericidal and tumoricidal activity. Loss of this function necessitates vaccination against capsulated microorganisms such as pneumococci in splenectomised patients.
- **Filter function**. Macrophages in the reticulum capture cellular and non-cellular material from the blood and plasma. This will include the removal of effete platelets and red blood cells. This process takes place in the sinuses and the splenic cords by the action of the endothelial macrophages. Iron is removed from the degraded haemoglobin during red cell breakdown and is returned to plasma. Removed non-cellular material may include bacteria and, in particular, pneumococci. This occurs in the red pulp of the spleen and needs red cells with the capability to change shape and traverse through the sinusoids. As the deformability is reduced in spherocytosis, the cells get removed in the spleen. Splenectomy is recommended in such patients to maintain the haemoglobin concentration.
- **Pitting**. Distorted red cells in sickle cell disease result in slowing of circulation with multiple splenic infarcts, leading to loss of splenic function – autosplenectomy. This leads to the appearance of circulating red cells with Howell–Jolly and Heinz bodies, which represent nuclear remnants and precipitated haemoglobin or globin subunits, respectively, and appear as target cells on a smear. These particulate inclusions within the red cells are removed, and the repaired red cells are returned to the circulation in the process of pitting.
- **Reservoir function**. This function in humans is less marked than in other species, but the spleen does contain approximately 8% of the red cell mass. An enlarged spleen may contain a much larger proportion of the blood volume. Massive splenic enlargement will be associated with a larger proportion of blood volume in the spleen, leading to pancytopenia, which can be corrected by splenectomy.
- **Cytopoiesis**. From the fourth month of intrauterine life, some degree of haemopoiesis occurs in the fetal spleen. Stimulation of the white pulp may occur following antigenic challenge, resulting in the proliferation of T and B cells and macrophages. This may also occur in myeloproliferative disorders, thalassaemias and chronic haemolytic anaemias.

Summary box 70.1

Functions of the spleen

- Immune
- Filter function
- Pitting
- Reservoir
- Cytopoiesis

William Henry Howell, 1860–1945, Professor of Physiology, Johns Hopkins University, Baltimore, MD, USA.
Justin Marie Jules Jolly, 1870–1953, Professor of Histopathology, Collège de France, Paris, France.
Robert Heinz, 1865–1962, Professor of Pharmacology and Toxicology, Erlangen, Germany.

INVESTIGATION OF THE SPLEEN

Conditions that result in splenomegaly can be diagnosed on the basis of the history and examination and laboratory examination. In haemolytic anaemia, a full blood count, reticulocyte count and tests for haemolysis will determine the cause of the anaemia. Splenomegaly associated with portal hypertension caused by cirrhosis is diagnosed on history, physical signs of liver dysfunction including ascites, abnormal tests of liver function, often anaemia, leukopenia and thrombocytopenia, as well as endoscopic evidence of oesophageal varices. Non-cirrhotic portal fibrosis, a condition common in tropical countries, is associated with massive splenomegaly and pancytopenia without stigmata of liver dysfunction. Sinistral or segmental portal hypertension may result from isolated occlusion of the splenic vein by thrombosis, pancreatic inflammation or tumour infiltration. As many conditions that cause splenomegaly are associated with lymphadenopathy, investigation should be directed at those disease processes known to be associated with both physical signs. Lymph node biopsy may be required.

Radiological imaging

Plain radiology is rarely used in investigation, but the incidental finding of calcification of the splenic artery or spleen may raise the possible diagnosis of a splenic artery aneurysm, an old infarct, a benign cyst or hydatid disease. Multiple areas of calcification may suggest splenic tuberculosis. Ultrasonography can determine the size and consistency of the spleen and whether a cyst is present. However, computed tomography (CT) with contrast enhancement is more commonly undertaken to better characterise the nature of the suspected splenic pathology and to exclude other intra-abdominal pathology. Magnetic resonance imaging (MRI) may be similarly useful, especially as T2-weighted images allow cystic lesions to be distinguished.

CONGENITAL ABNORMALITIES OF THE SPLEEN

Splenic agenesis is rare but is present in 5% of children with congenital heart disease. Polysplenia is a rare condition resulting from failure of splenic fusion.

Splenunculi are single or multiple accessory spleens that are found in approximately 10–30% of the population. They are located near the hilum of the spleen in 50% of cases and are related to the splenic vessels, or behind the tail of the pancreas in 30%. The remainder are located in the mesocolon, greater omentum or the splenic ligaments. Their significance lies in the fact that failure to identify and remove these at the time of splenectomy may give rise to persistent disease.

Hamartomas are rarely found in life and vary in size from 1 cm in diameter to masses large enough to produce an abdominal swelling. One form is mainly lymphoid and resembles the white pulp, whereas the other resembles the red pulp.

Non-parasitic **splenic cysts** are rare. Splenic cysts are classified as primary cysts (true) or pseudocysts (secondary) on the basis of the presence or absence of lining epithelium. True cysts form from embryonal rests and include dermoid and mesenchymal inclusion cysts (***Figure 70.4***). Rarely, the entire spleen may be replaced by a cystic mass (***Figure 70.5***). True cysts of the spleen are very rare and are frequently classified as cystic haemangiomas, cystic lymphangiomas and epidermoid and dermoid cysts. Splenectomy or partial splenectomy is usually considered for cysts larger than 5 cm in diameter. These should be differentiated from false or secondary cysts that may result from trauma and contain serous or haemorrhagic fluid. The walls of such degenerative cysts may be calcified and therefore resemble the radiological appearances of a hydatid cyst (***Figure 70.6***). The spleen is also a common site for pseudocyst development following a severe attack of pancreatitis (***Figure 70.7***). Pseudocysts can easily be diagnosed on scanning; intervention is normally required for symptomatic lesions that persist following a period of observation.

SPLENIC ARTERY ANEURYSM, INFARCT AND RUPTURE

Splenic artery aneurysm

Aneurysms involving the splenic artery are estimated to be identified at 0.04–1% of postmortem examinations. They are twice as common in women and are usually situated in the main arterial trunk. Although these are generally single, more than one aneurysm is found in one-quarter of cases. These may be a consequence of intra-abdominal sepsis and pancreatic necrosis, in particular. They are more likely to be associated with arteriosclerosis in elderly patients.

The aneurysm is symptomless unless it ruptures and is more likely to be detected on a plain abdominal radiograph or scan. It is unlikely to be palpable, although a bruit may be present. Rupture is unsuspected in the majority of cases and, as it will generally rupture into the peritoneal cavity, the symptoms mimic those of splenic rupture. Almost half the cases of rupture occur in patients younger than 45 years of age and one-quarter are in pregnant women, usually in the third trimester of pregnancy or at labour. Aneurysmal rupture carries a high mortality rate and this increases disproportionately in pregnant women, with almost inevitable fetal death.

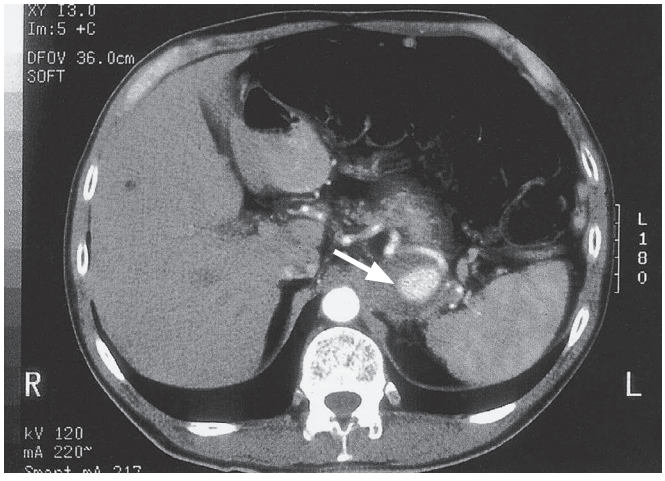

Figure 70.8 Computed tomography scan showing a pool of contrast in a pseudoaneurysm (arrow) situated in the tail of the pancreas adjacent to the spleen.

The treatment of choice previously consisted of splenectomy and removal of the diseased artery. Embolisation or endovascular stenting following selective splenic artery angiography can be considered and is now more commonly undertaken. In younger patients with an asymptomatic splenic artery aneurysm, surgery or interventional radiology is indicated, depending on local expertise, after CT scan, MRI or selective coeliac angiography has confirmed the diagnosis (***Figure 70.8***). In elderly patients with a calcified aneurysm, there is less risk of rupture and observation may be preferred.

Splenic infarction

This condition commonly occurs in patients with a massively enlarged spleen from myeloproliferative syndrome, portal hypertension or vascular occlusion produced by previous surgical intervention (such as spleen-preserving distal pancreatectomy), pancreatic disease, splenic vein thrombosis or sickle cell disease. The infarct may be asymptomatic or give rise to left upper quadrant and left shoulder tip pain. Contrast-enhanced CT will show the characteristic perfusion defect in the enlarged spleen (***Figure 70.9***). Treatment is conservative and splenectomy should be considered only when a septic infarct causes an abscess.

Splenic rupture due to trauma

The spleen is the most commonly injured intra-abdominal organ followed by the liver. Splenic rupture should be considered in any case of blunt abdominal trauma, particularly when

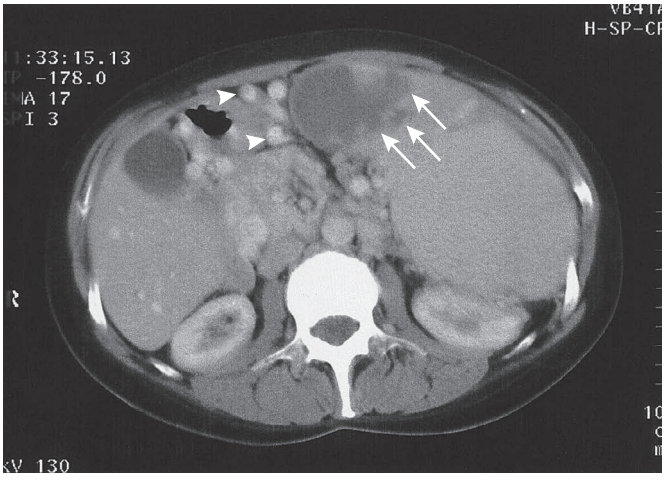

Figure 70.9 Computed tomography scan showing a splenic infarct (arrows) in a patient with splenomegaly and hypersplenism secondary to portal hypertension and portal vein thrombosis. Varices are evident at the hilus and at the greater curvature of the stomach (arrowheads).

TABLE 70.1 Criteria for grading of splenic injury based on computed tomography.

Grade 1	Subcapsular haematoma <10% of surface area Parenchymal laceration <1 cm depth Capsular tear
Grade 2	Subcapsular haematoma 10–50% of surface area; intraparenchymal haematoma <5 cm Parenchymal laceration 1–3 cm
Grade 3	Subcapsular haematoma >50% surface area; ruptured subcapsular or intraparenchymal haematoma ≥5 cm Parenchymal laceration >3 cm depth
Grade 4	Any injury in the presence of a splenic vascular injury or active bleeding confined within the splenic capsule Parenchymal laceration involving segmental or hilar vessels producing >25% devascularisation
Grade 5	Any injury in the presence of splenic vascular injury[a] with active bleeding extending beyond the spleen into the peritoneum – shattered spleen

[a]Vascular injury is defined as a pseudoaneurysm or arteriovenous fistula and appears as a focal collection of vascular contrast that decreases in attenuation with delayed imaging. Active bleeding from a vascular injury presents as vascular contrast, focal or diffuse, that increases in size or attenuation in the delayed phase.

the injury occurs to the left upper quadrant of the abdomen. Iatrogenic injury to the spleen remains a frequent complication of any surgical procedure, particularly those in the left upper quadrant when adhesions are present.

Based upon the extent of injury, spleen rupture is classified into five grades on the basis of CT, which is considered to be the most important investigation for assessment of abdominal trauma in a haemodynamically stable patient (***Table 70.1***). Vigorous resuscitation remains the key to management of blunt trauma. Splenectomy should be performed for severe grades of injury where control of bleeding takes precedence over measures to salvage the spleen. Splenic angiography with embolisation of actively bleeding vessels may obviate the need for splenectomy but should not delay laparotomy in a haemodynamically unstable patient.

Rupture of a malarial spleen

In tropical countries, rupture of a spleen enlarged as a result of malaria is not uncommon (see ***Tropical splenomegaly***). Delayed presentation following a 'trivial' injury is not infrequent. In such patients, radiological embolisation may be performed if available, and splenectomy should be considered before a perisplenic haematoma ruptures, a complication that is associated with a worse prognosis.

Surgery in such patients is challenging and early ligation of the splenic vessels along the superior border of the pancreatic body should be considered before disturbing the haematoma.

SPLENOMEGALY AND HYPERSPLENISM

Splenomegaly is a common feature of many disease processes, although the spleen has to enlarge threefold before it is palpable (***Table 70.2***). It should be borne in mind that many conditions affecting the spleen, such as idiopathic thrombocytopenic purpura (ITP), may be associated with enlargement but the spleen is seldom palpable. Few conditions that cause splenomegaly will require splenectomy as part of treatment.

Hypersplenism is an indefinite clinical syndrome that is characterised by splenic enlargement, any combination of anaemia, leukopenia or thrombocytopenia, compensatory bone marrow hyperplasia and improvement after splenectomy. Careful clinical judgement is required to balance the long- and short-term risks of splenectomy against continued conservative management.

Splenic abscess

Splenic abscess may arise from an infected splenic embolus or in association with typhoid and paratyphoid fever, osteomyelitis, otitis media and puerperal sepsis. In general surgical practice, it may be associated with pancreatic necrosis or other intra-abdominal infection (***Figure 70.10***). An abscess may rupture and form a left subphrenic abscess or result in diffuse peritonitis. Treatment involves that of the underlying cause; percutaneous drainage of the splenic abscess under radiological guidance is normally required, with splenectomy being reserved when interventional radiology is not available.

Tuberculosis

The diagnosis of tuberculosis should be considered in young adults with splenomegaly presenting with asthenia, loss of weight and fever. Tuberculosis of the spleen may produce portal hypertension or, rarely, cold abscess. CT shows small low-attenuation areas with central enhancement in the acute stage and MRI shows hypointense lesions (***Figure 70.11***). Multidrug chemotherapy with four drugs in the intensive phase of 2 months followed by two drugs in the maintenance

phase for a total duration of 12–18 months is preferred for treatment of extrapulmonary tuberculosis. Splenectomy is not normally required and is made difficult by inflammatory adhesions. Typical epithelioid cell granulomas are seen in the histopathology of the spleen only if splenectomy had to be performed (***Figure 70.12***).

Tropical splenomegaly

Massive splenic enlargement frequently occurs in the tropics from malaria, kala-azar and schistosomiasis. Occasionally, splenomegaly cannot be fully attributed to these diseases and may result from occult infection or be related to malnutrition. Massive splenomegaly may require removal because of anaemia, hypersplenism, local symptoms or the threat of rupture. Lifelong antimalarial therapy is indicated in endemic areas.

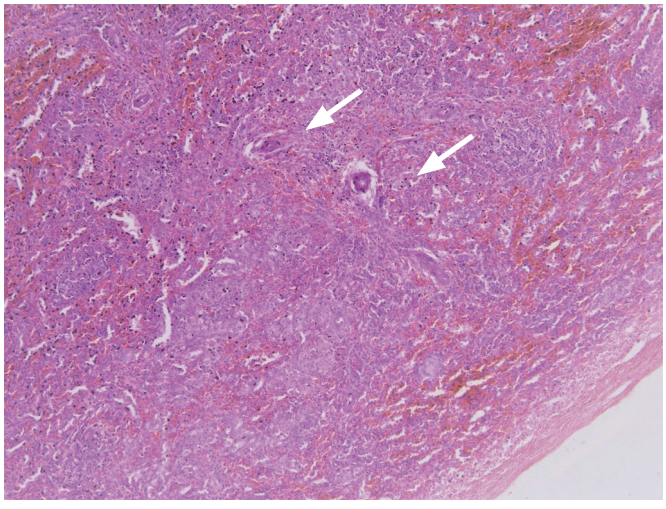

Figure 70.12 Splenic parenchyma showing epithelioid cell granulomas (arrows) in a human immunodeficiency virus-positive patient with disseminated cryptococcosis who presented with spontaneous splenic rupture necessitating splenectomy; haematoxylin and eosin; ×200 (courtesy of Dr Nita Khurana, New Delhi, India).

Schistosomiasis

This condition is prevalent in Africa, Asia and South America. It is caused by infection with *Schistosoma mansoni* in 75% of cases and by *Schistosoma haematobium* in the remainder. Splenic enlargement may result from portal hypertension associated with hepatic fibrosis, but can also result from hyperplasia induced by the phagocytosis of disintegrated worms, ova and toxin. Splenomegaly can occur at any age. The diagnosis is based on examination of the urine and faeces for ova, abnormal liver function tests and the presence of hypochromic anaemia.

Successful medical treatment does not result in the regression of splenomegaly. Removal of a painful spleen may be indicated or as part of a devascularisation procedure in patients with associated portal hypertension.

Leukaemia

Leukaemia should be considered in the differential diagnosis of splenomegaly. The diagnosis is made by examining a blood or bone marrow film. Splenectomy is reserved for hypersplenism that occurs during the chronic phase of chronic granulocytic leukaemia.

Idiopathic thrombocytopenic purpura

ITP, also known as immune and autoimmune thrombocytopenic purpura, results from antibodies to specific platelet membrane glycoproteins (antiplatelet IgG autoantibodies) that result in isolated thrombocytopenia in the presence of normal bone marrow and the absence of other causes of thrombocytopenia. Two distinct clinical types are evident: an

Sir Patrick Manson, 1844–1922, practised in Formosa (now Taiwan) and Hong Kong before becoming physician to the Dreadnought Hospital, Greenwich, London, UK. He is regarded as 'the father of tropical medicine'.

acute condition in children and a chronic condition in adults. Acute ITP often follows an acute infection and usually resolves spontaneously. Chronic ITP persists longer than 6 months without a specific cause being identified.

Clinical features

The adult form normally affects females between the ages of 15 and 50 years, although it can be associated with other conditions, including systemic lupus erythematosus, chronic lymphatic leukaemia and Hodgkin's disease. The childhood form is distributed equally between males and females and commonly presents before the age of 5 years.

Purpuric patches (ecchymoses) occur on the skin and mucous membranes. Following trauma or pressure, examination often reveals numbers of petechial haemorrhages in the skin. There is a tendency to spontaneous bleeding from mucous membranes (e.g. epistaxis); menorrhagia in women and prolonged bleeding of minor wounds are common. Haemorrhage from the urinary and gastrointestinal tracts and haemarthrosis are rare. Although intracranial haemorrhage is also uncommon, it is the most frequent cause of death. The diagnosis is indicated by the presence of cutaneous ecchymoses and a positive tourniquet test. The spleen is palpable in fewer than 10% of patients. The presence of gross splenic enlargement should raise suspicion of an alternative diagnosis.

Investigations

Coagulation studies are normal and a bleeding time is not helpful in diagnosis. Platelet count in the peripheral blood film is reduced (usually $<60 \times 10^9$/L). Bone marrow aspiration reveals a plentiful supply of platelet-producing megakaryocytes.

Treatment

The course of the disease differs in children and adults. The disease usually regresses spontaneously in paediatric cases. Short courses of corticosteroids in both adults and children are usually followed by recovery. Steroid therapy should not be prolonged.

Splenectomy is usually recommended for refractory or relapsing ITP. Up to two-thirds of patients will be cured by surgical intervention and 15% will be improved, but no benefit will be derived in the remainder. The response to steroids predicts a good response to splenectomy if the disease relapses.

Laparoscopic splenectomy is rapidly becoming the mainstay of treatment since the size of the spleen is usually normal or slightly enlarged and the spleen is not friable. It is important to identify and remove splenunculi as they have the potential to enlarge with time and lead to recurrence of symptoms.

In the acute setting, fresh blood transfusion or transfusion with platelet concentrates before operation may be necessary, although these are generally withheld until the splenic vessels have been controlled.

Haemolytic anaemias

There are four causes of haemolytic anaemia that are generally amenable to splenectomy.

Hereditary spherocytosis

Hereditary spherocytosis is an autosomal dominant hereditary disorder characterised by the presence of spherocytic red cells, caused by various molecular defects in the genes that code for alpha- and beta-spectrin, ankyrin, band 3 protein, protein 4.2 and other erythrocyte membrane proteins. These proteins are necessary to maintain the normal biconcave shape of the erythrocyte.

Spherocytosis arises essentially from an increase in permeability of the red cell membranes to sodium. As this ion leaks into the cell, the osmotic pressure rises, resulting in swelling and increased fragility of the spherocyte. As the sodium pump has to work harder to rid the cells of sodium, there is greater loss of membrane phospholipid, resulting in an increased fragility of the membrane, and the energy and oxygen requirements increase. A large number of red cells are destroyed in the spleen, where there is a relative deficiency of both glucose and oxygen.

The clinical presentation is generally in childhood but may be delayed until later life. Mild intermittent jaundice is associated with mild anaemia, splenomegaly and gallstones. Circulating bilirubin is not conjugated with glucuronic acid and is not therefore excreted in the urine as it is bound to albumin. Excretion of the resulting bilirubin complex by the liver favours formation of pigment gallstones. Once the disease manifests itself, spontaneous remissions are uncommon; the patient is often pale and jaundiced at presentation and, in established cases, lassitude and undue fatigue are present.

In some families, the disease is characterised by a severe crisis of red blood cell destruction, during which the erythrocyte count may fall from 4.5×10^6/mL to 1.5×10^6/mL within 1 week. Such crises are characterised by the onset of pyrexia, abdominal pain, nausea, vomiting and extreme pallor, followed by increasing jaundice. These episodes may be precipitated by acute infection. Any child with gallstone disease should be investigated for hereditary spherocytosis and a family history sought.

Examination reveals splenomegaly and the liver may also be palpable. Chronic leg ulcers may arise in adults.

Haematological investigations include the fragility test. Erythrocytes begin to haemolyse in 0.47% saline solution but, in this condition, haemolysis may occur in 0.6% or even stronger solutions. Immature red blood cells (reticulocytes), which differ from adult cells by possessing a reticulum, are discharged into the circulation by the bone marrow to compensate for the loss of erythrocytes by haemolysis.

Faecal urobilinogen is increased as this route excretes most of the urobilinogen.

Radioactive chromium (^{51}Cr) labelling of the patient's own red cells will demonstrate the severity of red cell destruction. Daily scanning over the spleen will show the degree of red cell sequestration by the spleen. The presence of high levels of splenic radioactivity generally predicts a good response to splenectomy.

All patients with hereditary spherocytosis should be treated by splenectomy but, in juvenile cases, this is generally delayed until 6 years of age to minimise the risk of postsplenectomy

infection, but before gallstones have had time to form. Ultrasonography should be performed preoperatively to determine the presence of gallstones.

Acquired autoimmune haemolytic anaemia

This condition is divided into immune- and non-immune-mediated forms. It may arise following exposure to agents such as chemicals, infection or drugs, e.g. alpha-methyldopa, or be associated with another disease (e.g. systemic lupus erythematosus). In most instances, the cause is unknown, and red cell survival is reduced because of an immune reaction triggered by immunoglobulin or complement on the red cell surface. The condition is more common in women after the age of 50 years. The spleen is enlarged in about half the patients and pigment gallstones are present in about 20%.

Anaemia is invariably present and may be associated with spherocytosis because of red cell membrane damage. In the immune type, antibody, which coats the red cells, can be detected by agglutination when anti-human globulin is added to a suspension of the patient's erythrocytes (Coombs' test positive). The disease runs an acute self-limiting course and no treatment is necessary. Splenectomy should, however, be considered if corticosteroids are ineffective, when the patient is developing complications from long-term steroid treatment or if corticosteroids are contraindicated; 80% of patients respond to splenectomy.

Thalassaemia (synonyms: Cooley's anaemia, Mediterranean anaemia)

This condition results from a defect in haemoglobin peptide chain synthesis and is transmitted most commonly as a recessive trait. The disease is really a group of related diseases, alpha, beta and gamma, depending upon which haemoglobin peptide chain rate of synthesis is reduced. Most patients have beta-thalassaemia, in which a reduction in the rate of beta-chain synthesis results in a decrease in haemoglobin A. Intracellular precipitates (Heinz bodies) contribute to premature red cell destruction.

Graduations of the disease range from heterozygous thalassaemia minor to homozygous thalassaemia major, which is associated with chronic anaemia, jaundice and splenomegaly. Patients with homozygous thalassaemia major frequently develop clinical signs in the first year of life, and these include retarded growth, enlarged head with slanting eyes and depressed nose, leg ulcers, jaundice and abdominal distension secondary to splenomegaly.

Red cells are small, thin and misshapen and have a characteristic resistance to osmotic lysis. In the more severe forms, nucleated red cells and other immature blood cells are seen. The diagnosis is confirmed by haemoglobin electrophoresis.

Blood transfusion may be required to correct profound anaemia, but the patient may become transfusion dependent because of hypersplenism. Splenectomy is therefore of benefit in patients who require frequent blood transfusion or if haemolytic antibodies have developed.

Sickle cell disease

Sickle cell disease is a hereditary, autosomal recessive haemolytic anaemia occurring mainly among those of African origin, in whom the normal haemoglobin A is replaced by haemoglobin S (HbS). The HbS molecule crystallises when blood oxygen tension is reduced, thus distorting and elongating the red cell. The resulting increased blood viscosity may obstruct the flow of blood in the spleen. Splenic microinfarcts are therefore common.

The sickle cell trait can be detected in 9% of those of African origin, but most are asymptomatic; sickle cell disease occurs in about 1% of Africans. Depending upon the vessels affected by vascular occlusion, patients may complain of bone or joint pain, priapism, neurological abnormalities, skin ulcers or abdominal pain due to visceral blood stasis. The diagnosis is made by finding characteristic sickle-shaped cells on blood film, although this investigation has largely been replaced by haemoglobin electrophoresis.

Hypoxia that provokes a sickling crisis should be avoided and is particularly relevant in patients undergoing general anaesthesia. Adequate hydration and partial exchange transfusion may help in a crisis. Splenectomy is of benefit in a few patients in whom excessive splenic sequestration of red cells aggravates the anaemia. Chronic hypersplenism usually occurs in late childhood or adolescence, although *Streptococcus pneumoniae* infection may precipitate an acute form in the first 5 years of life.

Porphyria

Porphyria is a hereditary error of haemoglobin catabolism in which porphyrinuria occurs. The urine may be orange and develops a port-wine colour after a few hours of exposure to the air. Splenectomy has little role to play in the management.

Gaucher's disease

This lipid storage disease is characterised by storage of glucocerebroside in the reticuloendothelial system and in the spleen. Enormous splenic enlargement may be associated with yellowish brown discoloration of the skin on the hands and face, anaemia and conjunctival thickening (pinguecula). Slavonic and Jewish races are more prone to the disease, and the detection of Gaucher cells in the bone marrow confirms the diagnosis. Splenectomy is indicated only for severe symptoms related to the splenomegaly.

Hypersplenism due to portal hypertension

Splenomegaly is an invariable feature of portal hypertension (***Figure 70.13***) and results in the thrombocytopenia and granulocytopenia observed in these patients. These may be improved if the portal hypertension is relieved by shunt surgery or liver transplantation. Splenectomy would normally be required only in those patients whose segmental portal hypertension has

Robin Royston Amos Coombs, 1921–2006, Quick Professor of Biology, University of Cambridge, Cambridge, UK, described this test in 1945.
Thomas Benton Cooley, 1871–1945, Professor of Pediatrics, Wayne University, Detroit, MI, USA, described this type of anaemia in 1927.

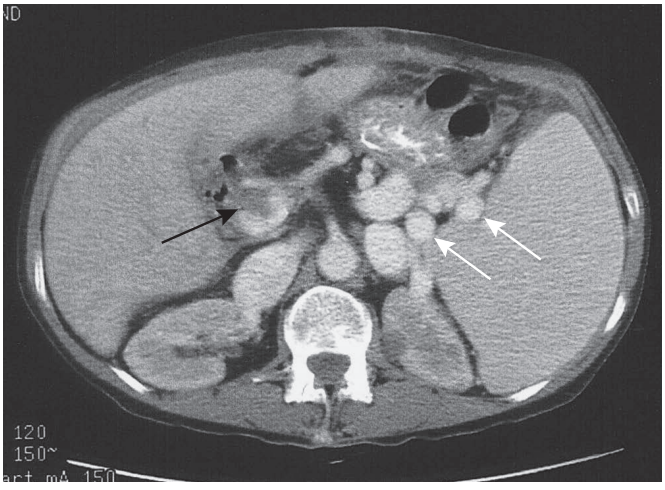

Figure 70.13 Computed tomography scan showing an enlarged spleen in a patient with portal hypertension secondary to portal vein thrombosis. Clot is evident within the lumen of the portal vein (black arrow) and large vessels of portosystemic shunts (white arrows) are present at the splenic hilus.

resulted in symptomatic oesophagogastric varices either as a standalone procedure in cases with massive splenomegaly due to extrahepatic portal vein obstruction or in combination with proximal lienorenal shunt (see ***Chapter 69***).

Felty's syndrome

Patients with rheumatoid arthritis may develop leukopenia. This is referred to as Felty's syndrome if it is extreme and associated with splenomegaly. Splenectomy produces only a transient improvement in the blood picture, but rheumatoid arthritis may respond to steroid therapy to which it had previously become resistant.

NEOPLASMS

Haemangioma is the most common benign tumour of the spleen. It may rarely develop into a haemangiosarcoma. The spleen is rarely the site of metastatic disease. Lymphoma is the most common cause of neoplastic enlargement and splenectomy may play a part in its management.

Splenectomy may be required to achieve a diagnosis in the absence of palpable lymph nodes or to relieve the symptoms of gross splenomegaly. However, the need for staging laparotomy or laparoscopy has largely receded with the advent of CT and guided biopsy. Its use has been restricted to those patients in whom a definite histological diagnosis of intra-abdominal disease will affect management. In the absence of obvious liver or intra-abdominal nodal disease, splenectomy is an integral part of the staging procedure to exclude splenic involvement, which would alter the method of treatment.

Myelofibrosis results from an abnormal proliferation of mesenchymal elements in the bone marrow, spleen, liver and lymph nodes. Most patients present over the age of 50 years, and the spleen may produce pain owing to its gross enlargement (***Figure 70.14***) or to splenic infarcts. Splenectomy reduces the need for transfusion and may relieve the discomfort resulting from the splenomegaly.

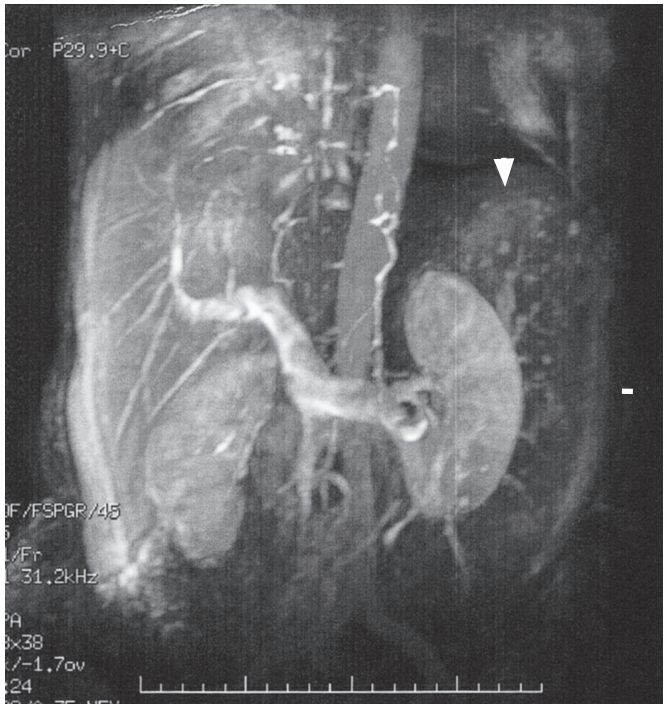

Figure 70.14 Magnetic resonance imaging scan showing massive hepatosplenomegaly secondary to myelofibrosis. Note the prominent portal system and the left kidney, which is superimposed over the grossly enlarged spleen (arrowheads).

SPLENECTOMY

The common indications for splenectomy are:

- trauma resulting from an accident or iatrogenic during a surgical procedure; for example, during mobilisation of the oesophagus, stomach, distal pancreas or splenic flexure of the colon;
- removal en bloc with the stomach as part of a radical gastrectomy or with the pancreas as part of a distal or total pancreatectomy;
- to treat anaemia or thrombocytopenia in spherocytosis, ITP or hypersplenism;
- in association with shunt or variceal surgery for portal hypertension.

Summary box 70.2

Indications for splenectomy

Trauma
- Accidental
- Iatrogenic

Oncological
- Part of *en bloc* resection
- Diagnostic
- Therapeutic

Haematological
- Spherocytosis
- Purpura (ITP)
- Hypersplenism

Portal hypertension
- Variceal surgery

Preoperative preparation

In the presence of a bleeding tendency, transfusion of blood, fresh-frozen plasma, cryoprecipitate or platelets may be required. Coagulation profiles should be as near normal as possible at operation, and platelets should be available for patients with thrombocytopenia during operation and in the early postoperative period.

Antibiotic prophylaxis appropriate to the operative procedure should be given, and consideration should be given to the risk of postsplenectomy sepsis (see ***Postoperative complications***).

Technique of open splenectomy

Most surgeons use a midline or transverse left subcostal incision for open splenectomy with the patient in the supine position. Rarely, a thoracoabdominal incision may be necessary for a massive spleen that is adherent to the diaphragm. Passage of a nasogastric tube following induction of the anaesthetic enables the stomach to be emptied.

In elective splenectomy, the gastrosplenic ligament is opened and the short gastric vessels are divided. The splenic vessels at the superior border of the pancreas are suture ligated. Division of the posterior leaf of the lienorenal ligament with long curved scissors on the posterior surface of the spleen helps to rotate and deliver the spleen medially into the laparotomy wound along with the tail and body of the pancreas. The posterior surface of the spleen is exposed and the spleen rotated medially along with the tail and body of the pancreas (***Figure 70.15***). The pancreas is separated from the hilar vessels, which are normally doubly ligated separately and divided. Accessory splenic tissue in the splenic hilum or omentum should be excluded by a careful search at operation. There is no need to drain the wound.

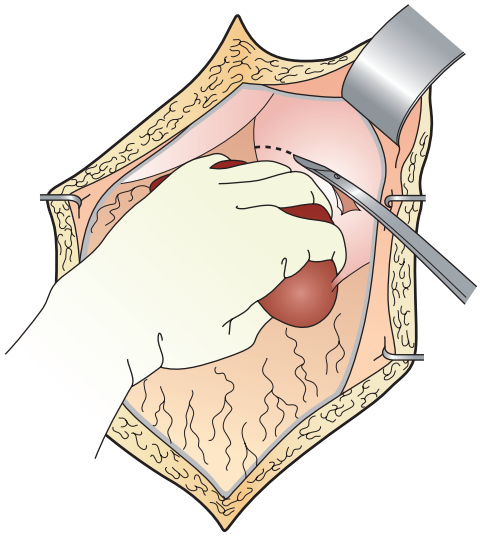

Figure 70.15 Diagrammatic view of the approach to mobilise the spleen at open surgery with division of the peritoneal fold of the lienorenal ligament posteriorly using Metzenbaum scissors, enabling delivery of the spleen into the laparotomy wound.

The segmental vasculature of the spleen does make it possible to undertake limited resection of the parenchyma. Haemostasis can be achieved by ligation of, or application of metal clips to, intrasplenic vessels and by careful application of topical haemostatic agents. Conservative splenic surgery is therefore possible in some cases of splenic trauma and other pathology such as splenic cysts.

Technique of laparoscopic splenectomy

The patient is placed on the right side with the space between the left ilium and costal margin exposed. Placement of access ports is often determined by the size of the patient and the spleen. Insufflation of the abdomen can be performed once access is obtained through an incision 1 cm from the costal margin at the left midclavicular line. A further trocar is inserted close to the costal margin below the xiphoid. A 12-mm trocar is inserted at a similar distance from the costal margin at the posterior axillary line. The splenocolic ligament is divided to give access to the lower splenic pole. The spleen is separated from the kidney and diaphragm before the gap between the splenic hilum and the tail of the pancreas is enlarged. The spleen is elevated to expose the splenic hilum, which is secured and divided with an endoscopic vascular stapler (***Figure 70.16***). Two or three applications of the instrument may be required to secure the hilum and the short gastric vessels. Any remaining attachments to the diaphragm are divided before a self-retaining opening bag is introduced through the incision of the open laparoscopy, after removal of the 12-mm port.

Postoperative complications

Immediate complications specific to splenectomy include haemorrhage resulting from a slipped ligature. Left basal

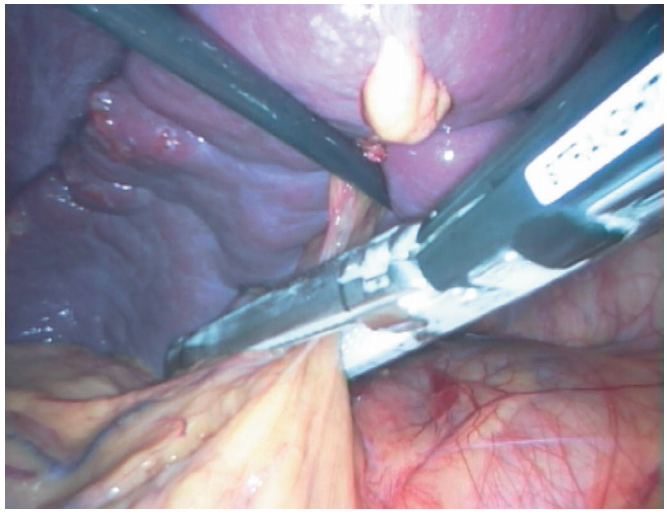

Figure 70.16 Photograph showing a stapling device across the splenic hilus for division of the splenic vessels during laparoscopic splenectomy.

Myron Firth Metzenbaum, 1876-1944, surgeon, Cleveland, OH, USA.

atelectasis is common and a pleural effusion may be present. Adjacent structures at risk during the procedure include the stomach and pancreas. A fistula may result from damage to the greater curvature of the stomach during ligation of the short gastric vessels. Damage to the tail of the pancreas during ligation of the splenic vessels at the hilum may result in pancreatitis, a localised abscess or a pancreatic fistula. Haematemesis from gastric mucosal damage and gastric dilatation are uncommon.

Postoperative thrombocytosis may arise and, if the blood platelet count exceeds 1×10^6/mL, prophylactic aspirin is recommended. Long-term surveillance programmes have emphasised an increased risk of deep vein thrombosis and pulmonary embolism. The relative risk and benefit of thromboprophylaxis in this setting has not been assessed adequately.

Postsplenectomy septicaemia may result from *S. pneumoniae, Neisseria meningitides, Haemophilus influenzae* or *Escherichia coli*. Long-term surveillance programmes have suggested that the risk of pneumonia, meningitis and major sepsis following splenectomy is increased threefold. However, the risk is greater in the young patient, in splenectomised patients treated with chemoradiotherapy and in patients who have undergone splenectomy for thalassaemia, sickle cell disease and autoimmune anaemia or thrombocytopenia.

Opportunist postsplenectomy infection (OPSI) is a major concern. Published guidelines emphasise that most infections after splenectomy could be avoided through measures that include offering patients appropriate and timely immunisation, antibiotic prophylaxis, education and prompt treatment of infection. The benefit of prophylactic antibiotics in this setting remains controversial. It is thought that children who have undergone splenectomy before the age of 5 years should be treated with a daily dose of penicillin until the age of 10 years. Prophylaxis in older children should be continued at least until the age of 16 years, but its use is less well defined in adults. Furthermore, compliance is problematic in the long term but, as the risk of overwhelming sepsis is greatest within the first 2–3 years after splenectomy, it seems reasonable to give prophylaxis during this time. However, all patients with compromised immune function should receive prophylaxis. Satisfactory oral prophylaxis can be obtained with penicillin, erythromycin, amoxicillin or co-amoxiclav. Suspected infection can be treated intravenously with these same antibiotics and cefotaxime or ceftriaxone, or chloramphenicol in patients allergic to penicillin and cephalosporins.

If elective splenectomy is planned, consideration should be given to vaccinating against pneumococcus, meningococcus C (both repeated every 5 years) and *H. influenzae* type b (Hib) (repeated every 10 years). The last two vaccines are commonly delivered as a combined preparation. Yearly influenza vaccination has been recommended, as there is some evidence that it may reduce the risk of secondary bacterial infection. Such vaccinations should be administered at least 2 weeks before elective surgery or as soon as possible after recovery from surgery but before discharge from hospital. Pneumococcal vaccination is recommended in those patients aged over 2 years. Hib vaccination is recommended irrespective of age. Asplenic patients should carry a medical alert and an up-to-date vaccination card. They require specific advice regarding travel and animal handling. OPSI due to *Capnocytophaga canimorsus* may result from dog, cat or other animal bites.

Vaccination can be given in the postoperative period following splenectomy for trauma, and the resulting antibody levels will be protective in the majority of cases. Antibody levels are, however, less than 50% of those achieved if vaccination is given in the presence of an intact spleen. Protection following vaccination is not always guaranteed.

Summary box 70.3

Splenectomy

- Remember preoperative immunisation
- Prophylactic antibiotics in children and immune compromised adults
- Opportunistic postsplenectomy infection is a real clinical danger
- Splenic conservation should be considered

PART 11 | Abdominal

CHAPTER 71

The gallbladder and bile ducts

Learning objectives

- To understand the surgical anatomy and physiology of the gallbladder and bile ducts
- To be familiar with the pathophysiology and management of gallstones
- To be aware of unusual disorders of the biliary tree
- To be aware of malignant disease of the gallbladder and bile ducts

SURGICAL ANATOMY AND PHYSIOLOGY

The gallbladder is a pear-shaped structure, 7.5–12 cm long, with a normal capacity of about 25–30 mL. Its anatomical divisions are fundus, body and neck, which terminates in a narrow infundibulum. The gallbladder lies on the underside of the liver in the main liver scissura at the junction of the right and left lobes. Its relationship to the liver varies from being embedded within the liver substance to being suspended by a mesentery. The muscle fibres in the wall of the gallbladder are arranged in a criss-cross manner, being particularly well developed in its neck. The mucous membrane contains indentations (crypts of Luschka) that sink into the muscle coat.

The cystic duct is about 3 cm in length, but this is variable. Its lumen is 1–3 mm in diameter; its mucosa is arranged in spiral folds (valves of Heister); and the wall is surrounded by the sphincter of Lütkens. The cystic duct joins the supraduodenal segment of the common hepatic duct in 80% of cases; however, the junction may be much lower in the retroduodenal or even retropancreatic part of the bile duct. Occasionally, the cystic duct may join the right hepatic duct or even a right hepatic sectorial duct (see ***Low insertion of the cystic duct***).

The common hepatic duct is usually less than 2.5 cm long and is formed by the union of the right and left hepatic ducts. The common bile duct (CBD) is about 7.5 cm long and is formed by the junction of the cystic and common hepatic ducts. It is divided into four parts:

1. supraduodenal portion, about 2.5 cm long, runs in the free edge of the lesser omentum;
2. retroduodenal portion;
3. infraduodenal portion, lies in a groove, at times in a tunnel, on the posterior surface of the pancreas;
4. intraduodenal portion, passes obliquely through the wall of the second part of the duodenum, where it is surrounded by the sphincter of Oddi and terminates by opening on the summit of the ampulla of Vater.

The cystic artery, a branch of the right hepatic artery, usually arises behind the common hepatic duct (***Figure 71.1***). Occasionally, an accessory cystic artery arises from the gastroduodenal artery. In 15% of cases the right hepatic artery and/or cystic artery cross in front of the common hepatic duct and cystic duct.

Calot's triangle, or the hepatobiliary triangle, was initially described by Calot as the space bordered by the cystic duct inferiorly, the common hepatic duct medially and the superior border of the cystic artery.

This has been modified in contemporary literature as the area bound superiorly by the inferior surface of the liver, laterally by the cystic duct and the medial border of the gallbladder and medially by the common hepatic duct ('hepatocystic triangle'). It is an important surgical landmark as the cystic artery usually can be found within its boundaries (***Figure 71.2a***). The cystic lymph node often lies superficial to the cystic artery and acts as a landmark to locate this artery in difficult cases.

The cystic plate is a flat ovoid fibrous sheet continuous with the liver capsule of segments IV (medially) and V

(laterally). It is located in the gallbladder bed and needs to be exposed to achieve the critical view of safety (CVS) during cholecystectomy. Rouvière's sulcus on the undersurface of the right lobe of the liver running to the right of the hepatic hilum marks the position of the right posterior sectoral pedicle. The advantage of identifying Rouvière's sulcus and the line joining the roof of the sulcus to the base of segment IV (R4U line) (Rouvière's sulcus→segment IV→umbilical fissure) is that the cystic duct and the cystic artery lie ventral (anterosuperior) to the line and the CBD lies below the line. CBD injury can be minimised by maintaining the dissection ventral to the line during cholecystectomy. In the case of difficulty, all dissection during laparoscopic cholecystectomy should be performed ventral to the R4U line (***Figure 71.3***).

Blood supply to the bile ducts

The supraduodenal CBD is supplied by the left and right choledochal arteries, arising from the posterior superior pancreaticoduodenal artery below and the right (RHA) and left (LHA) hepatic arteries and cystic arteries above (***Figure 71.1***). The choledochal arteries give small branches that form the epicholedochal plexus. The communicating arcade connects the RHA and LHA and lies cranial to the confluence of the right and left hepatic ducts.

The venous drainage of the extrahepatic bile ducts consists of the epicholedochal venous plexus that drains into two marginal veins that drain into the right gastric vein, posterior superior pancreaticoduodenal vein and superior mesenteric vein and connect to the hilar plexus.

Anatomical variations

The right hepatic artery can be tortuous (caterpillar turn/Moynihan's hump) and may lie very close to the gallbladder and the cystic duct before giving off a short cystic artery (***Figure 71.2b,c***).

Biliary and ductal anomalies include double cystic duct, separate insertion into the duodenum and anomalous low insertion of a right sectional duct (usually the posterior one, which puts this sectional duct at higher risk of injury).

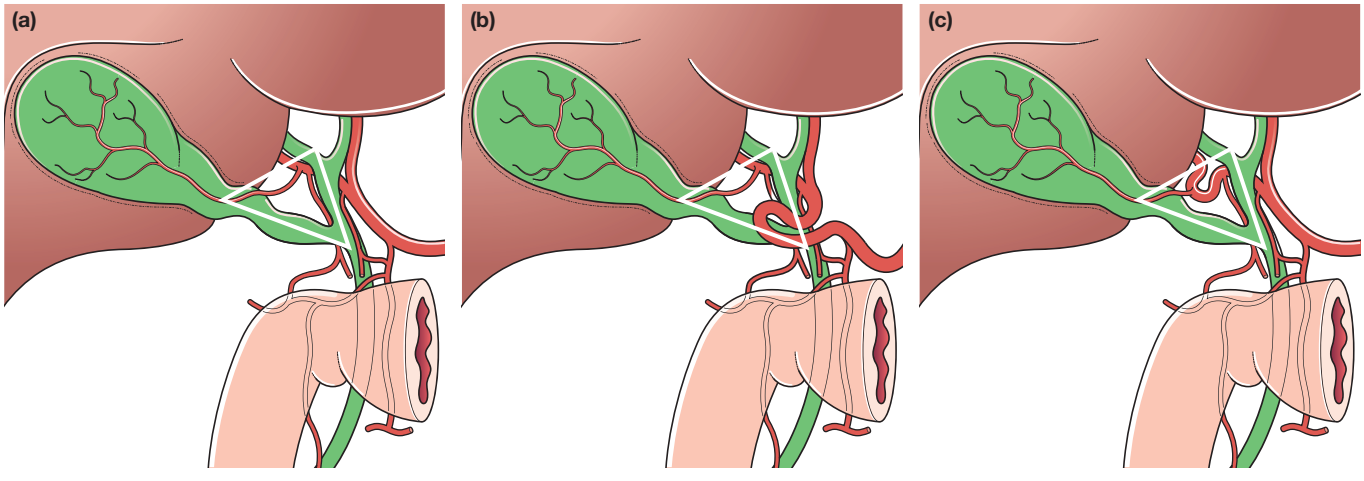

Figure 71.2 (a) The usual anatomy of the 'hepatocystic triangle'; **(b)** tortuous common hepatic artery; **(c)** tortuous right hepatic artery with a short cystic artery. **(b)** and **(c)** are examples of the 'caterpillar turn' or 'Moynihan's hump', which can lead to inadvertent arterial injury or bleeding during cholecystectomy.

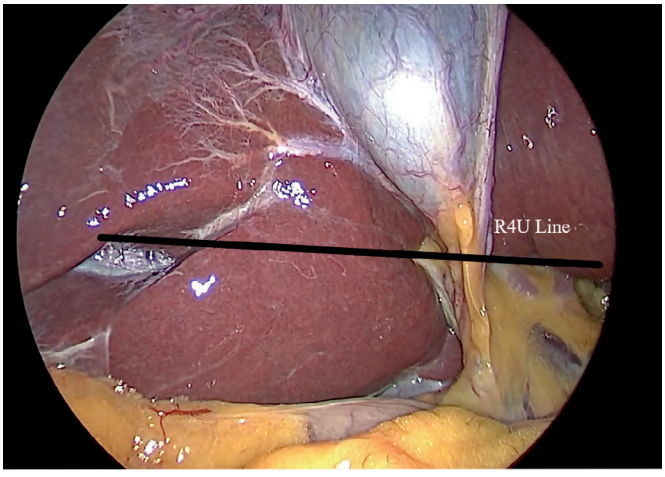

Figure 71.3 Rouvière's sulcus. R4U line, Rouvière's sulcus→segment IV→umbilical fissure.

Lymphatics

The subserosal and submucosal lymphatic vessels of the gallbladder drain into the cystic lymph node of Lund (the sentinel lymph node), which lies in the fork created by the junction of the cystic and common hepatic ducts. Efferent vessels from this lymph node go to the hilum of the liver and to the coeliac lymph nodes. The subserosal lymphatics also connect with the subcapsular lymph channels of the liver; this accounts for the frequent spread of carcinoma of the gallbladder to the liver.

Surgical physiology

Bile is produced by the liver and stored in the gallbladder before being released into the duodenum. The liver excretes bile at approximately 40 mL/h. As it leaves the liver its composition is 97% water; the remaining 3% consists of bile salts (cholic and chenodeoxycholic acids, deoxycholic and lithocholic acids), phospholipids, cholesterol and bilirubin. About 95% of bile salts are reabsorbed in the terminal ileum and returned to the liver (enterohepatic circulation).

Functions of the gallbladder

The gallbladder is a reservoir for bile. During fasting, the resistance to flow through the sphincter of Oddi is high, and bile excreted by the liver is diverted to the gallbladder. After feeding, the resistance to flow through the sphincter is reduced, the gallbladder contracts and bile enters the duodenum. The motor responses of the biliary tract are in part affected by the hormone cholecystokinin. An additional function of the gallbladder is the concentration of bile by 5–10 times by active absorption of water, sodium chloride and bicarbonate via the mucous membrane. The gallbladder mucosa also secretes approximately 20 mL of mucus per day. If the cystic duct is completely obstructed in an otherwise healthy gallbladder, a mucocele may develop as a result of ongoing mucus secretion.

Figure 71.4 Plain radiograph showing radio-opaque stones with the centre containing radiolucent gas in a triradiate or biradiate fissure ('Mercedes-Benz' or 'seagull' sign).

IMAGING

Plain radiographs

A plain radiograph of the gallbladder will show radio-opaque stones in 10% (***Figure 71.4***). It may also show calcification of the gallbladder – the rare 'porcelain' gallbladder (***Figure 71.5***).

Figure 71.5 Porcelain gallbladder.

Fred Bates Lund, 1865–1950, surgeon, Boston, MA, USA. The node was also named after the Italian anatomist and physician **Paolo Mascagni**, 1752–1815, who first identified the node around 1787.

The **Mercedes-Benz** sign takes its name from the insignia on the bonnet of a Mercedes-Benz car

Gas may be seen in the wall of the gallbladder (emphysematous cholecystitis) (***Figure 71.6***). Gas in the biliary tree may also be seen after endoscopic sphincterotomy or following a surgical anastomosis.

Cholecystography

Oral and intravenous cholecystography have been replaced by more accurate imaging modalities.

Ultrasonography

Transabdominal ultrasonography (USG) (***Figure 71.7***) is the initial imaging modality of choice as it is accurate, readily available, inexpensive and quick to perform. However, it is operator dependent and may be compromised by excessive body fat and intraluminal bowel gas. The size of the gallbladder and presence of stones or polyps can be determined. Acute calculous cholecystitis is diagnosed radiologically (sensitivity 90–95%) by thickening of the gallbladder wall (>3 mm), presence of pericholecystic fluid or direct tenderness when the probe is pushed against the gallbladder (ultrasonographic Murphy's sign). Additionally, the presence of inflammation around the gallbladder, the size of the CBD and, occasionally, the presence of stones within the extrahepatic biliary tree can be determined.

In a patient with obstructive jaundice, USG can identify intra- and extrahepatic biliary dilatation, the level of the obstruction and the cause of the obstruction – stones, common hepatic duct or CBD, lesions within the wall of the CBD suggestive of cholangiocarcinoma, gallbladder cancer or mass lesions in the pancreatic head.

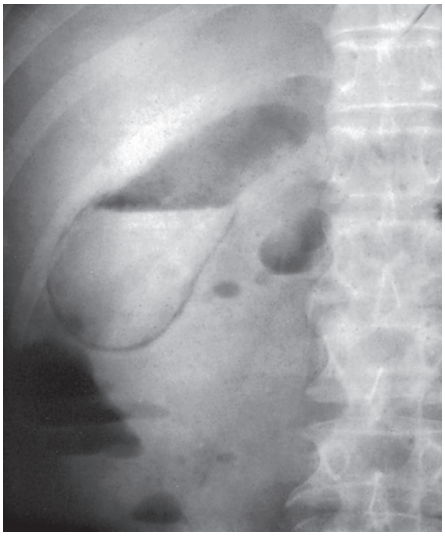

Figure 71.6 Gas in gallbladder and gallbladder wall (*Clostridium perfringens* infection). Emergency cholecystectomy is indicated.

Endoscopic ultrasonography

Endoscopic ultrasonography (EUS) utilises an endoscope with an ultrasound transducer at its tip, which allows the endoscopist to visualise the liver and biliary tree from within the stomach and duodenum (***Figure 71.8***). It is accurate in detecting choledocholithiasis and in the diagnosis and staging of pancreatic and periampullary cancers. Biopsies can be taken from suspicious areas for cytological and histological analysis.

Cholescintigraphy

Technetium-99m (^{99m}Tc)-labelled derivatives of iminodiacetic acid (hepatobiliary iminodiacetic acid [HIDA]; the utility of a hepatobiliary IDA or HIDA scan is that the radiotracer follows

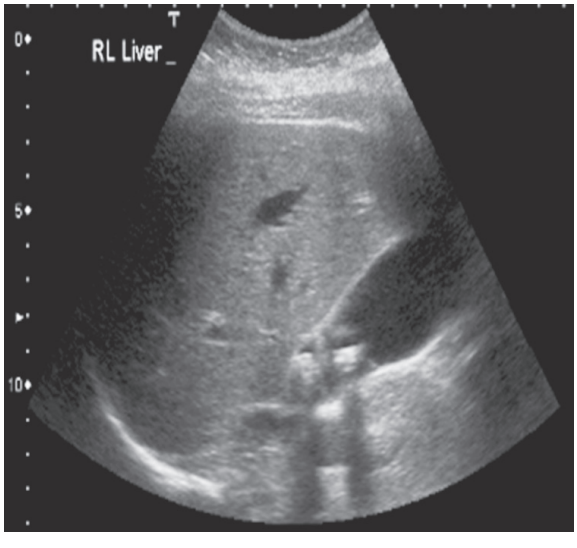

Figure 71.7 Ultrasound examination. Gallstones in neck of gallbladder with acoustic shadowing.

the bilirubin metabolic pathway) are excreted into the bile. This allows visualisation of the biliary tree and gallbladder. In 90% of normal individuals the gallbladder is visualised within 30 minutes following injection, with 100% being seen within 1 hour (***Figure 71.9***). The bowel is seen usually within an hour in the majority of patients.

Non-visualisation of the gallbladder is suggestive of acute cholecystitis. If the patient has a contracted gallbladder, as often occurs in chronic cholecystitis, visualisation may be reduced or delayed. An abnormally low gallbladder ejection fraction may be suggestive of gallbladder dyskinesia; however, interpretation of cholescintigraphy in this context is controversial. Biliary scintigraphy may also be helpful in diagnosing bile leaks, biliary obstruction and in testing the patency of a bilioenteric anastomosis.

Computed tomography

Unlike USG, computed tomography (CT) is less affected by body habitus and is not operator dependent. It allows visualisation of the liver, bile ducts, gallbladder and pancreas. CT findings in acute cholecystitis include gallbladder distension, gallbladder wall thickening, subserosal oedema, pericholecystic fat stranding and pericholecystic fluid collection. It is particularly useful in detecting hepatic and pancreatic lesions and is the modality of choice in the staging of cancers of the liver, gallbladder, bile ducts and pancreas. It can identify the extent of the primary tumour, define the relationship of the tumour to other organs and blood vessels (***Figure 71.10***) and detect the presence of enlarged lymph nodes or metastatic disease. However, as only 75% of gallstones are identified by CT, it is not used as a screening modality for uncomplicated gallstones.

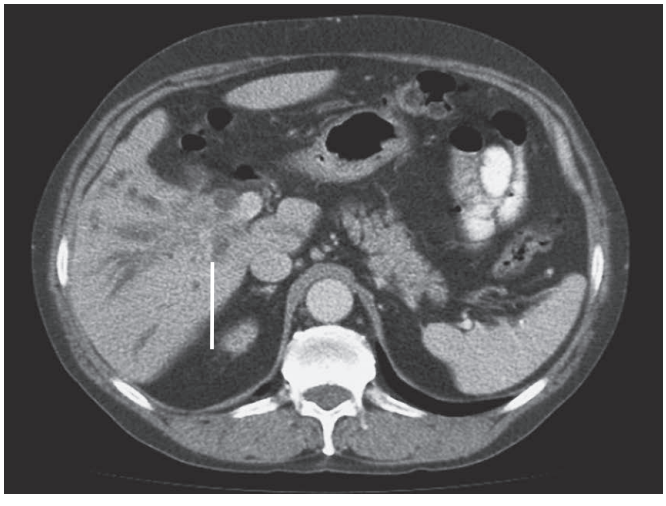

Figure 71.10 Computed tomography showing hilar mass (arrow).

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is a non-invasive modality that provides excellent images of the gallbladder and biliary system (***Figures 71.11 and 71.12***). These images are comparable to those obtained at endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) (see ***Percutaneous transhepatic cholangiography*** and ***Endoscopic retrograde cholangiopancreatography***) without the potential complications of the latter; they can demonstrate ductal abnormalities, including obstruction/stricture, stones and tumours.

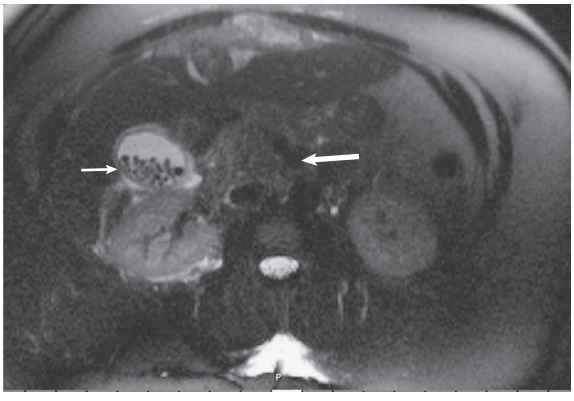

Figure 71.11 Magnetic resonance cholangiopancreatography: cross-sectional image demonstrating hilar mass (thick arrow) and gallstones (thin arrow).

Figure 71.12 Magnetic resonance cholangiopancreatography: projectional images demonstrating stones and hilar obstruction (arrow).

Endoscopic retrograde cholangiopancreatography

This technique is now used only as a therapeutic modality in patients with obstructive jaundice; USG and MRCP have taken over the diagnostic aspect. Using a side-viewing endoscope the ampulla of Vater is identified and cannulated. Injection of water-soluble contrast into the bile duct provides excellent images of the ductal anatomy (***Figure 71.13***) and can identify causes of obstruction such as calculi (***Figure 71.14***) and malignant strictures (***Figure 71.15***). Bile aspirates can be obtained and sent for cytological and microbiological examination and brushings can be taken from strictures for cytology. Therapeutic interventions such as stone removal or stent placement to relieve obstruction can be performed simultaneously.

Cholangioscopy is a relatively new technique in which a thin scope is inserted through the channel of an ERCP scope to visually inspect the bile duct. The main indications include indeterminate or unexplained biliary strictures, nodules or masses and crushing difficult-to-remove bile duct stones with lithotripsy.

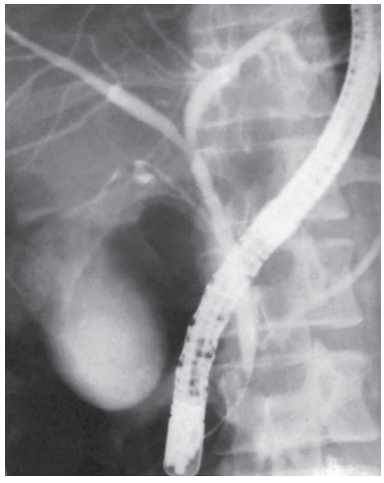

Figure 71.13 Endoscopic retrograde cholangiopancreatography: normal cholangiogram.

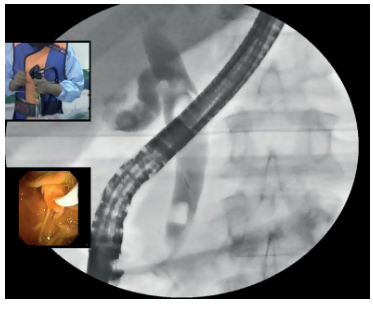

Figure 71.14 Endoscopic retrograde cholangiopancreatography: common duct obstruction due to stone (courtesy Dr Amit Maydeo, Mumbai, India).

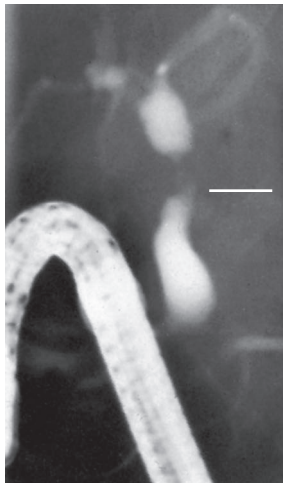

Figure 71.15 Endoscopic retrograde cholangiopancreatography: partial occlusion of bile duct by malignant stricture (arrow).

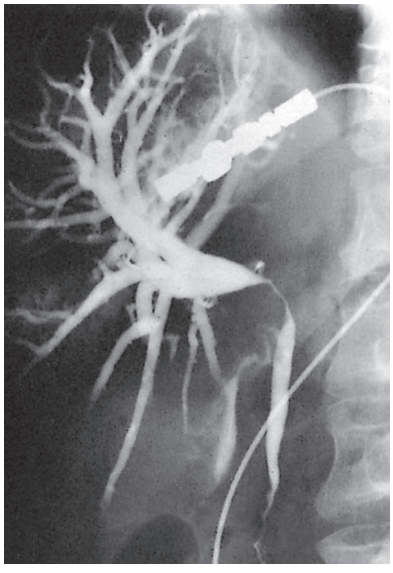

Figure 71.16 Transhepatic cholangiogram showing stricture of common hepatic duct (courtesy of Ms Phyllis George, FRCS, London, UK).

Percutaneous transhepatic cholangiography

This is an invasive technique in which the bile ducts are cannulated percutaneously. The main indication is to drain intrahepatic ducts when strictures cannot be accessed at ERCP. The procedure is undertaken after confirming normal coagulation parameters; antibiotics should be given prior to the procedure. Under fluoroscopic or sonographic control, a slender (Chiba or Okuda) needle is introduced percutaneously into the liver substance. Successful entry into the bile duct is confirmed by contrast injection or aspiration of bile. Water-soluble contrast medium is injected to visualise the biliary system and images are taken to demonstrate strictures or obstruction (***Figure 71.16***). Bile can be sent for cytology. This technique enables placement of a catheter into the bile ducts to provide external or internal biliary drainage and insertion of indwelling stents. The drainage catheter can be left *in situ* for a number of days and the track dilated sufficiently for the introduction of a fine flexible choledochoscope to diagnose strictures, take biopsies and remove stones.

Summary box 71.1

Radiological investigation of the biliary tree

- Plain radiograph: calcification, air within the biliary system
- USG: stones and biliary dilatation
- MRCP: anatomy and stones
- CT scan: anatomy, and liver, biliary and pancreatic cancer
- Radioisotope scanning (HIDA scan): function
- ERCP: anatomy, stones and biliary strictures, with or without cholangioscopy
- PTC: anatomy and biliary strictures
- EUS: anatomy, stones

Intraoperative imaging techniques

Peroperative cholangiography

During open or laparoscopic cholecystectomy, a catheter can be placed in the cystic duct and contrast injected directly into the biliary tree. The technique defines the anatomy and is used mainly to exclude the presence of stones within the bile ducts (***Figures 71.17–71.19***). A radiographic plate or image intensifier can be used to obtain and review the images intraoperatively. The operating table should be tilted head-down by approximately 20° to facilitate filling of the intrahepatic ducts.

Care should be taken when injecting contrast not to introduce air bubbles into the system as these may mimic the appearance of stones.

Operative biliary endoscopy (choledochoscopy)

At operation, a flexible fibreoptic endoscope can be passed either via the cystic duct or directly via a choledochotomy (open or laparoscopic) into the CBD, enabling stone identification and removal under direct vision. After exploration of

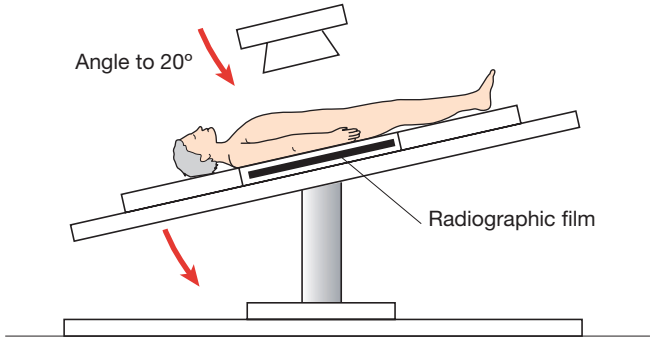

Figure 71.17 Peroperative cholangiography using a radiolucent tabletop.

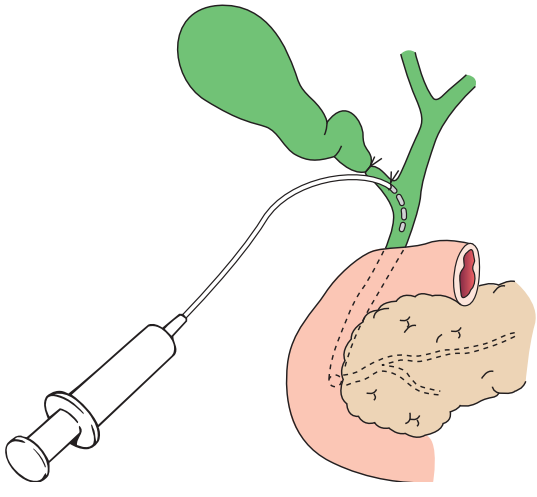

Figure 71.18 Peroperative cholangiography. Technique of introducing contrast.

Kunio Okuda, 1921–2003, Professor of Medicine, Chiba University, Chiba, Japan.

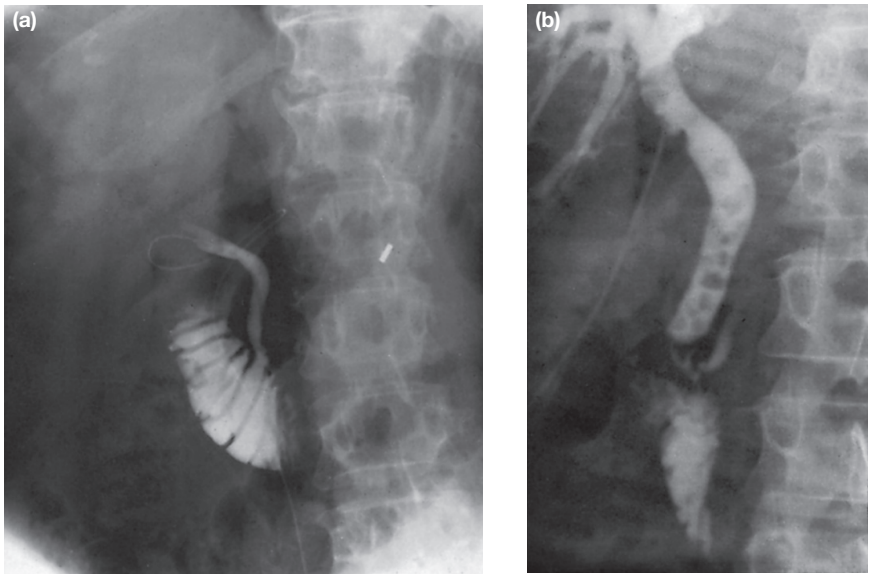

Figure 71.19 Peroperative cholangiography. **(a)** Gentle infusion of contrast, passing without hindrance into the duodenum. A normal duct. **(b)** Dilated duct containing multiple stones; there is a delay in contrast passing into the duodenum.

the bile duct, a tube can be left in the cystic duct remnant or in the CBD (T tube) and drainage of the biliary tree established. After 7–10 days, a track will be established. This track can be used subsequently for the passage of a choledochoscope or radiologically guided stone retrieval catheter (Burhenne technique) to remove residual stones.

Laparoscopic ultrasonography

At laparoscopy, a laparoscopic ultrasound probe can be used to closely image the extrahepatic biliary system. This technique is useful in biliary and pancreatic tumour staging as it can determine the relationship of the tumour to major vessels such as the hepatic artery, superior mesenteric artery, portal vein and superior mesenteric vein.

CONGENITAL ABNORMALITIES OF THE GALLBLADDER AND BILE DUCTS

Embryology

The hepatic diverticulum arises from the ventral wall of the foregut and elongates into a stalk to form the choledochus. A lateral bud is given off, which is destined to become the gallbladder and cystic duct. The embryonic hepatic duct sends out many branches that join up with the canaliculi between the liver cells. As is usual with embryonic tubular structures, hyperplasia obliterates the lumina of this ductal system; normally recanalisation occurs subsequently and bile begins to flow. During early fetal life the gallbladder is entirely intrahepatic.

Absence of the gallbladder

Rarely, the gallbladder is absent; failure to visualise it should not be mistaken for pathology.

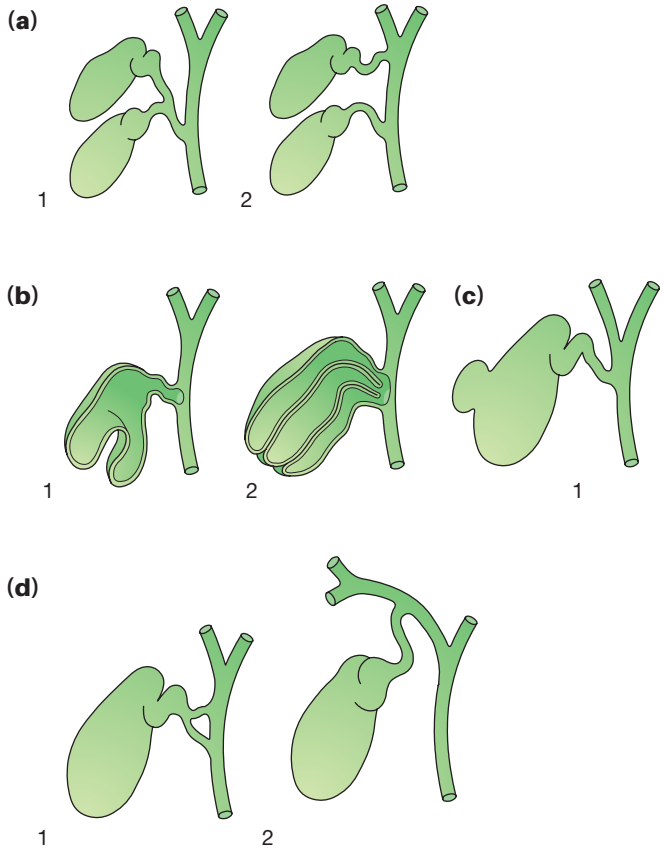

Figure 71.20 The main variations in gallbladder and cystic duct anatomy. **(a)** Double gallbladder. **(b)** Septum of the gallbladder: (1) is the most common ('Phrygian cap'). **(c)** Diverticulum of the gallbladder. **(d)** Variations in cystic duct insertion.

H Joachim Burhenne, 1925–1996, radiologist, Vancouver, Canada, described this technique in 1973.

The Phrygian cap

The Phrygian cap (*Figure 71.20*) is present in 5% of gallbladders and may be mistaken for a pathological deformity.

Floating gallbladder

The gallbladder may hang on a mesentery, which makes it liable to undergo torsion.

Absence of the cystic duct

This 'anomaly' is usually pathological, indicating the recent passage of a stone or, in the presence of jaundice, a stone at the lower end of the cystic duct ulcerating into the CBD (Mirizzi syndrome). The main danger at surgery is damage to the bile duct; care is essential before division of any duct.

Low insertion of the cystic duct

The operating surgeon must identify variations in the anatomy (*Figure 71.21*) to avoid inadvertent damage to the common hepatic duct or CBD. Complete dissection of the cystic duct (*Figure 71.22*) should be avoided because there is a potential to devascularise the CBD, which could result in stricture formation.

Accessory cholecystohepatic duct

Ducts passing directly into the gallbladder from the liver are not uncommon. Larger ducts should be closed, but before doing so the precise anatomy should be carefully ascertained to ensure that the right hepatic duct is not being ligated (*Figure 71.21*).

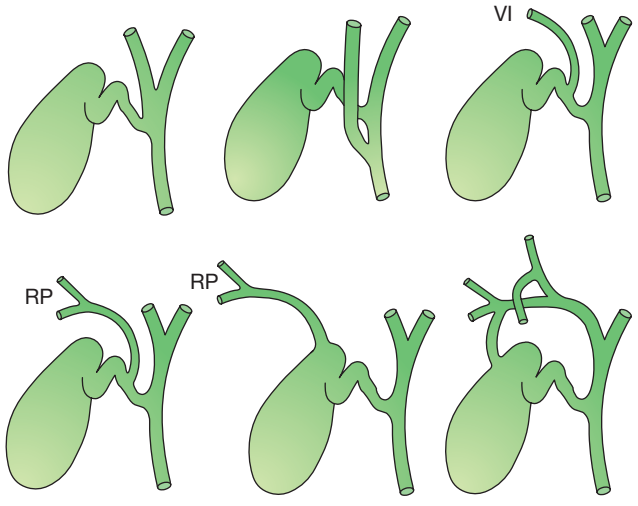

Figure 71.21 Patterns of cystic duct anatomy. Note segment VI drainage into the cystic duct and drainage of the right posterior sectorial duct (RP) into the neck of the gallbladder or an accessory duct (duct of Luschka).

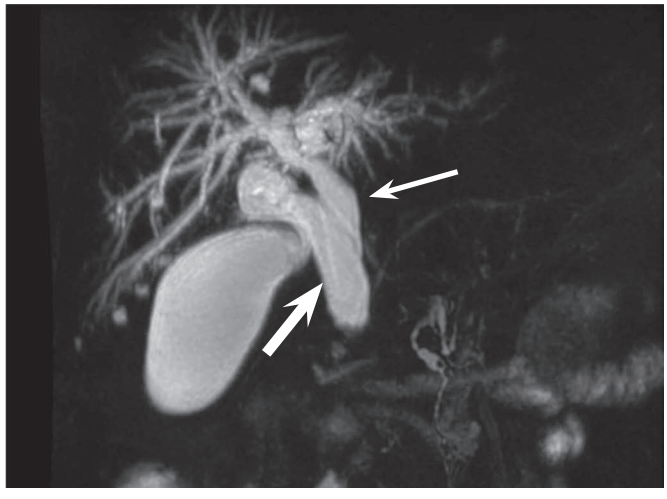

Figure 71.22 Magnetic resonance cholangiopancreatography demonstrating low insertion of the cystic duct (thick arrow) into the common bile duct (thin arrow).

EXTRAHEPATIC BILIARY ATRESIA

Aetiology and physiology

Biliary atresia is present in approximately 1 in 12 000 live births and affects males and females equally. The aetiology is unclear; the extrahepatic bile ducts are progressively destroyed by an inflammatory process that starts around the time of birth. Intrahepatic changes also occur and eventually result in biliary cirrhosis and portal hypertension. Untreated, death from the consequences of liver failure occurs before the age of 3 years.

The Japanese and Anglo-Saxon classification describes three main types (Kasai) (*Figure 71.23*):

- type I: atresia restricted to the CBD;
- type II: atresia of the common hepatic duct:
  - type IIa: a patent gallbladder and a patent CBD are present;
  - type IIb: the gallbladder, cystic duct and CBD are also obliterated;
- type III: atresia of the right and left hepatic ducts and the entire extrahepatic biliary tree.

Clinical features

About one-third of patients are jaundiced at birth; in all affected babies, jaundice is present by the end of the first week and deepens progressively. The meconium may be a little bile-stained, but later the stools are pale and the urine is dark. Pruritus is severe. Clubbing and skin xanthomas, probably related to raised serum cholesterol, may be present. Prolonged steatorrhea gives rise to osteomalacia (biliary rickets). Liver function tests show an obstructive pattern with elevated bilirubin and alkaline phosphatase (ALP). Associated anomalies occur in about 20% of cases and include cardiac lesions,

Hats worn by the **people of Phrygia**, an ancient country in Asia Minor; they resemble the liberté cap of the French Revolution.
Pablo Luis Mirizzi, 1893–1964, surgeon, Córdoba, Argentina.
Morio Kasai, 1922–2008, Professor of Surgery, Tokyo University, Tokyo, Japan.

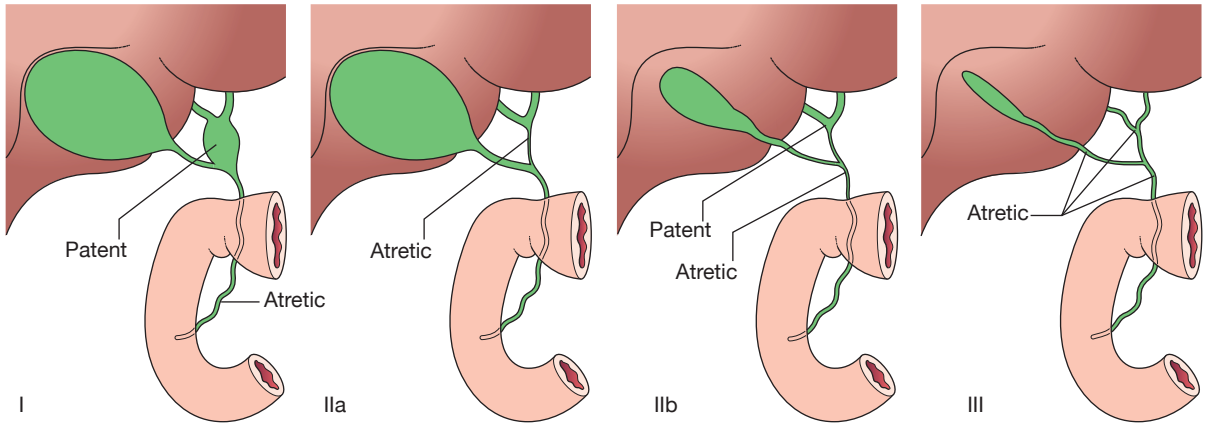

Figure 71.23 Classification of biliary atresia. Gallbladder filling provides a clue to the type of atresia.

polysplenia, situs inversus, absent vena cava and preduodenal portal vein. Biliary atresia may be suspected prenatally, when a cystic structure is observed in the porta hepatis on fetal USG.

Imaging studies and biopsy

Fasting USG is the gold standard when biliary atresia is suspected. A shrunken gallbladder, a hyperechogenic liver hilum ('triangular cord sign') or a cyst at the liver hilum without bile duct dilatation with associated anomalies support the diagnosis. Hepatobiliary scintigraphy may reveal the diagnosis but MRCP is highly sensitive and specific in the diagnosis. Inflammatory cells, a fibrotic liver parenchyma exhibiting signs of cholestasis and biliary neoductal structures establishes the definite diagnosis on liver biopsy. Cholangiography is required to define the surgical anatomy.

Differential diagnosis

This includes all causes of cholestatic jaundice in a neonate; namely, α_1-antitrypsin deficiency, cholestasis associated with intravenous feeding, choledochal cyst and inspissated bile syndrome. The most common differential diagnoses are Alagille syndrome (biliary atresia, congenital heart disease, skeletal and other abnormalities), progressive familial intrahepatic cholestasis and cystic fibrosis. Neonatal hepatitis is the most difficult to differentiate. Liver biopsy and radionuclide excretion scans are helpful.

Treatment

For breast-fed infants, introducing supplemental formula feeds using a medium-chain triglyceride-based feed and fat-soluble vitamin supplementation (titrated according to growth) is a priority.

Patent segments of proximal bile duct are found in 10% of type I lesions. A direct Roux-en-Y hepaticojejunostomy will achieve bile flow in 75%, but progressive fibrosis results in disappointing long-term results. A simple biliary–enteric anastomosis is not possible in the majority of cases in which the proximal hepatic ducts are either very small (type II) or atretic (type III). These are treated by the Kasai procedure, in which radical excision of all bile duct tissue up to the liver capsule is performed. A Roux-en-Y loop of jejunum is anastomosed to the exposed area of liver capsule above the bifurcation of the portal vein, creating a portoenterostomy. The chances of achieving effective bile drainage after portoenterostomy are maximal when the operation is performed before the age of 8 weeks, and approximately 90% of children whose bilirubin falls to normal can be expected to survive for 10 years or more. Early referral for surgery is critical.

Postoperative complications include bacterial cholangitis, which occurs in 40% of patients. Repeated attacks lead to hepatic fibrosis, and 50% of long-term survivors develop portal hypertension, with one-third having variceal bleeding.

Liver transplantation should be considered in children in whom a portoenterostomy is unsuccessful. Results are improving, with 70–80% alive 2–5 years following transplant.

CONGENITAL DILATATION OF INTRAHEPATIC DUCTS (CAROLI'S DISEASE)

This rare congenital condition is characterised by multiple irregular saccular dilatations of the intrahepatic ducts, separated by segments of normal or stenotic ducts, with a normal extrahepatic biliary system. In Caroli's syndrome, the biliary dilatation is associated with congenital hepatic fibrosis. The presentation is varied, with most patients presenting with abdominal pain, cholangitis or end-stage liver disease. The majority of patients present before the age of 30 years. The sex distribution is equal. Malignancy is a complication of longstanding disease.

Daniel Alagille, 1925–2005, paediatric hepatologist, Hôpital Bicêtre, Paris, France.
César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described the Roux-en-Y loop in 1908.
Jacques Caroli, 1902–1979, gastroenterologist, Hôpital St Antoine, Paris, France, described cavernous ectasia in the biliary tree in 1958.

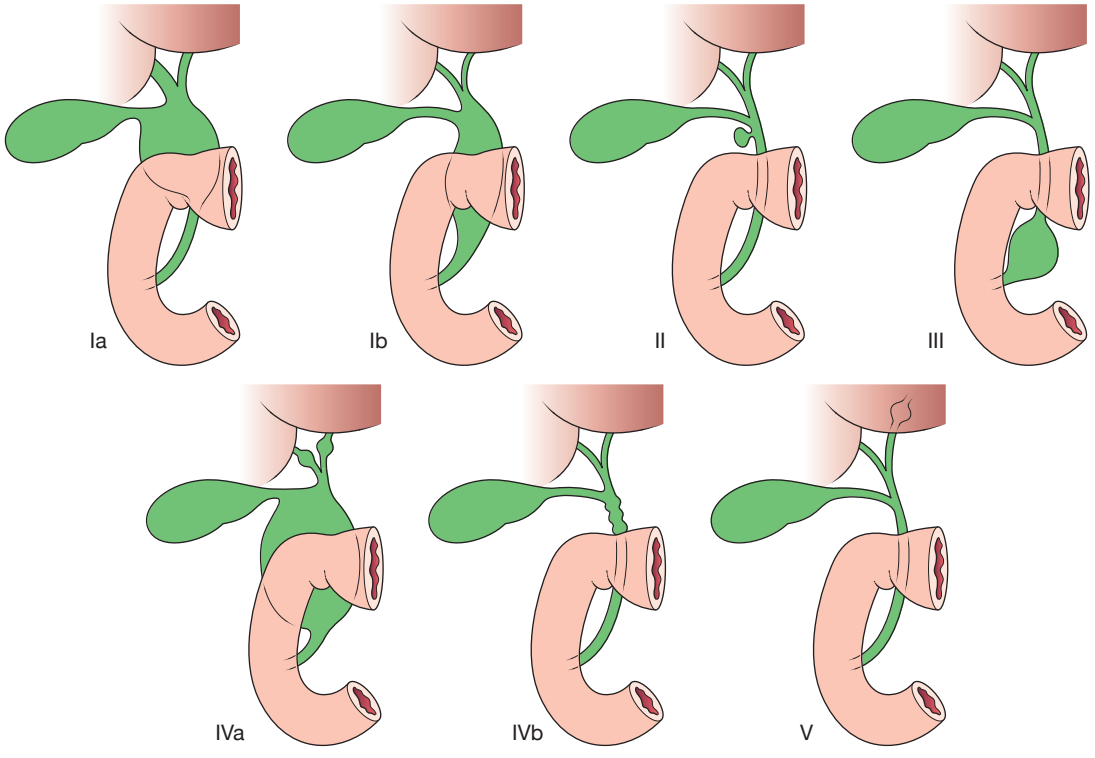

Figure 71.24 Classification of choledochal cysts. Type Ia and Ib (80–90%): diffuse cystic dilatation; note the extension into the intrapancreatic portion in type Ib. Type II (3%): diverticulum of the common bile duct. Type III (5%): diverticulum within the intrapancreatic portion. Type IV (10%): extension into the liver; type IVa: fusiform dilatation of the entire extrahepatic bile duct with extension into the intrahepatic ducts; type IVb: multiple cystic dilatations involving only the extrahepatic bile duct. Type V: cystic dilatation only of the intrahepatic ducts.

Management is multidisciplinary: cholangitis or jaundice are treated with appropriate antibiotic therapy and endoscopic or interventional stenting. Hepatic resection may be considered in patients with limited disease. Patients with diffuse disease and concomitant hepatic fibrosis are candidates for liver transplantation. Recurrence is common, particularly after resection, and long-term surveillance is required.

CHOLEDOCHAL CYST

Choledochal cysts are congenital dilatations of the intra- and/or extrahepatic biliary system. The pathogenesis is unclear. Anomalous insertions of the biliary–pancreatic junction are frequently observed, but whether or not these play a role in the pathogenesis of the condition is unclear. Todani and colleagues proposed a classification of cystic disease of biliary tract (***Figure 71.24***).

Patients may present at any age with jaundice, fever, abdominal pain and a right upper quadrant mass on examination; 60% of cases are diagnosed before the age of 10 years. Pancreatitis is not an infrequent presentation in adults. Patients with choledochal cysts have an increased risk of developing cholangiocarcinoma, with the risk varying directly with the age at diagnosis.

USG confirms the presence of an abnormal cyst and magnetic resonance imaging (MRI)/MRCP will reveal the anatomy, in particular the relationship between the lower end of the bile duct and the pancreatic duct. CT is also useful for delineating the extent of intra- or extrahepatic dilatation.

Radical excision of the cyst is the treatment of choice, with reconstruction of the biliary tract using a Roux-en-Y loop of jejunum. Complete resection is important because of an association with the later development of cholangiocarcinoma. Resection and Roux-en-Y reconstruction is also associated with a reduced incidence of stricture formation and recurrent cholangitis. Type III needs endoscopic management with sphincterotomy. It should be accompanied by biopsy of the cyst epithelium to exclude dysplasia in symptomatic cases and in young patients without symptoms.

TRAUMA

Injury to the gallbladder and extrahepatic biliary tree is rare and may occur as a result of blunt or penetrating abdominal trauma. Iatrogenic injury is perhaps more frequent than external trauma. Physical signs are those of an acute abdomen. Management depends on the location and extent of biliary and associated injury. In a stable patient, a transected bile duct

Takuji Todani, b. 1931, Department of Surgery, Okayama University Medical School, Okayama, Japan, modified Alonso-Lej's classification of choledochal cysts in 1977.

is best repaired by Roux-en-Y choledochojejunostomy. Injuries to the gallbladder can be dealt with by cholecystectomy.

TORSION OF THE GALLBLADDER

This is a very rare complication, requires a long mesentery and therefore occurs most often in an older patient with a mucocele of the gallbladder. Presentation is with extreme right upper quadrant abdominal pain. Urgent exploration is indicated, with cholecystectomy as the only treatment.

GALLSTONES (CHOLELITHIASIS)

Gallstones are the most common biliary pathology. It is estimated that gallstones affect 10–15% of the population in western societies. In the UK, the prevalence of gallstones at the time of death is estimated to be 17%. Gallstones are asymptomatic in the majority of cases (>80%). Approximately 1–2% per year will develop symptoms requiring surgery, making cholecystectomy one of the most common operations performed.

Causal factors

Gallstones can be divided into three main types: cholesterol, pigment (brown/black) and mixed stones. In the USA and Europe, 80% of gallstones are cholesterol or mixed stones, whereas in parts of Asia 80% are pigment stones. Cholesterol or mixed stones contain 50–99% pure cholesterol plus an admixture of calcium salts, bile acids, bile pigments and phospholipids.

Cholesterol is insoluble in water and is secreted from the canalicular membrane in phospholipid vesicles. Whether cholesterol remains in solution depends on the type and relative concentrations of phospholipids and bile acids in the bile. When bile is supersaturated with cholesterol and/or bile acid concentrations are low, unstable unilamellar phospholipid vesicles form, from which cholesterol crystals may nucleate. Obesity, a high-calorie diet and certain medications (e.g. oral contraceptives) can increase the secretion of cholesterol, while ileal disease or resection can deplete the bile acid pool and result in lithogenic bile (***Figure 71.25***). Nucleation of cholesterol monohydrate crystals from multilamellar vesicles is a crucial step in gallstone formation. Abnormal emptying of the gallbladder may aid the aggregation of nucleated cholesterol crystals; thus, removing gallstones without removing the gallbladder will inevitably lead to gallstone recurrence.

Pigment stones contain <30% cholesterol. Overall, 20–30% of pigment stones are black; the incidence rises with age. For reasons that are unclear, patients with cirrhosis have a higher incidence of pigment stones. Black pigment stones are composed largely of an insoluble bilirubin pigment polymer mixed with calcium phosphate and calcium bicarbonate. These stones are associated with haemolysis, as in hereditary spherocytosis and sickle cell disease.

Brown pigment stones contain calcium bilirubinate, calcium palmitate and calcium stearate, as well as cholesterol. Brown stones are more common in the bile ducts and are related to bile stasis and infection secondary to deconjugation of bilirubin glucuronide by bacterial β-glucuronidase. Insoluble unconjugated bilirubinate precipitates. Brown pigment stones are also associated with the presence of foreign bodies within the bile ducts, such as endoprostheses (stents) or parasites such as *Clonorchis sinensis* and *Ascaris lumbricoides*.

Clinical presentation

Gallstones are being increasingly detected incidentally during imaging for other symptoms. Prophylactic cholecystectomy is not usually indicated since the risk of developing serious complications is low. Longitudinal follow-up study of individuals with silent gallstones has shown that over 20 years only 18% developed biliary pain; the mean yearly probability was 2% during the first 5 years, 1% during the second 5 years and 0.5% during the third 5 years.

If symptoms occur, patients typically complain of right upper quadrant or epigastric pain, which may radiate to the back. This may be described as colicky but the typical biliary 'colic' more often is dull, continuous and severe, lasting for several minutes or even hours, with associated nausea and vomiting (***Chapter 63***). Frequently, pain starts during the night and wakes the patient; minor episodes may occur intermittently during the day. In the majority of cases the process is limited by the stone slipping back into the body of the gallbladder. The development of acute cholecystitis is marked by fever. Associated symptoms that have a questionable relation to gallstones include dyspepsia, flatulence, food intolerance, particularly to fats, and some alteration in bowel frequency. As pain resolves (spontaneously or with medications) the patient improves and is able to eat and drink again, often only to suffer further episodes. A patient may have several such episodes over a few weeks and then no symptoms for some months. This may culminate in a contracted non-functioning gallbladder with the

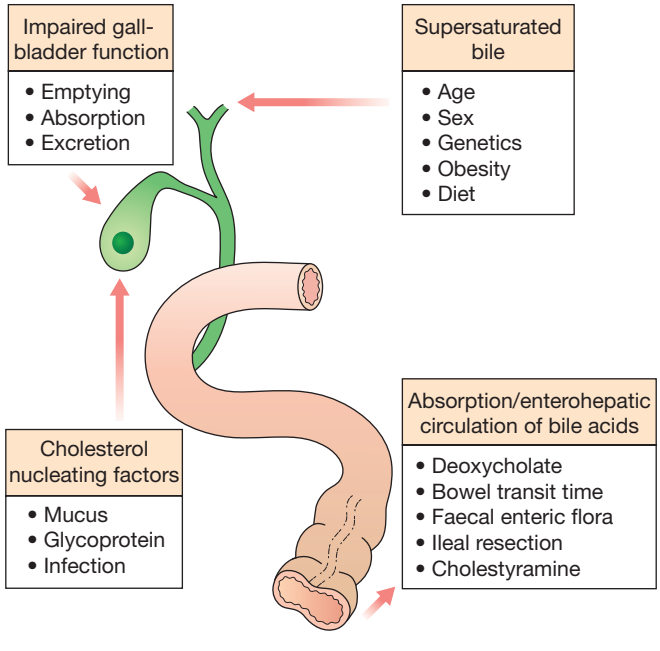

Figure 71.25 Factors associated with gallstone formation.

development of chronic cholecystitis. The differential diagnosis is given in ***Summary box 71.3***.

In acute cholecystitis the right upper quadrant tenderness is exacerbated during inspiration by palpation in the right subcostal region (Murphy's sign). A mass may become palpable as the omentum walls off an inflamed gallbladder. If resolution does not occur, empyema of the gallbladder may result. The wall may become necrotic and perforate, with the development of localised peritonitis (***Table 71.1***). Occasionally, complete obstruction of the cystic duct leads to reabsorption of bile salts by the gallbladder epithelium and secretion of uninfected mucus, resulting in a mucocele of the gallbladder.

Jaundice may ensue if the gallstone migrates from the gallbladder and obstructs or compresses the CBD (Mirizzi). Rarely, a large solitary gallstone may erode the gallbladder wall, causing a cholecystoduodenal fistula and subsequent bowel obstruction, known as gallstone ileus.

A palpable, non-tender gallbladder in the presence of jaundice may portend a more sinister diagnosis as a palpable gallbladder in the presence of jaundice is unlikely to be due to gallstones (Courvoisier) and usually results from a distal common duct obstruction secondary to periampullary malignancy.

Summary box 71.2

Effects and complications of gallstones

- Biliary colic
- Acute cholecystitis
- Chronic cholecystitis
- Empyema of the gallbladder
- Mucocele of the gallbladder
- Perforation of the gallbladder
- Biliary obstruction (jaundice)
- Acute cholangitis
- Acute pancreatitis
- Intestinal obstruction (gallstone ileus)

Summary box 71.3

Differential diagnosis of acute cholecystitis

Common

- Appendicitis
- Perforated peptic ulcer
- Acute pancreatitis

Uncommon

- Acute pyelonephritis
- Myocardial infarction
- Pneumonia – right lower lobe

Diagnosis

A clinical diagnosis of acute cholecystitis must be confirmed with radiological and laboratory investigations. USG is the first choice for imaging; however, the sensitivity and specificity of diagnosing acute cholecystitis is increased when combined with positive clinical and/or laboratory findings (***Table 71.1***).

TABLE 71.1 Tokyo Consensus Guidelines diagnostic criteria for acute cholecystitis.

A. Local signs of inflammation, etc.
   1) Murphy's sign
   2) Right upper quadrant pain/tenderness/mass

B. Systemic signs of inflammation, etc.
   1) Fever
   2) Elevated CRP
   3) Elevated WBC count

C. Imaging findings

Imaging findings characteristic of acute cholecystitis:

Suspected diagnosis: 1 item in A + 1 item in B

Definite diagnosis: 1 item in A + 1 item in B + C

CRP, C-reactive protein; WBC, white blood cell.

Treatment

Asymptomatic gallstones do not need intervention, however prophylactic cholecystectomy may be performed for asymptomatic cholelithiasis in the following situations:

- large (>3 cm) gallstones;
- choledocholithiasis;
- chronic haemolytic conditions (sickle cell disease, hereditary spherocytosis);
- gallbladder polyps >1 cm in diameter;
- suspicion/risk of malignancy (anomalous pancreatic ductal drainage);
- calcification of the wall (porcelain gallbladder);
- some ethnic groups or subjects living in areas with a high prevalence of gallbladder cancer associated with gallstones (some parts of northern India, Native Americans, Mexican Americans, Colombia, Chile, Bolivia);
- transplant patients (during transplantation);
- bariatric surgery.

For patients with symptomatic gallstones, cholecystectomy is the treatment of choice if there are no medical contraindications. The initial non-operative treatment is based on four steps:

1. Nil by mouth and intravenous fluid administration until the pain resolves.
2. Analgesics.
3. Antibiotics. As the cystic duct is blocked in most instances, the concentration of antibiotic in the serum is more important than the concentration in the bile. A broad-spectrum antibiotic effective against Gram-negative aerobes is most appropriate (e.g. cefazolin, cefuroxime or ciprofloxacin).
4. Subsequent management. When the temperature, pulse and other physical signs show that the inflammation is subsiding, oral fluids are reinstated, followed by a regular diet.

Ludwig Georg Courvoisier, 1843–1918, surgeon, Basel, Switzerland, made his observation in 1890. No mention was made of either gallbladder tenderness or malignancy.

USG is performed to confirm the diagnosis (***Table 71.1***). If jaundice with deranged ALP and enzyme levels is present, MRCP should be performed to exclude choledocholithiasis. If there is any concern regarding the diagnosis or the presence of complications such as perforation, CT should also be performed.

The timing of surgery in acute cholecystitis remains controversial. Early cholecystectomy, undertaken by an experienced surgeon with excellent operating facilities within 5–7 days of the onset of the attack, is safe and shortens total hospital stay. Nevertheless, the conversion rate in laparoscopic cholecystectomy is higher in acute than in elective surgery. If early operation is not indicated, one should wait approximately 6 weeks for the inflammation to subside before operating. The Tokyo Guidelines (2013/2018) allow the assessment of severity and grading of acute cholecystitis (***Table 71.2***) and provide a consensus-derived treatment algorithm based on grading, patient comorbidity and the facilities and expertise available (***Figure 71.26***).

TABLE 71.2 Tokyo Consensus Guidelines for severity grading of acute cholecystitis.

Grade III (severe) acute cholecystitis	
Associated with dysfunction of any one of the following organs/systems:	
1 Cardiovascular dysfunction	Hypotension requiring treatment with dopamine ≥5 μg/kg/min, or any dose of epinephrine
2 Neurological dysfunction	Decreased level of consciousness
3 Respiratory dysfunction	PaO_2/F_iO_2 ratio <300
4 Renal dysfunction	Oliguria; creatinine >2.0 mg/dL
5 Hepatic dysfunction	Prothrombin time (PT-INR) >1.5
6 Haematological dysfunction	Platelet count <100 000/mm^3
Grade II (moderate) acute cholecystitis	
Associated with any one of the following conditions:	
1 Elevated white cell count (>18 000/mm^3)	
2 Palpable tender mass in the right upper abdominal quadrant	
3 Duration of complaint >72 hours	
4 Marked local inflammation (gangrenous cholecystitis, pericholecystic abscess, hepatic abscess, biliary peritonitis, emphysematous cholecystitis)	
Grade I (mild) acute cholecystitis	
Does not meet the criteria of grade II or grade III acute cholecystitis. Grade I can also be defined as acute cholecystitis in a healthy person with no organ dysfunction and mild inflammatory changes in the gallbladder, making cholecystectomy a safe and low-risk operative procedure	

PaO_2/F_iO_2 ratio is the ratio of arterial oxygen partial pressure (PaO_2 in mmHg) to fractional inspired oxygen (F_iO_2) expressed as a fraction (not a percentage) at sea level, the normal PaO_2/F_iO_2 ratio is ~400–500 mmHg (~55–65 kPa); PT-INR, prothrombin time–international normalised ratio.

Reproduced with permission from Yokoe M *et al*. Tokyo Guidelines 2018: diagnostic criteria and severity grading of acute cholecystitis (with videos). *J Hepatobiliary Pancreat Sci* 2018; **25**(1) 41–54.

Acalculous cholecystitis

Acute and chronic inflammation of the gallbladder can occur in the absence of stones and give rise to a clinical picture similar to that of calculous cholecystitis. Some patients have non-specific inflammation of the gallbladder, whereas others have one of the cholecystoses. Acute acalculous cholecystitis is particularly seen in critically ill patients and those recovering from major surgery, trauma and burns. The diagnosis is often missed and the mortality rate is high. The treatment is cholecystectomy for patients who are able to tolerate surgery. In selected patients, non-surgical treatment (such as antibiotics or percutaneous cholecystostomy) may be an effective alternative to surgery.

CHOLECYSTOSES (CHOLESTEROLOSIS, POLYPOSIS, ADENOMYOMATOSIS AND CHOLECYSTITIS GLANDULARIS PROLIFERANS)

This is a relatively uncommon group of conditions affecting the gallbladder, in which there are chronic inflammatory changes with hyperplasia of all tissue elements.

Cholesterolosis ('strawberry gallbladder')

Cholesterolosis (cholesterosis) is characterised by the accumulation of lipids (triglycerides, cholesterol precursors and cholesterol esters) in the mucosa of the gallbladder wall. These nodules are less than 1 mm in diameter in about two-thirds of cases, which gives the mucosa a coarse and granular appearance. The nodules in the remaining one-third of cases are larger and polypoid in appearance (polypoid form). The lipid accumulation creates yellow deposits on a background of hyperaemic mucosa ('strawberry gallbladder'). It may be associated with cholesterol stones (***Figure 71.27***).

Cholesterol polyposis of the gallbladder

USG may show a non-mobile defect in the gallbladder lumen with no acoustic shadow. The differential is an adenomatous polyp, and interval follow-up is indicated to ensure stability. Surgery is advised only if there is a diagnostic dilemma.

Cholecystitis glandularis proliferans (adenomyomatosis)

Adenomyomatosis is an abnormality of the gallbladder characterised by overgrowth of the mucosa and thickening of the muscle wall, leading to cyst-like structures in the gallbladder wall or polypoid projections from the mucosa of the gallbladder and intramural diverticulae (*diffuse* adenomyomatosis). While generally not considered to be a premalignant condition, there is a clear association of adenomyomatosis with cholelithiasis.

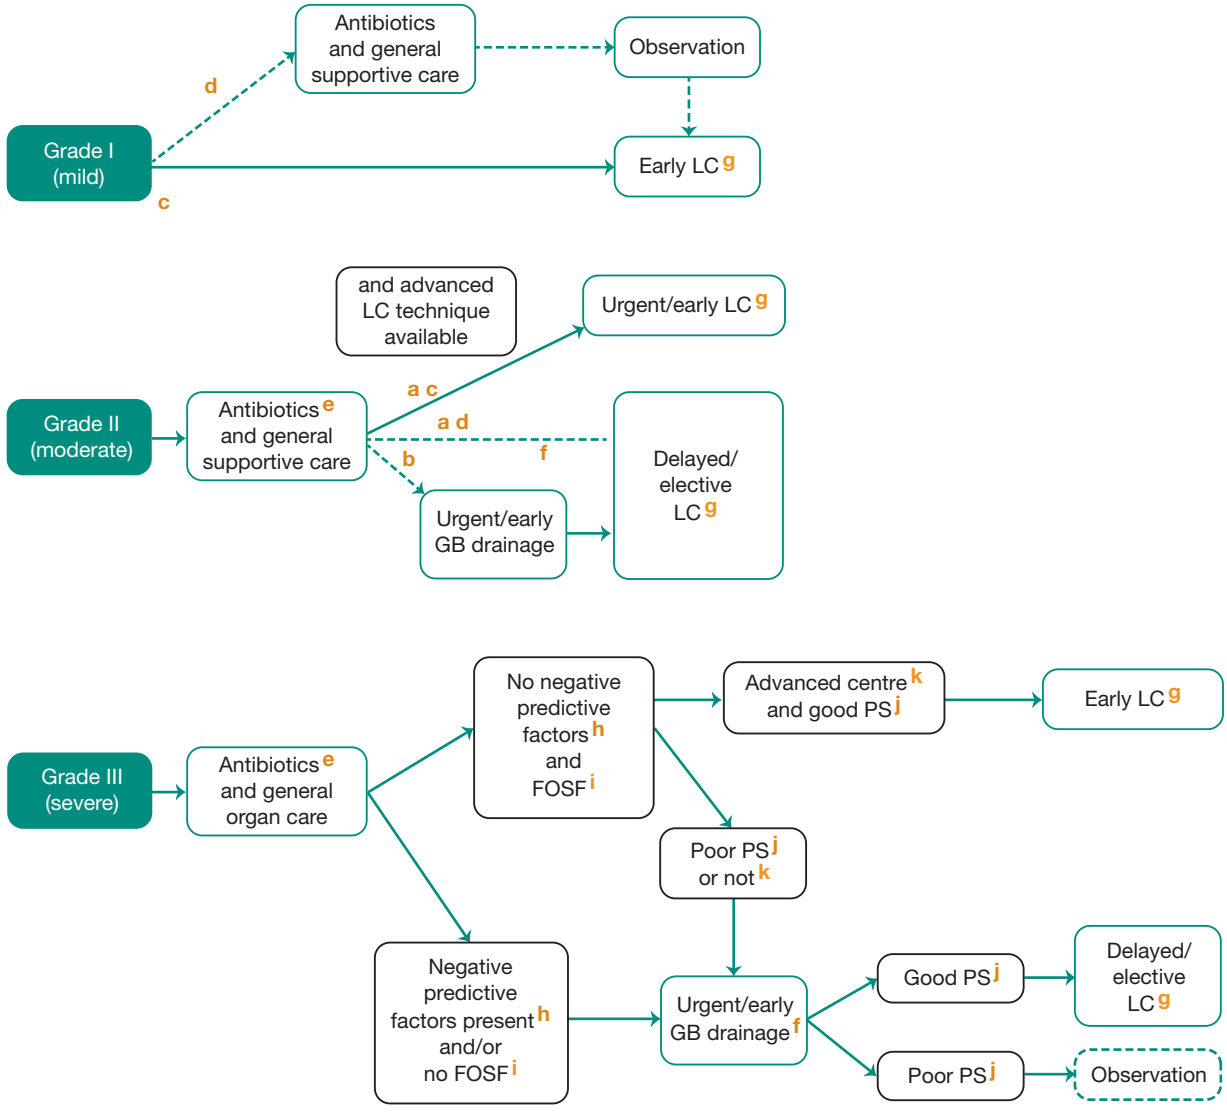

Figure 71.26 Tokyo Guidelines for the management of acute cholecystitis. [a]Antibiotics and general supportive care successful. [b]Antibiotics and general supportive care fail to control inflammation. [c]CCI 5 or less and/or ASA-PS class II or less (low risk). [d]CCI 6 or greater and/or ASA-PS class III or greater (not low risk). [e]Blood culture should be taken before initiation of administration of antibiotics. [f]A bile culture should be performed during GB drainage. [g]In cases of serious operative difficulty, bail-out procedures including conversion should be considered. [h]Negative predictive factors: jaundice (TBil ≥2 mg/dL), neurological dysfunction, respiratory dysfunction. [i]FOSF: favourable organ system failure = rapidly reversible after admission and before early LC. [j]CCI 4 or greater, ASA-PS 3 or greater are high risk. [k]Advanced centre = intensive care and advanced laparoscopic techniques are available. ASA-PS, American Society of Anesthesiologists physical status; CCI, Charlson comorbidity index; GB, gallbladder; LC, laparoscopic cholecystectomy; PS, performance status; TBil, total bilirubin. (Reproduced with permission from Okamoto K *et al*. Tokyo Guidelines 2018: flowchart for the management of acute cholecystitis. *J Hepatobiliary Pancreat Sci* 2018; **25**(1): 55–72.)

These can be complicated by intramural, and later extramural, abscess and potentially fistula formation. If symptomatic, the patient is treated by cholecystectomy (***Figure 71.28***).

Diverticulosis of the gallbladder

Diverticulosis of the gallbladder is usually manifest as black pigment stones impacted in the outpouchings of the lacunae of Luschka. This may be demonstrated by cholecystography, especially when the gallbladder contracts after a fatty meal. There are small dots of contrast medium within and outside the gallbladder wall (***Figure 71.29***). The treatment is cholecystectomy.

Typhoid infection of the gallbladder

Salmonella Typhi or *Salmonella* Typhimurium can infect the gallbladder. Acute or, more frequently, chronic cholecystitis

Mary E Charlson, contemporary, Clinical Epidemiologist, Weill Cornell Medical Center, New York, NY, USA.
Daniel Elmer Salmon, 1850–1914, veterinary pathologist, Chief of the Bureau of Animal Industry, Washington, DC, USA.

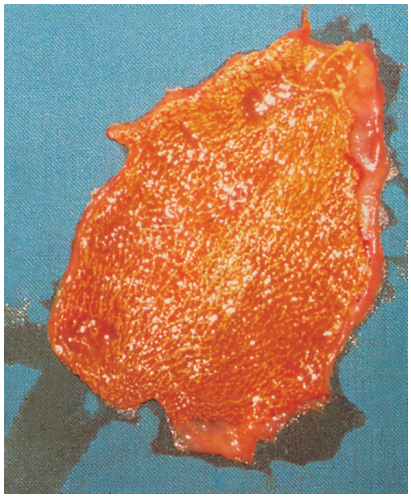

Figure 71.27 The interior of a strawberry gallbladder (cholesterosis) (courtesy of Dr Sanjay P Thakur, Patna, India).

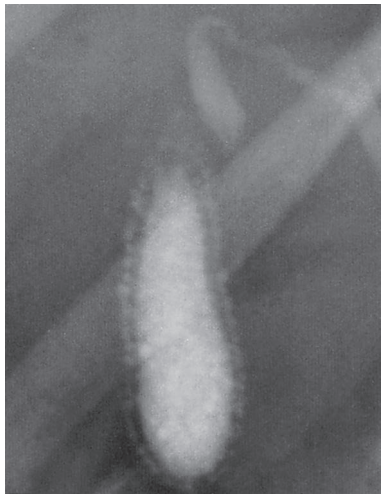

Figure 71.29 Cholecystogram showing diverticulosis with dots of contrast medium in the gallbladder wall.

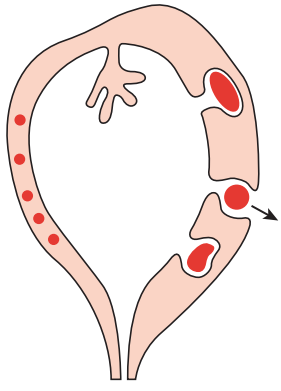

Figure 71.28 Types of cholecystitis glandularis proliferans (polyps, intramural or diverticular stones and fistula).

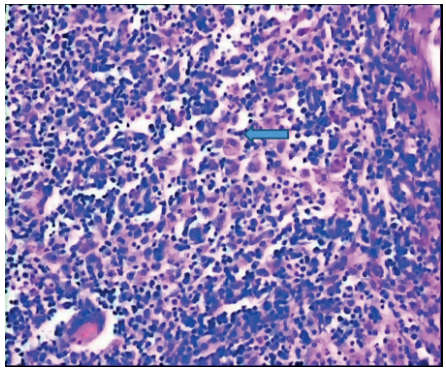

Figure 71.30 Xanthogranulomatous cholecystitis. Infiltrates in the wall of the gallbladder show foamy macrophages (arrow), giant cells and lymphoplasma cells in the background (courtesy of Dr Amita Joshi, Mumbai, India).

occurs, with the patient becoming a typhoid carrier excreting the bacteria in the bile. Gallstones may be present (surgeons should not give patients their stones after their operation if there is any suspicion of typhoid). It is debatable whether the stones are secondary to the *Salmonella* cholecystitis or whether pre-existing stones predispose the gallbladder to chronic infection. Treatment with ampicillin and cholecystectomy are indicated. In the case of penicillin allergy, a quinolone antibiotic can be used.

Gallbladder polyps

Polyps of the gallbladder are incidental findings during radiological imaging of the abdomen. The polyps are more often benign (cholesterol polyps, adenomyomas, inflammatory, adenomas or miscellaneous) but may be malignant (adenocarcinoma [80%] or squamous cell carcinoma, or cystadenomas).

A majority of polyps remain stable. Cholecystectomy should be considered in symptomatic patients or as prophylaxis to prevent malignant transformation in those who also have gallstones, primary sclerosing cholangitis (PSC), biliary colic or pancreatitis. Polyps in patients older than 50 years, sessile polyps with wall thickening greater than 4 mm and polyps larger than 10 mm merit cholecystectomy. Smaller polyps should be kept under observation and need surgery if the size is increasing.

Xanthogranulomatous cholecystitis

Xanthogranulomatous cholecystitis (***Figure 71.30***) is an uncommon inflammation of the gallbladder, more frequently seen in India and Japan. It is more common in females. It is caused by extravasation of bile into the gallbladder wall from rupture of the Rokitansky–Aschoff sinuses or by mucosal ulceration as a result of a focal or diffuse destructive inflammatory process, with accumulation of lipid-laden macrophages (xanthoma cells), fibrous tissue and acute and chronic inflammatory cells. USG shows gallbladder wall

Carl Freiherr von Rokitansky, 1804–1878, pathologist, Vienna, Austria.
Karl Albert Ludwig Aschoff, 1866–1942, pathologist, Freiburg, Germany.

thickening (diffuse or focal, with intact mucosal lining), intramural hypoechoic nodules or bands and often the presence of gallstones. CT shows 5- to 20-mm intramural hypoattenuating nodules and poor/heterogeneous contrast enhancement. As with acute cholecystitis, early enhancement of the adjacent liver parenchyma may occur. Extension into the liver along with enlarged hepatoduodenal lymph nodes closely mimics gallbladder carcinoma. Diagnosis is difficult and depends on pathological examination. Intraoperatively, frozen-section examination should be carried out to differentiate xanthogranulomatous cholecystitis from carcinoma of the gallbladder (coexistence of gallbladder cancer 2.3–13.3%). Because of diagnostic difficulties if there is preoperative suspicion of xanthogranulomatous cholecystitis open cholecystectomy should be considered.

Gallstones in pregnancy

Acute cholecystitis is the second most common non-obstetric indication for surgery in pregnant women. Hormonal (oestrogen) changes during pregnancy increase cholesterol secretion and progesterone reduces bile acid secretion, reducing the ability of bile to solubilise cholesterol; bile becomes supersaturated with cholesterol. Progesterone also slows gallbladder emptying, which further promotes the formation of stones owing to bile stasis. Prepregnancy obesity, multiparity, increasing age and genetic predisposition are risk factors.

Acute right upper quadrant/epigastric pain in pregnancy may be due to severe pre-eclampsia and the HELLP syndrome (haemolysis, elevated liver enzymes, low platelet count), acute fatty liver, abruptio placentae, uterine rupture or intra-amniotic infection. USG and non-contrast MRI are acceptable diagnostic modalities.

For women in their first trimester, the mainstay of treatment for mild cases is conservative. Non-steroidal anti-inflammatory drugs are effective analgesics but are generally avoided in pregnancy, especially after 32 weeks of gestation, because of potential adverse fetal effects, e.g. premature closure of the ductus arteriosus.

In the second trimester, with moderate or severe disease, good surgical candidates (American Society of Anesthesiologists [ASA] I or II) should undergo cholecystectomy during their initial hospitalisation as there is a high risk of recurrence or serious complications. In the third trimester, non-operative medical management with antibiotics and fluid therapy should be initiated. The patient should be re-evaluated after delivery. Generally, a waiting period of 6 weeks following delivery is preferred to allow the mother to recover from the delivery, bond with the infant and regain her strength.

Gallstone ileus

Gallstone ileus is an infrequent complication (0.4%) of cholelithiasis, occurring as a result of impaction of one or more gallstones within the gastrointestinal tract. It is seen more frequently in the elderly and in women. Frequently an episode of acute cholecystitis leads to erosion of inflamed tissues, resulting in a cholecystointestinal fistula.

A majority of small gallstones pass through the intestines spontaneously. However, gallstones of size 2–5 cm get impacted, usually in the terminal ileum or at the ileocecal valve owing to the relatively narrow lumen and less active peristalsis here. Less common locations include the stomach and the duodenum (Bouveret's syndrome). Impacted stones may lead to necrosis and perforation followed by peritonitis.

Clinical manifestations include acute, intermittent or chronic episodes of partial or complete gastrointestinal obstruction. Physical examination may be non-specific or may show signs of obstruction: dehydration, abdominal distension and tenderness, with high-pitched bowel sounds, and obstructive jaundice. A plain abdominal radiograph shows:

- partial or complete intestinal obstruction;[a]
- pneumobilia or contrast material in the biliary tree;[a]
- an aberrant rim-calcified or total-calcified gallstone;[a]
- a change in the position of such a gallstone on serial films ('tumbling sign').

CT is considered superior to plain radiographs or USG, with a sensitivity of up to 93%. It additionally shows an abnormal gallbladder with air, an air–fluid level or fluid accumulation with an irregular wall.

In addition to the management of intestinal obstruction, enterolithotomy has been the most common surgical procedure performed. A longitudinal incision is made on the antimesenteric border proximal to the site of gallstone impaction, and the gallstone is brought proximally to a non-oedematous segment of the bowel by gentle manipulation and extracted. A cholecystoenteric fistula should not be resected unless the patient is stable and there are residual gallstones that may cause infection or recurrent ileus (see ***Chapter 78***).

CHOLECYSTECTOMY

Preparation for operation

After appropriate history taking and assessment of the patient's fitness for the procedure, routine laboratory investigations including a coagulation screen and liver function tests should be checked. The patient must sign a consent form to indicate that he or she is fully aware of the procedure being undertaken, the alternative options and the risks involved including complications that may occur. Prophylactic antibiotics should be administered at the time of induction of anaesthesia. A second-generation cephalosporin is appropriate. Subcutaneous heparin and antiembolic stockings should be prescribed (***Summary box 71.4***).

The various factors identified as predictors of difficult cholecystectomy are listed in ***Table 71.3***, and the risk factors for the presence of CBD stones are listed in ***Table 71.4***.

Leon Bouveret, 1850–1929, physician, Lyon, France.

[a]These three constitute Rigler's triad.

Leo George Rigler, 1896–1979, Professor of Radiology, University of California, Los Angeles, CA, USA.

Summary box 71.4

Preparation for cholecystectomy

- Appropriate history taking (jaundice) and assessment
- Full blood count
- Renal and liver function tests
- Prothrombin time
- Chest radiograph and electrocardiogram (if medically indicated)
- Antibiotic prophylaxis, second-generation cephalosporin at the time of induction
- Deep vein thrombosis prophylaxis
- Informed consent: patient is aware of the procedure being undertaken, the alternative options and the risks involved

TABLE 71.3 Risk factors of difficult cholecystectomy.

History
Male gender, >65 years, interval between onset and presentation (>72–96 hours) in acute cholecystitis, previous multiple attacks, previous upper abdominal surgery, prior attempt at cholecystectomy (cholecystostomy)
Physical examination
Morbid obesity, high ASA score
Laboratory tests
Abnormal liver function tests
Imaging (USG/CT/MRI–MRCP)
Thick-walled gallbladder (>4–5 mm) Contracted gallbladder Distended gallbladder with impacted stone in the neck Gangrenous gallbladder/gallbladder perforation Mirizzi's syndrome/cholecystoenteric fistula Cirrhosis/extrahepatic portal vein obstruction (portal cavernoma) with portal hypertension
Intraoperative
Shrunken gallbladder, liver edge retracted with fissure/depression/puckering near the fundus, fatty/firm cirrhotic liver (difficulty in retraction)

ASA, American Society of Anesthesiologists; CT, computed tomography; MRCP, magnetic resonance cholangiopancreatography; MRI, magnetic resonance imaging; USG, ultrasonography.

TABLE 71.4 Risk factors for common bile duct (CBD) stones.

Risk of CBD stones	History of cholangitis or pancreatitis	Liver function tests	Abdominal USG: CBD diameter	Further evaluation required
Low, 2–3%	Absent	Normal	≤6 mm	None
Medium, 20–40%	Present	2× normal	8–10 mm	MRCP +/– ERCP stone extraction
High, 50–80%	Present, with jaundice	2× normal	≥10 mm	MRCP +/– ERCP stone extraction

ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; USG, ultrasonography.

Laparoscopic cholecystectomy

Laparoscopic cholecystectomy is the procedure of choice for the majority of patients. The indications and preparation for cholecystectomy are the same whether it is performed by laparoscopy or by open technique.

The patient is placed supine on the operating table. Following induction and maintenance of general anaesthesia, the abdomen is prepared in a standard fashion. Pneumoperitoneum is established. The authors' preference is to use an open subumbilical cut down with direct visualisation of the peritoneum to place the initial port. This port will function as the camera port. An angled telescope (30°) is preferred. Many surgeons prefer a 'closed' technique using a Verres needle to establish pneumoperitoneum (see ***Chapter 7***). Recently, single-port laparoscopic cholecystectomy has been described. Proponents report decreased postoperative pain and improved cosmesis. However, systematic reviews have reported a higher failure rate, longer operative time and increased blood loss without any substantive benefits with the technique.

Additional operating ports are inserted in the subxiphoid area and in the right subcostal area. The patient is placed in a reverse Trendelburg position slightly rotated to the left. This exposes the fundus of the gallbladder, which is retracted towards the diaphragm. The neck of the gallbladder is then retracted towards the right iliac fossa, exposing Calot's triangle. The key, as in open surgery, is the identification and safe dissection of Calot's triangle (***Table 71.5***). This area is laid wide open by dividing the peritoneum on the posterior and anterior aspects. The cystic duct is carefully defined, as is the cystic artery. The gallbladder is separated from the liver bed for about 2 cm to allow confirmation of the anatomy. Unless there are specific indications, routine cholangiogram is not performed. However, if doubt exists regarding the anatomy, cholangiogram is warranted. Real-time intraoperative imaging using indocyanine green (ICG) fluorescence cholangiography (with special scopes and imaging system) improves visualisation of the biliary tree during laparoscopic cholecystectomy and enables better visualisation and identification of the biliary tree. It can be considered a means of increasing the safety of laparoscopic cholecystectomy. This is likely to reduce risk of biliary duct injury. Once the anatomy is clearly defined and the triangle of Calot has been laid wide open, the cystic duct and artery are clipped and divided. The gallbladder is then removed from its bed by sharp or cautery dissection and, once free, removed via the umbilicus in a retrieval bag.

Open cholecystectomy

For patients in whom a laparoscopic approach is not indicated or in whom conversion from a laparoscopic approach is required, open cholecystectomy is performed.

Janos Verres, 1903–1979, chest physician and chief of the Department of Internal Medicine, The Regional Hospital, Kapuvar, Hungary.

TABLE 71.5 Important operative steps during cholecystectomy.

Operative steps	Purpose
Retraction (*Figure 71.31a*) Proper retraction in the correct direction: the fundus is retracted towards the patient's right shoulder and the infundibulum is retracted inferolaterally towards the patient's right side	• Opens the hepatocystic triangle • Increases the angle between the cystic duct and the CBD • Limits the dissection above Rouvière's sulcus • Mental and spatial orientation of the anatomy, variation and landmarks
Look out for red flag signs • Failure of timely progression of the dissection • Anatomical disorientation • Difficulty in visualisation of the operative field	**Time out** The surgeon should recognise these clues, stop dissection and decide on the strategy for safe operation before proceeding **Do not hesitate to seek a second opinion**
Achieve CVS (*Figure 71.31b*) Clearance of the hepatocystic triangle of all fibrofatty and soft areolar tissue to see **only 2 structures enter the gallbladder** (cystic artery and duct) **Exposure of the cystic plate** (*Figure 71.31c*) This is done by separating the gallbladder from its liver bed to expose at least the medial third of the cystic plate	Difficulty achieving CVS is a **warning** • Further dissection may be hazardous, with an increased risk of biliary and/or vascular injury • **Stop and reconfirm** (with the team/second surgeon) that CVS has been achieved May be documented by photographs and/or video recordings
Separate the gallbladder from the fossa This is done by leaving the cystic plate attached to liver	To avoid bleeding from the liver sinuses and bile leak

CBD, common bile duct; CVS, critical view of safety.

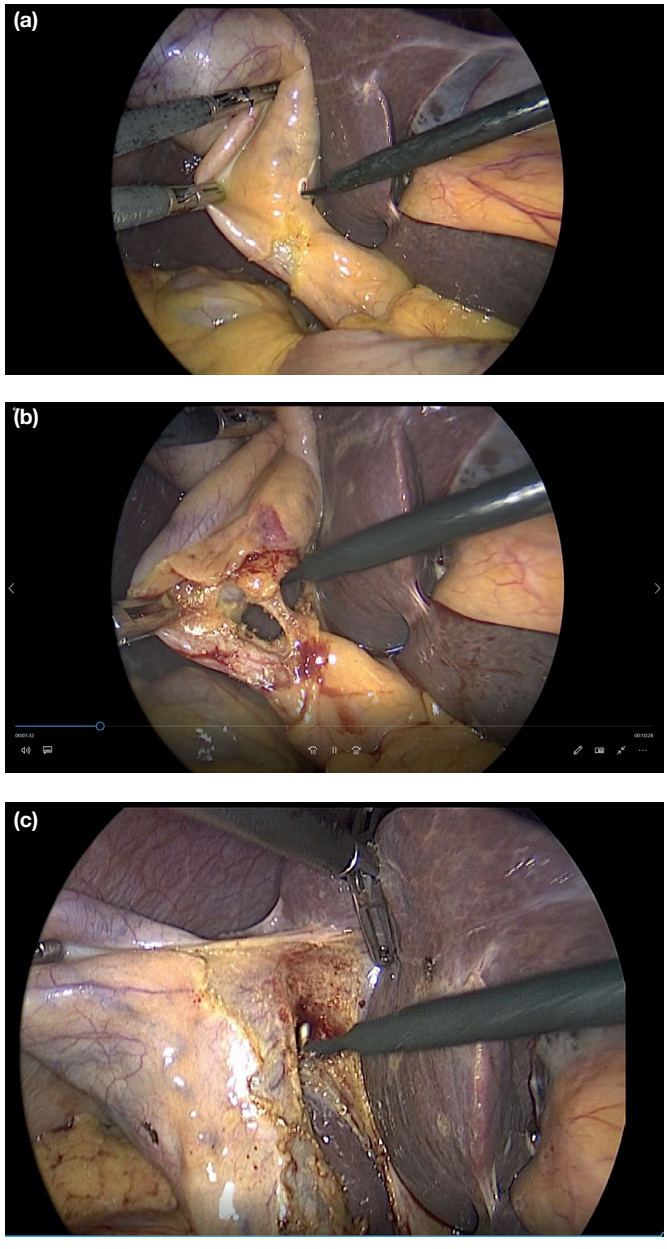

Figure 71.31 (a–c) Operative images of laparoscopic cholecystectomy. See ***Table 71.5*** for the important steps during operation (courtesy of Dr Sameer Rege, Mumbai, India).

An upper midline, short subcostal (Kocher) or right upper transverse incision is made, centred over the lateral border of the rectus muscle. The gallbladder is appropriately exposed and packs are placed on the hepatic flexure of the colon, the duodenum and the lesser omentum to ensure a clear view of the anatomy of the porta hepatis. These packs may be retracted by the assistant's hand ('It is the left hand of the assistant that does all the work' – Moynihan).

An artery or Duval forceps is placed on the infundibulum of the gallbladder and the peritoneum overlying Calot's triangle is placed on a stretch. The peritoneum is then divided close to the wall of the gallbladder and the fat in the triangle of Calot carefully dissected away to expose the cystic artery and the cystic duct. The cystic duct is cleaned down to the CBD, whose position is clearly ascertained. The cystic artery is tied and divided. The whole of the triangle of Calot is displayed to ensure that the anatomy of the ducts is clear and the cystic duct is then divided between ligatures (***Figure 71.32***). The gallbladder is then dissected away from its bed.

Tenets for safe cholecystectomy (*Table 71.5*)

Safe zone of dissection

The safe zone of dissection lies cephalad to a line extending from the roof of Rouvière's sulcus to the umbilical fissure across the base of segment IV (R4U line). The operating surgeon tends to zoom the laparoscope closer to the surgical field to get a better view during difficulty, but this results in

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Bern, Switzerland, first surgeon to win the Nobel Prize in Physiology or Medicine (1909) for his work on the physiology and surgery of the thyroid gland.
Pierre Alfred Duval, 1874–1941, Professor of Surgery, Paris, France

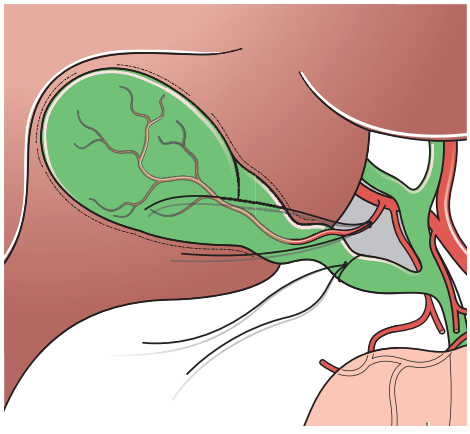

Figure 71.32 Ligatures are passed and tied around the cystic artery and cystic duct. The grey shaded area represents Calot's triangle.

non-visualisation of the normal clues/landmarks necessary for correct orientation. Dissection on the posterior aspect of the hepatocystic triangle can be safely started immediately ventral and cephalad to the sulcus. The **B-SAFE method** uses five anatomical landmarks (B, bile duct; S, sulcus of Rouvière; A, hepatic artery; F, umbilical fissure; E, enteric/duodenum) to correctly place a cognitive map during dissection.

Concept of 'time out'

During difficult gallbladder surgery, the surgeon may become disoriented and enter the zone of danger. To avoid this, the concept of time out has been introduced as it serves as a procedural cognitive aid to recall and apply essential safety measures.

Judicious use of energy sources

With a monopolar energy device (mostly hook cautery), it is important to:

- keep a low setting (approximately 30 W) to avoid arcing of the current to the bile duct;
- divide small amounts of the tissue at a time after a gentle pull to avoid injury to the deeper structures by the heel of the cautery hook;
- use intermittent short bursts of current at intervals to avoid thermal lateral spread;
- avoid blind use of cautery in brisk bleeding.

Lateral thermal spread occurs less with an ultrasonic energy source, but it may be cumbersome to use the long and straight jaws to dissect in the hepatocystic triangle.

Concept of the critical view of safety

The aim of the CVS is the conclusive identification of the cystic duct and cystic artery to avoid misidentification injury.

'Stopping rules'

With the help of red flag signs (severe adhesions, severe acute inflammation, large impacted stone in the neck of the gallbladder, Mirizzi syndrome, chronic inflammation with fibrosis or scarring), the operating surgeon should be able to identify or pre-empt difficult situations that increase the risk of biliary/vascular injury and to stop in time.

Call for help/second opinion

The operating surgeon should not hesitate to seek a second opinion whenever needed, and this should be considered a sign of good clinical practice rather than of surgical ineptitude.

Bailout techniques/strategies

The primary aim is the safety of the patient from biliary/vascular injury. It is important to perform an alternative procedure (bailout technique) that allows the surgeon to complete the operation in a safe manner. There are five bailout strategies:

1. abort the procedure altogether;
2. convert to an open procedure;
3. carry out a tube cholecystostomy using a 14 Fr Foley catheter (a simple procedure to provide symptomatic relief until a definitive procedure can be performed);
4. carry out a subtotal cholecystectomy (open/laparoscopic): leaving behind a part of the gallbladder is safer than a difficult dissection in the hepatocystic triangle with a potential for bile duct injury in an attempt to remove the entire gallbladder;
5. fundus-first approach.

The choice of bailout procedure depends on the clinical situation and the experience/expertise of the surgeon. Conversion to open cholecystectomy should be 'by choice' at an early stage in a difficult cholecystectomy, e.g. the anatomy is not clear, the pathology is too difficult or no progress is being made, rather than the surgeon having to convert because of a complication, e.g. bleeding or bile duct injury.

Complications of cholecystectomy

Recovery after laparoscopic cholecystectomy is associated with less pain and faster return to normal activity than open cholecystectomy. The majority of elective patients can have this performed as a day case; however, any patient looking unwell in the postoperative period, with untoward symptoms such as fever, chills or abdominal pain, should be kept under observation.

Complications can occur in 10–15% of cases. Serious complications fall into two major areas: access complications and bile duct injuries. The latter are rare, occurring in approximately 0.5% following laparoscopic cholecystectomy. In the main, biliary injury results from poor dissection and a failure to define the surgical anatomy adequately. Controversy exists as to whether operative cholangiography reduces the incidence of bile duct injury. The majority of surgeons use cholangiography only in selected cases. The operative mortality for cholecystectomy is less than 1%. Factors increasing the risk for postoperative mortality include advanced age, comorbid conditions and an acute presentation.

Patients who develop jaundice in the postoperative period need urgent investigation. This is especially true if the jaundice

Frederic Eugene Basil Foley, 1891–1965, urologist, The Miller and Anker Hospitals, St. Paul, MN, USA.

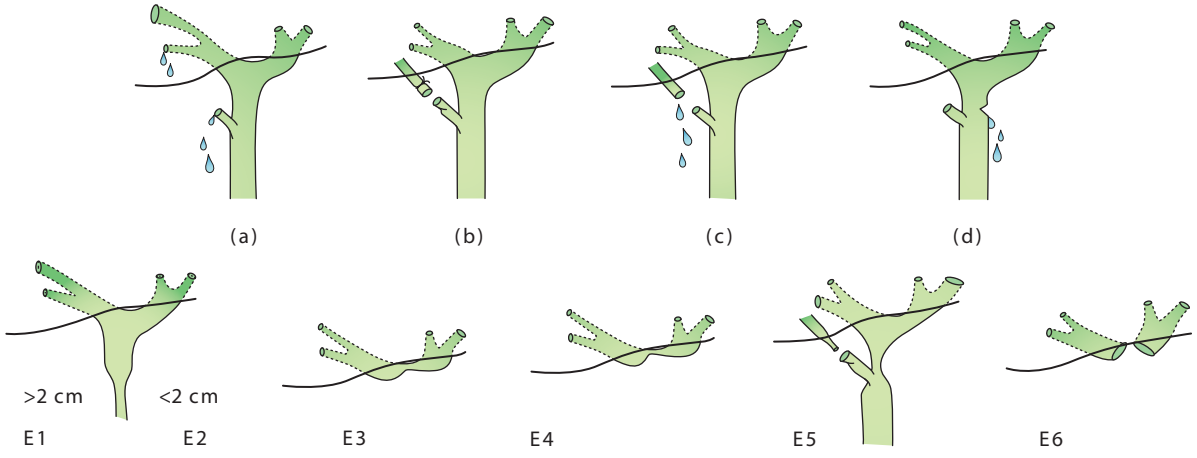

Figure 71.33 Schematic representation of the Strasberg classification of bile duct injuries. **(a)** A bile leak from the cystic duct stump or minor biliary radical in the gallbladder fossa. **(b)** An occluded right posterior sectoral duct. **(c)** A bile leak from the divided right posterior sectoral duct. **(d)** A bile leak from the main bile duct without any major tissue loss. **E1**, transected main bile duct with a stricture more than 2 cm from the hilus. **E2**, transected main bile duct with a stricture less than 2 cm from the hilus. **E3**, stricture of the hilus with the right and left ducts in communication. **E4**, stricture of the hilus with separation of the right and left hepatic ducts. **E5**, stricture involving the right aberrant sectoral duct and the main bile duct. **E6**, complete excision of the extrahepatic ducts involving the confluence (this injury is not described in Strasberg's classification). (After Connor S, Garden OJ. Bile duct injury in the era of laparoscopic cholecystectomy. *Br J Surg* 2006; **93**(2): 158–68.)

is attributed to infection and cholangitis. The first step following resuscitation and administration of appropriate antibiotics is to undertake urgent USG. This will demonstrate whether there is intra- or extrahepatic ductal dilatation. The anatomy may need to be defined by MRCP or ERCP. The latter is undertaken when therapeutic manoeuvres are planned, such as the removal of an obstructing stone or the insertion of a stent across a biliary leak. If a fluid collection is present in the subhepatic space, drainage catheters may be required. These can be inserted under radiological control or, if this expertise is not available, at open operation. Small biliary leaks will usually resolve spontaneously, especially if there is no distal obstruction. If the CBD is damaged, the patient should be referred to an appropriate expert for reconstruction.

Bile duct injuries

About 15% of injuries to the bile ducts are recognised at the time of operation; in the remainder, the injury declares itself postoperatively either by profuse and persistent leakage of bile (if drainage has been provided; bile peritonitis if no drainage provided) or by deepening obstructive jaundice. When the obstruction is incomplete, jaundice is delayed until subsequent fibrosis renders the lumen of the duct inadequate.

Any postoperative elevation in the serum bilirubin or suggestion of duct damage requires investigation to determine the nature of the injury. Abdominal USG may show collections, dilatation of the CBD and any associated vascular lesions. Abdominal CT defines the presence of focal fluid collections, ascites, biliary obstruction with an upstream dilatation in the acute phase or long-term sequelae of longstanding bile stricture, such as hepatic atrophy or signs of secondary biliary cirrhosis. CT may identify an associated vascular injury, such as to the right hepatic artery.

MRCP is the 'gold standard' for complete morphological evaluation of the biliary tree as it offers detailed information about the integrity of the biliary tract. It is helpful in determining the level and degree of injury. MRCP with magnetic resonance angiography is more informative as it may identify associated vascular injuries.

A HIDA scan can confirm the presence of a bile leak or biliary obstruction. If available, ERCP should be considered because this is diagnostic of a bile leak, demonstrates ductal continuity, detects the site and type of injury, identifies residual/retained CBD stones and is potentially therapeutic. The most common bile leak following cholecystectomy is from the cystic duct. This can be treated by placing a biliary endoprosthesis (stent) in the CBD across the origin of the cystic duct.

Surgical repair and the subsequent outcome are related to the level and degree of injury, in conjunction with the presence or absence of concomitant vascular injury. A number of classification systems have been proposed, with the Strasberg classification being commonly used (***Figure 71.33***).

In a debilitated patient, temporary external biliary drainage may be achieved by passing a catheter percutaneously into an intrahepatic duct. Also, stents may be passed through strictures at the time of ERCP and left to drain into the duodenum. When the general condition of the patient improves, definitive surgery can be undertaken. The principles of surgical repair are the maintenance of the duct length and the restoration of biliary drainage. For a stricture of recent onset through which a guidewire can be passed, balloon dilatation with insertion of a stent is an acceptable option, provided the services of an experienced endoscopist are available. For benign stricture or duct transection, the preferred treatment is a Roux-en-Y hepaticojejunostomy performed by an experienced hepatobiliary surgeon. Biliary reconstruction in the presence of peritonitis, combined vascular and bile duct injuries and injury at or above

the level of the biliary bifurcation are significant predictors of poor surgical outcome. The long-term impact of bile duct injury is a significant decrease in the patient's quality of life and work-related limitations.

Late symptoms after cholecystectomy

In up to 15% of patients, cholecystectomy fails to relieve the symptoms for which the operation was performed. Such patients may be considered to have a 'postcholecystectomy' syndrome. In most such cases, this is merely a continuation of earlier symptoms. A detailed history with full investigation should be undertaken to confirm the diagnosis and exclude the presence of a stone in the bile duct, a stone in the cystic duct stump or operative damage to the biliary tree. This is best performed by MRCP or ERCP, the latter having the advantage that a stone in the CBD can be removed.

Postcholecystectomy choledocholithiasis

Any obstruction to the flow of bile can give rise to stasis, with the formation of stones within the duct. Duct stones may be detected many years after cholecystectomy and may also be related to the development of new pathology, such as infection of the biliary tree or infestation by *Ascaris lumbricoides* or *Clonorchis sinensis*. The consequence of duct stones is either obstruction to bile flow or infection. Stones in the bile ducts are more often (80%) associated with infected bile than with stones in the gallbladder.

Symptoms

The individual may be asymptomatic; symptomatic patients with cholangitis have bouts of pain, jaundice and fever ('Charcot's triad').

Signs

Febrile, icteric tenderness may be elicited in the epigastrium and right hypochondrium.

Management

It is essential to confirm that the jaundice is due to duct obstruction. Liver function tests and USG are the initial tests, and MRCP will identify the nature of the obstruction.

Pus may be present within the biliary tree and liver abscesses may develop. Measures required include rehydration, attention to clotting, exclusion of diabetes and the administration of appropriate broad-spectrum antibiotics. Once resuscitation has taken place, relief of the obstruction is essential. Endoscopic papillotomy/sphincterotomy is the preferred technique, followed by removal of the stones using a Dormia basket or placement of a stent or a nasobiliary drain for flushing if stone removal is not possible (***Figures 71.34 and 71.35***). If this fails, PTC drainage can be done, with subsequent percutaneous choledochoscopy. Surgery, in the form of choledochotomy, is now rarely used for this situation as most patients can be managed by minimally invasive techniques.

Choledochotomy

When faced with a patient with cholangitis due to stones in the CBD, and minimally invasive techniques for stone extraction are not possible, the surgeon must undertake laparotomy, drain the CBD and remove the stones through a longitudinal incision in the duct. When the duct is clear of stones, on-table

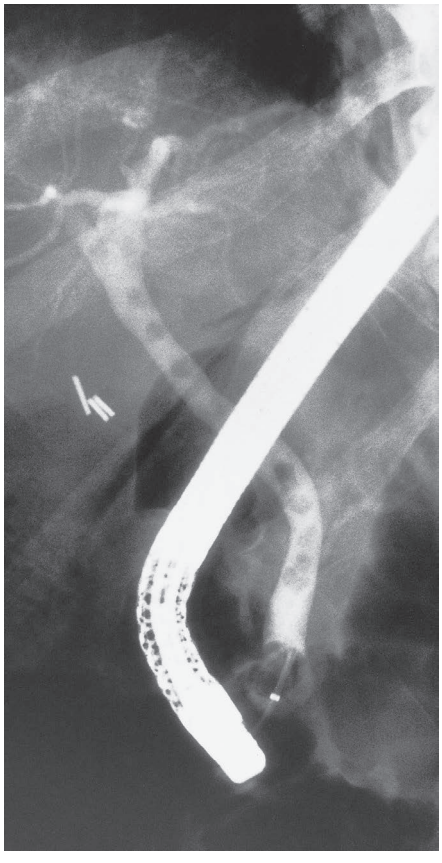

Figure 71.34 This patient presented with jaundice 4 days after laparoscopic cholecystectomy. The duct contained multiple stones.

Enrico Dormia, 1928–2009, Professor of Urology, University of Milan and Chief of the Department of Urology, S Carlo Hospital, Milan, Italy.

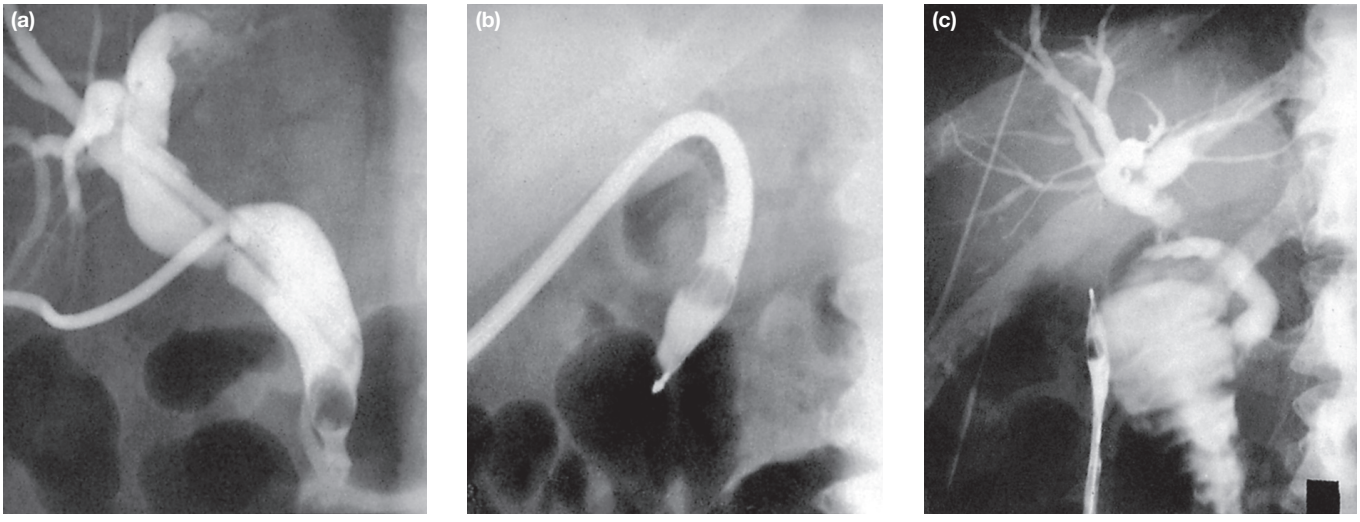

Figure 71.36 Extraction of a stone from the common bile duct by the Burhenne technique. **(a)** A T-tube *in situ* with a stone in the bile duct. **(b)** A steerable catheter is manipulated into the duct and a basket placed around the stone. **(c)** The stone is extracted from the duct along the T-tube track.

choledochoscopy should be performed to confirm clearance. A T-tube is inserted and the duct closed around it; the long limb is brought out on the right side and bile is allowed to drain externally. When the bile becomes clear and the patient has recovered, a cholangiogram is performed. If residual stones are found, the tube is left in place for 6 weeks so that the track is 'mature'. The radiologist can then use the track for percutaneous removal of the stones (Burhenne) (***Figure 71.36***). Once the radiologist has removed the tube, the track will close and the patient will recover. Such residual small stones are now usually managed with endoscopic methods.

Stricture of the bile duct

The causes of benign biliary stricture are given in ***Summary box 71.5***. Bile duct strictures may be investigated radiologically as described in ***Summary box 71.6***.

Summary box 71.5

Causes of benign biliary stricture

Congenital
- Biliary atresia

Bile duct injury at surgery
- Cholecystectomy
- Choledochotomy
- Gastrectomy
- Hepatic resection
- Transplantation

Inflammatory
- Stones
- Cholangitis
- Parasitic
- Pancreatitis
- Sclerosing cholangitis
- Radiotherapy

Trauma

Idiopathic

Summary box 71.6

Radiological investigation of biliary strictures
- USG
- MRCP
- ERCP (with brush cytology in cases of a dominant stricture)
- PTC
- CT

PRIMARY SCLEROSING CHOLANGITIS

PSC is a rare idiopathic and progressive biliary tract disease characterised by inflammation and destruction of the intrahepatic and extrahepatic bile ducts that can lead to liver fibrosis and cirrhosis. Association with hypergammaglobulinaemia and markers such as anti-smooth muscle antibodies and anti-nuclear factor suggest an immunological basis; *cystic fibrosis* transmembrane conductance regulator (*CFTR*) gene mutations have been associated with the development of PSC. The majority of patients are between 30 and 60 years of age. There appears to be a male predominance and a strong association with inflammatory bowel disease (IBD), especially ulcerative colitis (IBD in PSC, 80%; PSC in IBD, 5%).

Patients may be asymptomatic, but common symptoms include pruritus, fever, fatigue, right upper quadrant discomfort, jaundice and weight loss. Liver function tests reveal a cholestatic pattern, elevated serum ALP and gamma-glutamyl transpeptidase (GGTP) and smaller rises in the aminotransferases; bilirubin values can be variable. MRCP (or ERCP) may demonstrate stricturing and beading of the bile ducts (***Figure 71.37***). Liver biopsy is helpful to confirm the diagnosis (concentric periductal 'onion skinning') and may help guide therapy by excluding cirrhosis. Important differential diagnoses are secondary sclerosing cholangitis, immunoglobulin G4 (IgG4) cholangitis, autoimmune hepatitis, human immunodeficiency

Figure 71.37 Sclerosing cholangitis in a patient with ulcerative colitis, visualised by endoscopic retrograde cholangiopancreatography.

virus (HIV) cholangiopathy and cholangiocarcinoma. The last may arise in patients with PSC and is difficult to diagnose; a high index of suspicion is required, especially in the setting of unexplained clinical deterioration.

Patients with PSC are at increased risk for cholangiocarcinoma and gallbladder cancer, as well as colon cancer in those with concurrent IBD. Medical management with antibiotics, vitamin K, cholestyramine, steroids and immunosuppressant drugs may not relieve symptoms. Endoscopic stenting of dominant strictures and, in selected patients with predominantly extrahepatic disease, operative resection may be worthwhile. For patients with cirrhosis, liver transplantation is the best option; 5-year survival following transplantation in high-volume centres is in excess of 80%. Screening for malignancies involving the gallbladder (polyp) and bile ducts and colonoscopy for IBD or malignancy are therefore critical, and bone densitometry for bone density is mandatory.

Immunoglobulin G4-related cholangitis

This recently recognised entity presents with diffuse or segmental narrowing of the intra- or extrahepatic bile ducts. Its features may make differentiation from PSC, cholangiocarcinoma and pancreatic cancer difficult. However, patients often have elevated serum IgG4 levels and concomitant autoimmune pancreatitis, IgG4-related sialadenitis or retroperitoneal fibrosis. Biliary biopsies show lymphoplasmacytic sclerosing cholangitis. Treatment is with systemic steroids. Failure to respond to steroid therapy should make one reconsider the diagnosis and exclude an underlying malignancy.

PARASITIC INFESTATION OF BILIARY TRACT

Biliary ascariasis

The roundworm *Ascaris lumbricoides* commonly infests the intestines of inhabitants in Asia, Africa and Central America. It may enter the biliary tree through the ampulla of Vater and cause biliary pain. Complications include obstruction, strictures, suppurative cholangitis, liver abscesses and empyema of the gallbladder. In uncomplicated cases, antispasmodics can be given to relax the sphincter of Oddi and the worms may return to the intestine to be dealt with by anthelminthic drugs. Worms can be extracted by ERCP. Operation may be necessary to remove the worms or deal with complications.

Clonorchiasis (Asiatic cholangiohepatis)

This disease is endemic in the Far East. The fluke inhabits the bile ducts, including the intrahepatic ducts. Fibrous thickening of the duct walls occurs. Many cases are asymptomatic. Complications include biliary pain, stones, cholangitis, cirrhosis and bile duct carcinoma. Because a process of recurrent stone formation is established, choledochojejunostomy with a Roux loop fixed to the adjacent abdominal wall is performed in some centres to allow easy subsequent access to the duct system.

Hydatid disease

A large hydatid cyst may obstruct the hepatic ducts. Sometimes, a cyst will rupture into the biliary tree and its contents cause obstructive jaundice or cholangitis, requiring appropriate surgery (see ***Chapter 6***).

TUMOURS OF THE BILE DUCT

Benign tumours of the bile duct

Benign neoplasms such as papilloma, adenoma, papillomatosis, leiomyoma and neural and endocrine tumours causing biliary obstruction are uncommon and may be an incidental finding. For symptomatic patients, the duration of symptoms may vary from a few days to months.

Intraductal papillary neoplasm of the bile duct

Intraductal papillary neoplasm of the bile duct (IPNB) is a rare variant of bile duct tumours characterised by papillary growth within the bile duct lumen with ductal dilatation. It is regarded as the biliary counterpart of an intraductal papillary mucinous neoplasm of the pancreas. IPNBs display a spectrum from premalignant lesions to invasive cholangiocarcinoma. The most common radiological findings are bile duct dilatation and intraductal masses. USG, CT and MRI are usually performed to assess tumour location and extension. Cholangioscopy can confirm the histology and assess the extent of the tumour, including superficial spread along the biliary

epithelium. Patients without distant metastasis are considered for surgical resection in a manner similar to that for other types of intrahepatic cholangiocarcinomas and extrahepatic bile duct carcinomas, i.e. major hepatectomy with or without extrahepatic bile duct resection.

Malignant tumours of the bile duct

Summary box 71.7

Bile duct cancer (cholangiocarcinoma)

- Malignancy arising from the biliary epithelium; histologically of three types: mass forming, intraductal growing and periductal infiltrating
- Rare, but incidence increasing
- Most patients present with abnormal liver function tests or frank jaundice
- Diagnosis by USG, CT or MRI
- Majority of patients receive palliative care only
- Complete surgical excision possible in <10%
- Prognosis poor: 90% die within 1 year from liver failure or biliary sepsis
- Adjuvant chemoradiation therapy has a limited role

Cholangiocarcinoma

Incidence

Cholangiocarcinoma is an uncommon malignancy. The overall annual incidence is 1–1.5 per 100 000 with the peak incidence in the eighth decade. The male-to-female ratio is approximately 1.5:1. Anatomically, tumours involving the biliary confluence (hilar cholangiocarcinoma or Klatskin tumours) account for 60% of cases, with the remainder involving the distal bile duct (20–30%) or intrahepatic ducts (10–20%).

Risk factors

A minority of patients have a known risk factor; the major risk factor in western practice is PSC. It is estimated that a longstanding history of PSC increases the risk of developing biliary tract cancer 20-fold compared with the normal population; those with concomitant IBD are at significantly higher risk. Cholangiocarcinoma appears to occur at an earlier age in patients with PSC (30–50 years of age) than in the general population. In addition, disease is usually multifocal and detected at an advanced stage with a resultant poor prognosis compared with the general population.

Congenital cystic disease, hepatolithiasis, oriental cholangiohepatitis, hepatitis C virus infection and infestation with liver flukes have also been associated with an increased risk of cholangiocarcinoma. While the pathophysiology is unclear, it is thought that these parasites cause chronic inflammation that leads to DNA mutations through production of carcinogens and free radicals; the latter can stimulate cellular proliferation in the intrahepatic bile ducts and ultimately lead to invasive cancer (***Summary box 71.8***).

Clinical features

Early symptoms are often non-specific, with abdominal pain, early satiety, anorexia and weight loss commonly seen. Symptoms associated with biliary obstruction (pruritus and jaundice) may be present in a minority of patients. In these patients, examination often demonstrates clinical signs of jaundice, cachexia is often noticeable and the gallbladder is palpable if the obstruction is in the distal CBD (Courvoisier's sign).

Summary box 71.8

Risk factors for cholangiocarcinoma

Chronic inflammatory conditions

- PSC
- Oriental cholangiohepatitis
- Hepatitis C infection

Parasitic infections

- *Opisthorchis viverrini*
- *C. sinensis*

Congenital

- Choledochal cysts
- Caroli's disease

Chemical agents

- Thorium dioxide (Thorotrast)
- Vinyl chloride
- Dioxin
- Asbestos

Post surgical

- Biliary–enteric anastomosis

Non-alcoholic fatty liver disease

Investigations

Biochemical investigations (elevated bilirubin, ALP and GGTP) will confirm obstructive jaundice. The tumour marker carbohydrate 19-9 (CA19-9) may also be elevated. Imaging studies such as USG, CT and MRI/MRCP are essential for diagnosis, staging and assessing the anatomical relationship between the tumour and the major perihilar vascular structures (***Figure 71.38***). These studies allow the level of biliary obstruction to be defined and determine the locoregional extent of disease and the presence of metastases. Direct cholangiography using ERCP or PTC is also used following non-invasive studies. Both can define the level of obstruction and allow biopsy (non-diagnostic in 40–80% of patients) and placement of endobiliary stents for biliary drainage. The choice between the modalities depends on local availability and the anatomical site of the tumour, with PTC preferred for more proximal lesions and ERCP favoured for distal tumours. Despite a higher incidence of postoperative infection with stenting, patients undergoing anticipated major liver resection need preoperative biliary drainage as hyperbilirubinaemia (bilirubin level >6 mg/dL) may impair hepatic regeneration and hypertrophy. Cholangioscopy is an adjunct to ERCP, with diagnostic accuracy increased from 78% to 93% and sensitivity from 58% to 100%.

Positron emission tomography (PET) is useful in detecting lymph node and distant metastases but has limited value in the assessment of local resectability.

Gerald Klatskin, 1910–1986, hepatologist, VA Hospital, Newington, CT, USA.

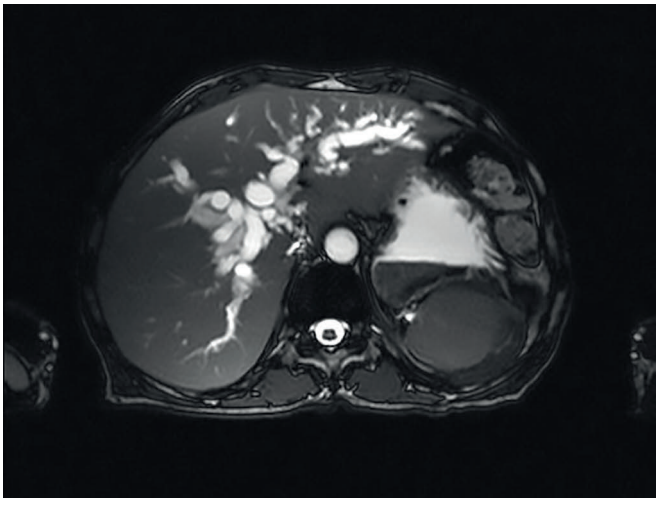

Figure 71.38 Magnetic resonance imaging scan showing a hilar cholangiocarcinoma with dilatation of the intrahepatic biliary tree.

The anatomical extent of the disease is classified according to either the Bismuth–Corlette (***Figure 71.39***) or the Memorial Sloan Kettering Cancer Center (MSKCC) classification.

The MSKCC classification T-stage criteria for hilar cholangiocarcinoma are as follows:

- T1 tumour involving the biliary confluence without extension to second-order biliary radicles.
- T2 tumour involving the biliary confluence with unilateral extension to second-order biliary radicles and ipsilateral portal vein involvement or ipsilateral hepatic atrophy.
- T3 tumour involving the biliary confluence with bilateral extension to second-order biliary radicles; or unilateral extension to second-order biliary radicles with contralateral portal vein involvement; or unilateral extension to second-order biliary radicles with contralateral hepatic lobar atrophy; or main or bilateral portal venous involvement.

Treatment

A multidisciplinary approach is required. The choice of treatment depends on the site and extent of the disease. Unfortunately, the majority of patients present with advanced disease. However, 10–15% are suitable for surgical resection, which offers the only hope for long-term survival. The aim of surgical resection is to achieve complete resection with negative pathological margins (R0 resection) and safely restore biliary–enteric continuity.

Whether or not the disease is resectable depends on patient factors (comorbidities, presence or absence of chronic liver disease) and tumour factors (extent of disease within the biliary tree, vascular involvement, remnant liver volume, increase in the remnant after portal vein embolisation, presence or absence of metastatic disease). Depending on the site of disease, surgery involves either a standard or extended hepatic resection with caudate lobe excision with en bloc lymphadenectomy and reconstruction of the biliary tree. Distal common duct tumours may require pancreaticoduodenectomy (Whipple procedure). Local resection should be avoided.

In selected patients, liver transplantation has been recommended for those with locally unresectable disease without evidence of distant metastases. Transplantation is often preceded by neoadjuvant chemoradiation therapy and staging laparoscopy. While emerging data are encouraging, this aggressive approach remains controversial and is reserved for selected patients in specialised centres (Mayo protocol).

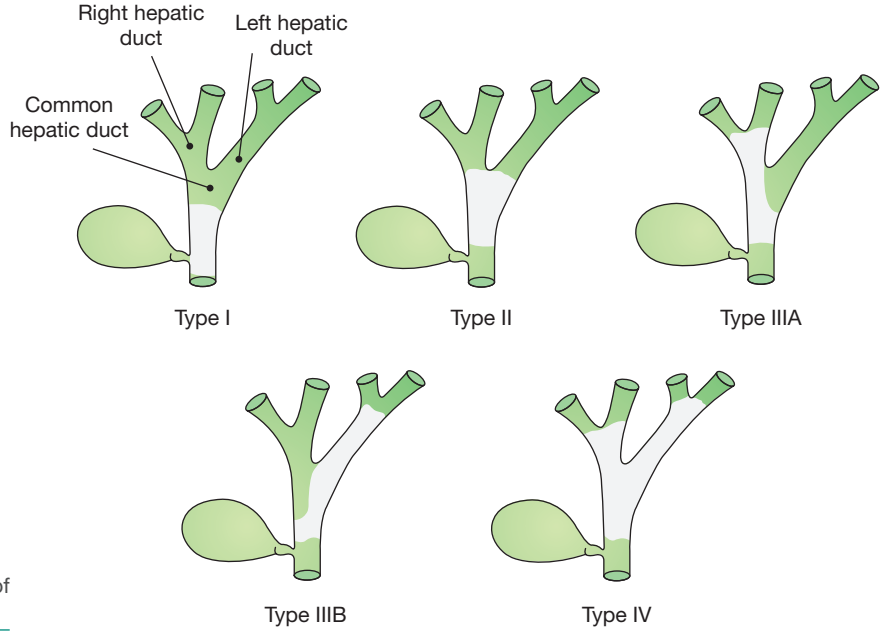

Figure 71.39 Bismuth–Corlette classification of cholangiocarcinoma.

Henri Bismuth, b. 1934, surgeon, Hôpital Paul Bruce, Villejif, France, and **Marvin Corlette** described the classification of cholangiocarcinoma in 1975.
Allen Oldfather Whipple, 1881–1963, surgeon, Columbia-Presbyterian Medical Center, New York, NY, USA.
Mayo Clinic, Rochester, MN, USA, established in the 1880s by Dr William Worral Mayo and his sons William and Charles, both surgeons.

Following resection, disease-specific survival is related to the T-stage, margin status, metastatic lymph node spread, perineural and perivascular invasion, non-papillary tumour subtypes and poor tumour differentiation. Of these, the only variable in which the surgeon plays a major role is margin-negative resection, and emphasis needs to be placed on achieving R0 resection. Approximately 35% of patients will survive 5 years after surgery. Adjuvant chemotherapy and radiotherapy have a limited role and have not been demonstrated to add survival benefit following surgical resection. However, patients at high risk for recurrence (positive surgical margins or node positive) may benefit from adjuvant therapy and should be referred for medical or radiation oncology opinion. The majority of patients who present with unresectable disease are candidates for palliative chemotherapy – gemcitabine with cisplatin. The aim is to maintain or improve quality of life by relieving symptoms and preventing cholestatic liver failure. Biliary obstruction can be relieved by endoscopic (ERCP) or percutaneous (PTC) methods. Surgical bypass rarely has a role apart from in patients with a distal bile duct lesion found to have unresectable disease at operation.

Cancer of the gallbladder

Incidence

Gallbladder cancer is extremely variable by geographical region and racial–ethnic groups; the highest incidence is among Chileans, Native Americans and residents in parts of northern India, where it accounts for as much as 9% of all biliary tract disease. Women appear to have a higher incidence across all geographical areas. In western practice, gallbladder cancer accounts for less than 1% of new cancer diagnoses. The disease usually presents in the seventh or eighth decade. The aetiology is unclear but there is a suggested association with pre-existing gallstone disease, implying that chronic inflammation may play a role. Calcification of the gallbladder wall, presumably due to chronic inflammation (porcelain gallbladder), is also associated with a small increased risk of cancer (***Figure 71.5***). Chronic infection may promote the development of cancer and the risk in typhoid carriers is significantly increased over that of the general population. Patients with PSC, especially with concomitant IBD, and those with an abnormal pancreatic–biliary junction are at greater risk of gallbladder cancer.

In patients with gallbladder polyps (***Figure 71.40***) the risk of malignant transformation increases with increasing size of the polyp.

Summary box 71.9

Gallbladder cancer

- Rare
- Similar presentation to benign biliary disease (gallstones)
- Diagnosis by USG, CT, MRI/MRCP
- Most patients present with advanced disease
- Surgical resection in less than 10% – remainder receive palliative treatment
- Prognosis is poor

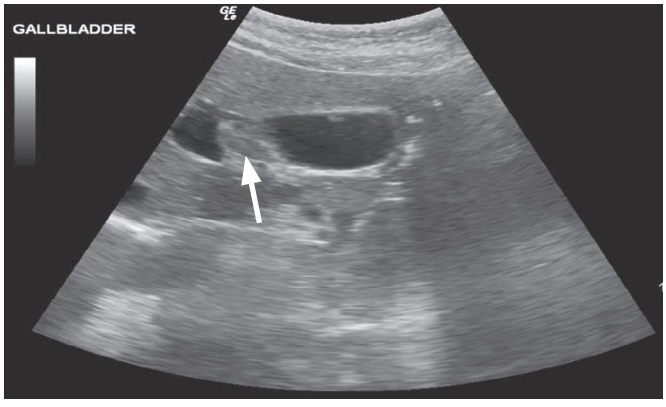

Figure 71.40 Ultrasonography demonstrating a gallbladder polyp. Note the absence of an acoustic shadow (arrow).

Pathology

The majority (90%) of tumours are adenocarcinomas. Squamous carcinomas may arise from areas of mucosal squamous metaplasia.

At operation, localised carcinomas are difficult to differentiate from chronic cholecystitis; the tumour most commonly is nodular and infiltrative, with thickening of the gallbladder wall, often extending to the whole gallbladder. The tumour spreads by direct extension into the liver, seeding of the peritoneal cavity and involvement of the perihilar lymphatics and neural plexuses. At the time of presentation, the majority of tumours are advanced.

Clinical features

Patients may be asymptomatic; symptoms, if present, are usually indistinguishable from those of benign gallbladder disease such as biliary colic or cholecystitis, particularly in older patients. Jaundice and anorexia are late features, heralding a low resectability rate and even fewer negative margins. A palpable mass is a late sign.

Investigation

Laboratory findings are generally non-specific but may be consistent with biliary obstruction. Non-specific findings include anaemia, leukocytosis and a mild elevation in transaminases. Serum CA19-9 and carcinoembryonic antigen may be elevated in approximately 80% of patients.

The preoperative diagnosis is often made on USG and confirmed by CT thorax, abdomen and pelvis or MRI/MRCP. Preoperative staging should aim to determine the local extent of disease and exclude the presence of distant metastases. Percutaneous biopsy under radiological guidance may be considered to obtain tissue for pathological examination, but only in unresectable disease prior to palliative treatment. Laparoscopic examination is useful in staging the disease. Laparoscopy can detect peritoneal or liver metastases, which would preclude further surgical resection (***Figure 71.41***). PET scanning has a role in detecting metastatic disease.

Treatment and prognosis

The majority of patients have advanced disease at presentation and are not candidates for surgical therapy. Staging

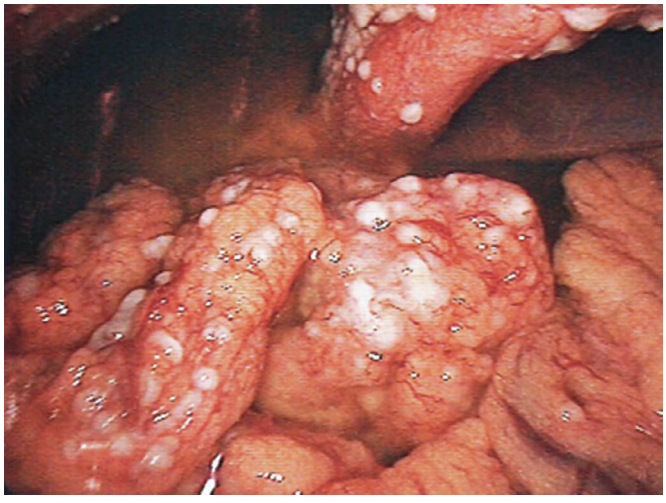

Figure 71.41 Laparoscopic staging in a patient with gallbladder cancer demonstrating gross peritoneal metastases.

laparoscopy is mandatory prior to formal laparotomy to detect occult metastases not picked up on imaging. Radical en bloc resection includes the gallbladder, wedge hepatectomy (2 cm of liver in the gallbladder bed or segments IVb and V if there is concomitant liver infiltration) or extended hepatectomy and bile duct resection if the bile duct is involved or the cystic duct margin is positive on intraoperative frozen section. Regional lymphadenectomy (paracholedochal portal, along the right hepatic artery and retroduodenal nodes) should be considered. The aim is to remove the tumour entirely and achieve negative histopathological margins.

Some patients have the disease diagnosed following histopathological examination of the gallbladder after it has been removed for presumed benign disease (incidental gallbladder cancer). In these cases, the need for further surgery is determined by the stage of disease. For early-stage disease confined to the mucosa of the gallbladder with a negative cystic duct margin and no evidence of recurrence on imaging, no further treatment is indicated. However, for transmural disease, a radical en bloc resection of the gallbladder fossa and surrounding wedge of liver along with the regional lymph nodes should be performed. If the initial procedure was performed laparoscopically, the surgeon should examine the laparoscopic port sites. Routine resection of port sites is no longer recommended. However, it is recognised that the finding of disease at the port sites is a sign of generalised peritoneal disease and carries a very poor prognosis. Adjuvant oral chemotherapy (capecitabine alone is preferred or in combination with gemcitabine/oxaliplatin) may derive survival benefit.

Gallbladder cancer is a lethal disease with a grim prognosis; the median survival is less than 6 months and 5-year survival figures of 50% for localised gallbladder cancer (with chemotherapy) and 2-5% in patients with distant metastasis have been reported.

For the majority of patients with advanced disease a non-operative approach to palliation is best. Obstructive jaundice can be relieved by endoscopic and/or percutaneous methods after discussion in the multidisciplinary team.

Summary box 71.10

Aims of staging gallbladder cancer

- Assessment of local disease
- Detection of metastatic disease:
  - Liver
  - Peritoneum
  - Lymphatics
  - Extra-abdominal disease

PART 11 | Abdominal

CHAPTER

72 The pancreas

Learning objectives

To understand:

- The anatomy and physiology of the pancreas
- Investigations of the pancreas
- Congenital abnormalities of the pancreas
- Assessment and management of pancreatitis
- Diagnosis and treatment of pancreatic cancer

ANATOMY AND PHYSIOLOGY

Anatomy

The name 'pancreas' is derived from the Greek 'pan' (all) and 'kreas' (flesh). For a long time, its glandular function was not understood and it was thought to act as a cushion for the stomach. The pancreas is situated in the retroperitoneum. It is divided into a head, which occupies 30% of the gland by mass, and a body and tail, which together constitute 70%. The head lies within the curve of the duodenum, overlying the body of the second lumbar vertebra and the vena cava. The aorta and the superior mesenteric vessels lie behind the neck of the gland. Coming off the side of the pancreatic head and passing to the left and behind the superior mesenteric vein is the uncinate process of the pancreas. Behind the neck of the pancreas, near its upper border, the superior mesenteric vein joins the splenic vein to form the portal vein (***Figures 72.1 and 72.2***). The tip of the pancreatic tail extends up to the splenic hilum.

The pancreas weighs approximately 80 g. Of this, 80–90% is composed of exocrine acinar tissue, which is organised into lobules. The main pancreatic duct branches into interlobular and intralobular ducts, ductules and, finally, acini. The main duct is lined by columnar epithelium, which becomes cuboidal in the ductules. Acinar cells are clumped around a central lumen, which communicates with the duct system. Clusters of endocrine cells, known as islets of Langerhans, are distributed throughout the pancreas. Islets consist of different cell types: 75% are B cells (producing insulin); 20% are A cells (producing glucagon); and the remainder are D cells (producing somatostatin) and a small number of pancreatic polypeptide cells. Within an islet, the B cells form an inner core surrounded by the other cells. Capillaries draining the islet cells drain into the portal vein.

There are nine key processes that occur during pancreatic embryogenesis (***Table 72.1***). Malrotation of the ventral bud in the fifth week results in an annular pancreas, while the mode of

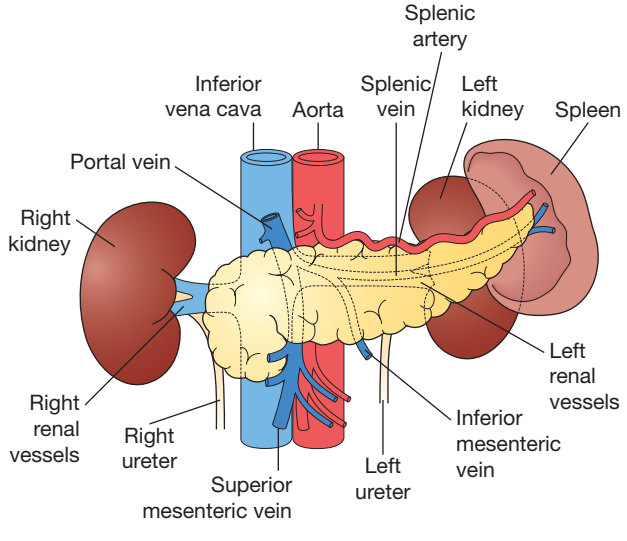

Figure 72.1 The posterior relations of the pancreas.

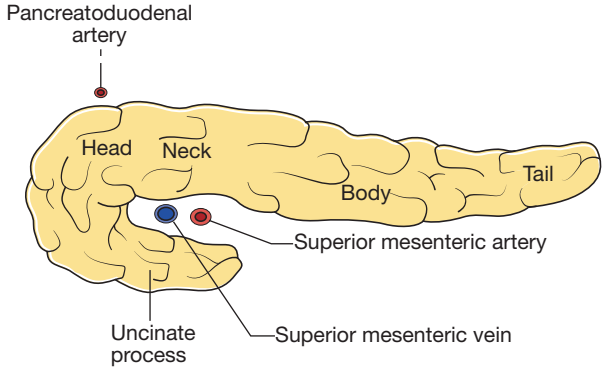

Figure 72.2 Transverse section of the pancreas. Note the position of the uncinate process behind the vessels.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany, described the islets in 1869, in his doctoral thesis.

ductule fusion in the seventh week produces the various possible ductular patterns. Between the 12th and 40th weeks of fetal life, the pancreas differentiates into exocrine and endocrine elements. The primitive ducts and their ductules are responsible for the lobular arrangement of the pancreas. Congenital anomalies of the pancreas are varied and arise during the early phase of development. The anatomy of the pancreatic duct is variable as a result of the primordial bud development. The dorsal duct is expressed in a variable manner in the adult, as outlined in ***Figure 72.3***. Approximately 10% of patients will have a significant flow from the main duct through the accessory papilla. The anatomy of the main duodenal papilla, also known as the ampulla of Vater, is also variable (***Figure 72.4***).

The outlet of each duct is protected by a complex sphincter mechanism (sphincter of Oddi) (***Figure 72.5***).

TABLE 72.1 Steps in the development of the pancreas.

1	Day 26	Dorsal pancreatic duct arises from the dorsal side of the duodenum
2	Day 32	Ventral bud arises from the base of the hepatic diverticulum
3	Day 37	Contact occurs between the two buds. Fusion by the end of week 6
4	Week 6	Ventral bud produces the head and uncinate process
5	Week 6	Ducts fuse
6	Week 6	Ventral duct and distal portion of the dorsal duct form the main duct (duct of Wirsung)
7	Week 6	Proximal dorsal duct forms the duct of Santorini
8	Month 3	Acini appear
9	Months 3–4	Islets of Langerhans appear and become biologically active

Physiology

In response to a meal, the pancreas secretes digestive enzymes in an alkaline (pH 8.4) bicarbonate-rich fluid. Spontaneous secretion is minimal; the hormone secretin, which is released from the duodenal mucosa, evokes a bicarbonate-rich fluid. Cholecystokinin (CCK) (synonym: pancreozymin) is released from the duodenal mucosa in response to food. CCK is responsible for enzyme release. Vagal stimulation increases the volume of secretion. Protein is synthesised at a greater rate (per gram of tissue) in the pancreas than in any other tissue, with the possible exception of the lactating mammary gland. About 90% of this protein is exported from the acinar cells as a variety of digestive enzymes. Approximately 6–20 g of digestive enzymes enters the duodenum each day. Nascent proteins are synthesised as preproteins and undergo modification in a sequence of steps. The proteins move from the rough endothelial endoplasmic reticulum to the Golgi complex, where lysosomes and mature zymogen storage granules containing proteases are stored, and then to the ductal surface of the cell, from which they are extruded by exocytosis. During this phase, the proteolytic enzymes are in an inactive form, which is important in preventing pancreatitis.

INVESTIGATIONS

Estimation of pancreatic enzymes in body fluids

Investigations of the pancreas are listed in ***Table 72.2***.

When the pancreas is damaged, enzymes such as amylase, lipase, trypsin, elastase and chymotrypsin are released into the serum. Measurement of serum amylase is the most widely used test of pancreatic damage (serum lipase is more sensitive and specific but is not widely available). The serum amylase rises within a few hours of pancreatic damage and declines over the next 4–8 days. A markedly elevated serum level is highly suspicious but not diagnostic of acute pancreatitis. Urinary amylase and amylase–creatinine clearance ratios add little to diagnostic accuracy. If confirmation of the diagnosis is required, computed tomography (CT) of the pancreas is of greater value.

Summary box 72.2

Causes of raised serum amylase level other than acute pancreatitis

- Upper gastrointestinal tract perforation
- Mesenteric infarction
- Torsion of an intra-abdominal viscus
- Retroperitoneal haematoma
- Ectopic pregnancy
- Macroamylasaemia
- Renal failure
- Salivary gland inflammation

Pancreatic function tests

Pancreatic exocrine function can be assessed by directly measuring pancreatic secretion in response to a standardised stimulus. The stimulus to secretion can be physiological, e.g. ingestion of a test meal, as in the Lundh test, or pharmacological, e.g. intravenous injection of a hormone such as secretin

Camillo Golgi, 1844–1926, Professor of Anatomy and Histology at Pavia, and later at Siena, Italy, developed silver staining of neural tissue and received the Nobel Prize in 1906 (with Ramón y Cajal).
Göran Lundh, 1926–1999, surgeon, Södersjukhuset, Stockholm, Sweden.

or CCK. Duodenal intubation has to be performed with a triple-lumen tube so that the gastric and duodenal juices can be aspirated, and a non-absorbable marker such as polyethylene glycol is used to assess the completeness of the aspiration. The nitroblue tetrazolium–para-aminobenzoic acid (NBT–PABA) test provides an indirect measure of pancreatic function. The substance is administered orally and degraded in the gut by a pancreatic enzyme, and the breakdown product (PABA) is absorbed by the intestine and excreted in the urine; its urinary level is measured. The pancreolauryl test works on a similar principle. These tests are cheap and easy to perform but are non-specific, especially following gastrectomy and in conditions that may alter gastrointestinal transit and intestinal absorptive capacity. They are rarely used now in the clinical setting. Measurement of the enzyme elastase in stool is simple, specific and now used widely. A low level of faecal elastase indicates exocrine insufficiency.

Imaging investigations

Ultrasonography

Ultrasonography is the initial investigation of choice in patients with jaundice to determine whether or not the bile duct is dilated, the coexistence of gallstones or gross disease within the liver such as metastases. It may also define the presence or absence of a mass in the pancreas (***Figure 72.6***). However, obesity and overlying bowel gas often make interpretation of the pancreas itself unsatisfactory.

Computed tomography

Most significant pathologies within the pancreas can be diagnosed on high-quality CT scans, with three-dimensional reconstruction if necessary. A specific pancreatic protocol should be followed. An initial unenhanced CT scan is essential to determine the presence of calcification within the pancreas and gallbladder (***Figure 72.7***). Then, following rapid injection of intravenous contrast, scanning is performed in the arterial and venous phases. The stomach and duodenum should be outlined with water and distended to define the duodenal loop.

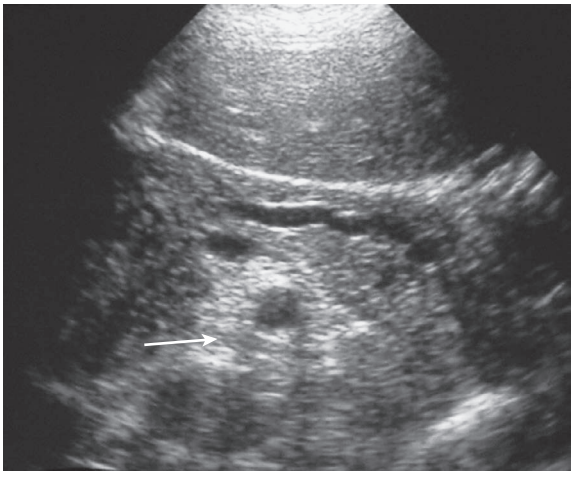

Figure 72.6 Ultrasound scan showing a mass in the head of the pancreas (marked by an arrow) and a dilated pancreatic duct in the body of the gland (courtesy of Dr Alison McLean).

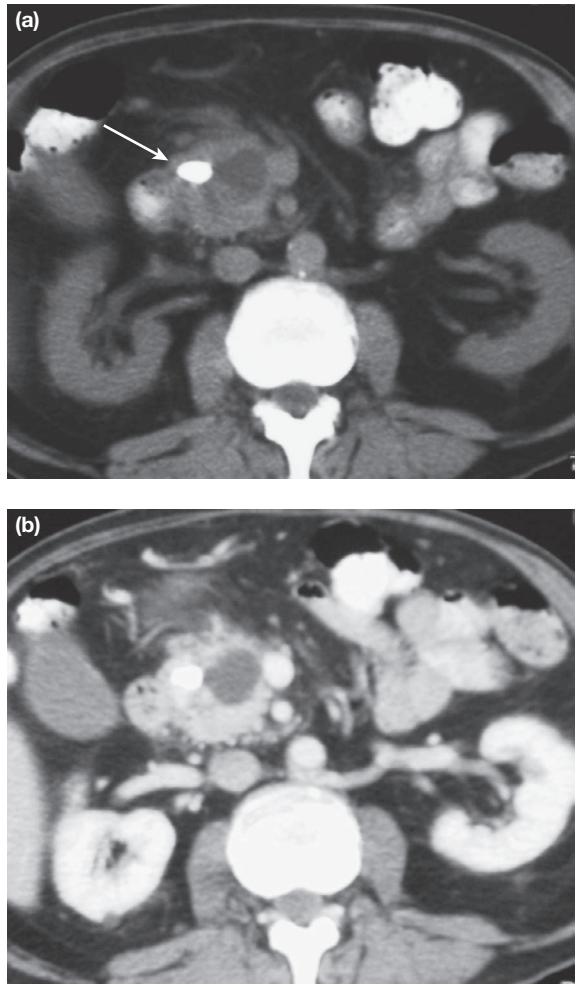

Figure 72.7 (a) Unenhanced computed tomography scan of a man with chronic pancreatitis, showing a focus of calcification (marked by an arrow) in the head of the pancreas and a cyst adjacent to that. Oral contrast has been administered. **(b)** The same area after injection of intravenous contrast.

Pancreatic carcinomas of 1–2 cm in size can usually be demonstrated (***Figure 72.8***). Endocrine tumours are also well imaged on CT (***Figure 72.9***). In patients with pancreatitis, necrotic areas within the gland can be identified by the absence of contrast enhancement on CT. Inflammatory collections and pseudocysts can be seen (***Figure 72.10***). CT-guided drainage is helpful in the treatment of pancreatic collections, cysts and pseudocysts, and facilitates percutaneous fine-needle or Trucut biopsy.

Magnetic resonance imaging

With magnetic resonance imaging (MRI) the pancreas can be clearly identified, and the anatomy of the bile duct and the pancreatic duct, together with fluid collections, can be defined. Magnetic resonance cholangiography and pancreatography (MRCP) has largely replaced diagnostic endoscopic cholangiography and pancreatography (ERCP) as it is non-invasive and less expensive (***Figure 72.11***). Using the technique in conjunction with intravenous injection of secretin, emptying of the pancreatic duct can be demonstrated to show the absence or presence of obstruction.

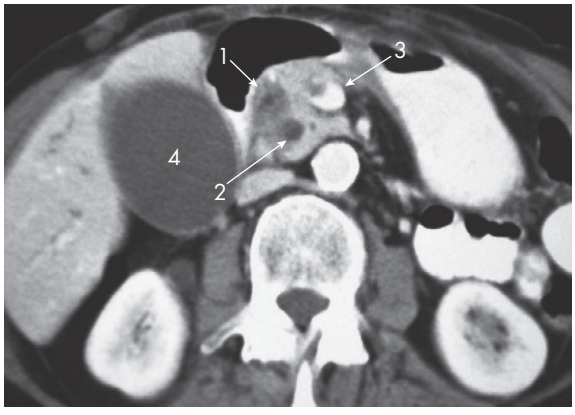

Figure 72.8 Contrast-enhanced computed tomography scan of a patient with a carcinoma of the pancreatic head. The main bulk of the tumour lies inferior to the section shown here. The dilated bile duct (1) and main pancreatic duct (2) can be seen, with tumour infiltration around them. There is a thrombus in the superior mesenteric vein (3). The gallbladder is distended (4).

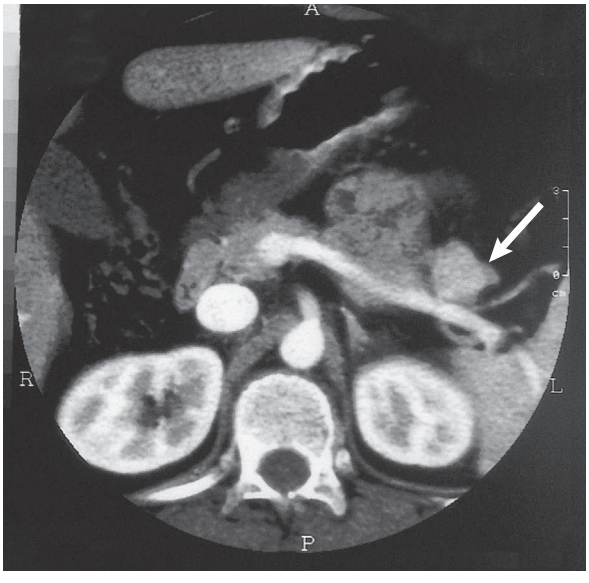

Figure 72.9 Computed tomography scan showing a hypervascular insulinoma (arrow) adjacent to the splenic vein. Local excision of the tumour resulted in normoglycaemia.

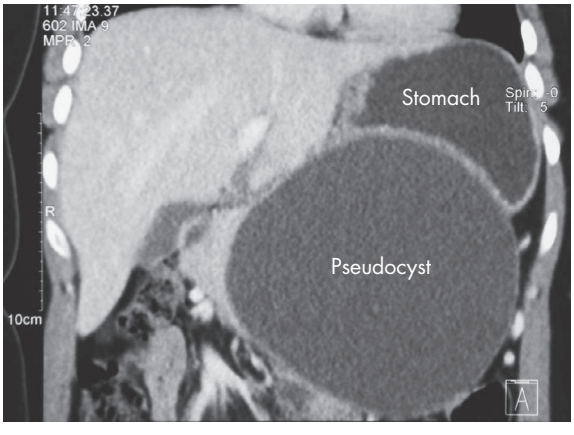

Figure 72.10 Computed tomography scan of a large pseudocyst in relation to the body and tail of the pancreas.

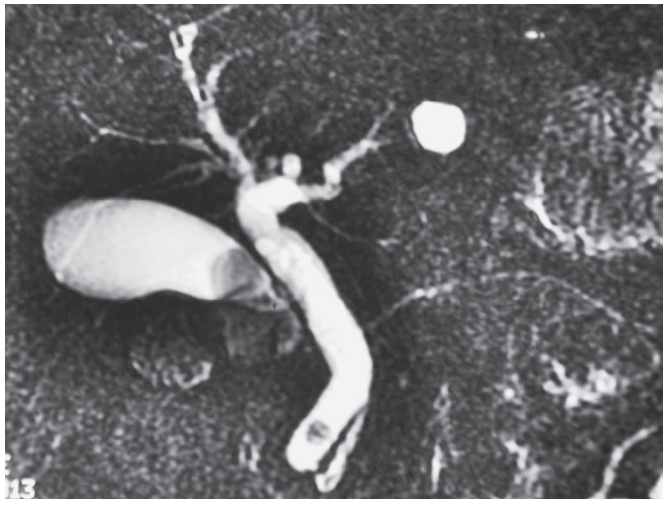

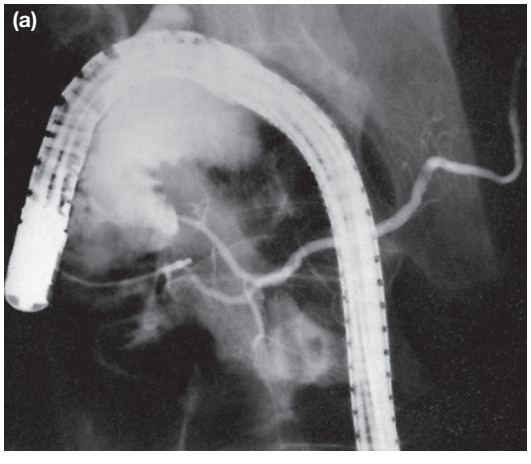

Figure 72.11 Magnetic resonance cholangiopancreatography in a patient with obstructive jaundice. A dilated common bile duct was seen on ultrasonography, but no pancreatic mass lesion was visible on computed tomography. The bile duct and the main pancreatic duct are seen very well, with a stone visible in the lower part of the bile duct and another in the neck of the gallbladder.

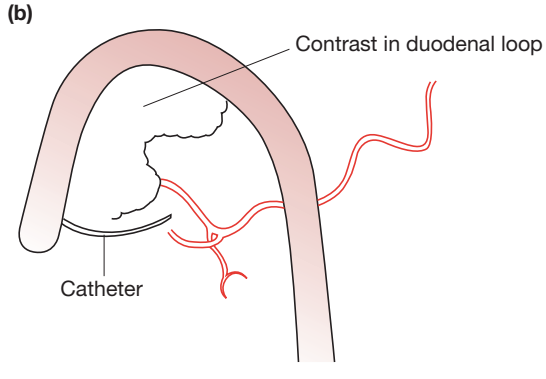

Figure 72.12 Endoscopic retrograde cholangiopancreatography. **(a)** Normal pancreatic duct with filling of the duct of Santorini from the duct of Wirsung. **(b)** Diagrammatic outline of **(a)**.

Endoscopic retrograde cholangiopancreatography

ERCP is performed using a side-viewing fibreoptic duodenoscope. The ampulla of Vater is intubated, and contrast is injected into the biliary and pancreatic ducts to display the anatomy radiologically (***Figure 72.12***). In pancreatic carcinoma, the main pancreatic duct may be narrowed or completely obstructed at the site of the tumour (***Figure 72.13***), or the distal bile duct may be narrowed. Concurrent narrowing of both ducts results in the so-called double duct sign (***Figure 72.14***). Changes seen in chronic pancreatitis include the presence of pancreatic duct strictures, dilatation of the main pancreatic duct with stones, abnormalities of pancreatic duct side branches, communication of the pancreatic duct with cysts and bile duct strictures (***Figures 72.15–72.17***). A plain radiograph before contrast studies is essential to delineate calcification (***Figure 72.18***). In addition to imaging, bile or pancreatic fluid and brushings from duct strictures can yield cells that confirm the suspected diagnosis of carcinoma (***Figure 72.19***). Brush cytology taken from malignant strictures at the time of ERCP yields a positive diagnosis in 40–50% of patients. ERCP also allows the placement of biliary and pancreatic stents.

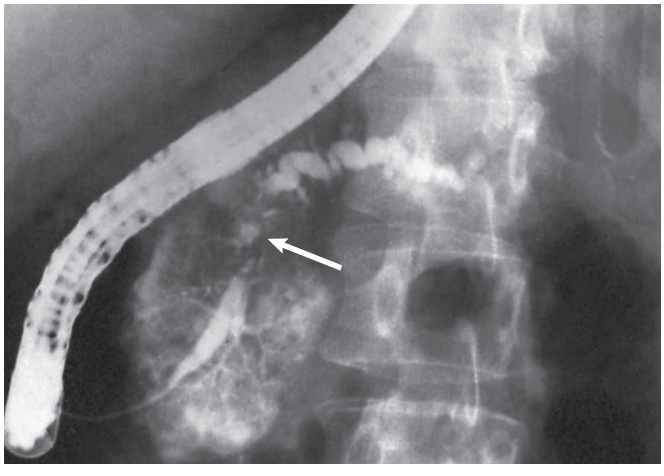

Figure 72.13 Endoscopic retrograde cholangiopancreatography: pancreatic carcinoma. Irregular stricture of the main pancreatic duct (arrow) with dilatation distal to the obstruction.

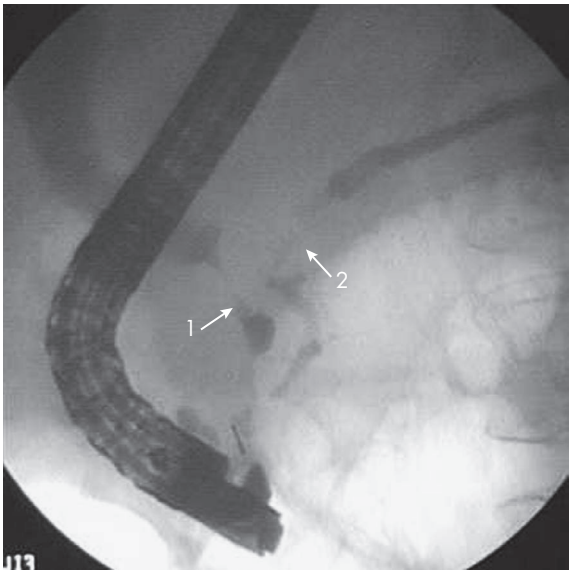

Figure 72.14 Endoscopic retrograde cholangiopancreatography depicting a malignant stricture in the lower part of the common bile duct (1) and in the main pancreatic duct (2), an appearance referred to as the double duct sign (courtesy of Dr George Webster).

Figure 72.15 Endoscopic retrograde cholangiopancreatography: chronic pancreatitis. Most of the opacities lie within the duct system and are stones. Gross dilatation of ducts in the body and tail are due to obstruction by stones in the head of the pancreas.

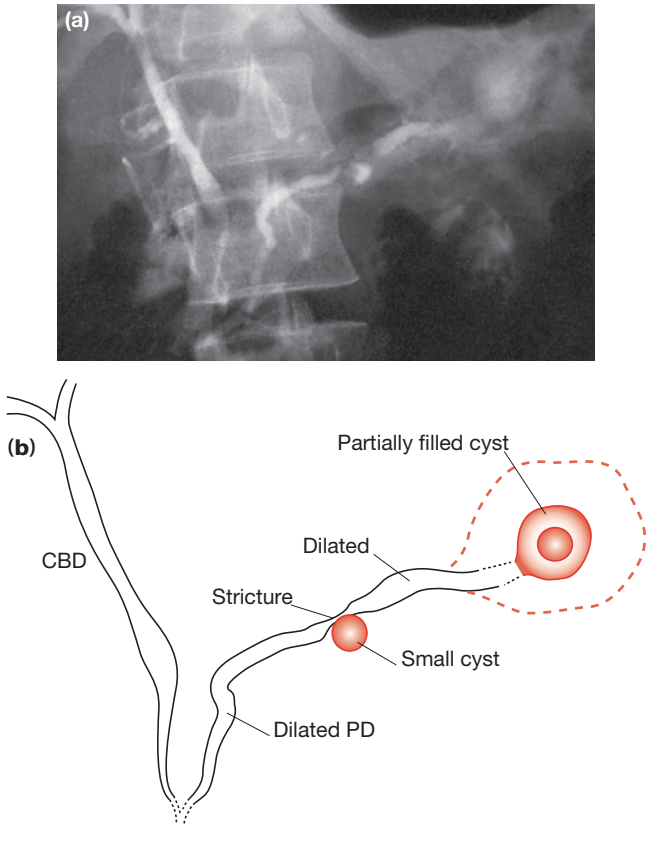

Figure 72.16 (a) Endoscopic retrograde cholangiopancreatography: relapsing acute pancreatitis. Normal biliary tree. Pancreatogram shows stricture of the main duct in the body with distal dilatation and cyst formation. **(b)** Diagrammatic outline of **(a)**. CBD, common bile duct; PD, pancreatic duct.

Figure 72.18 Plain abdominal radiograph: chronic pancreatitis. Multiple opacities can be seen in the region of the head and tail of the pancreas.

Endoscopic ultrasonography

Endoscopic ultrasonography (EUS) is performed using a special endoscope that has a high-frequency ultrasonic transducer at its tip. When the endoscope is in the lumen of the stomach or duodenum, the pancreas and its surrounding vasculature and lymph nodes can be assessed (***Figure 72.20***).

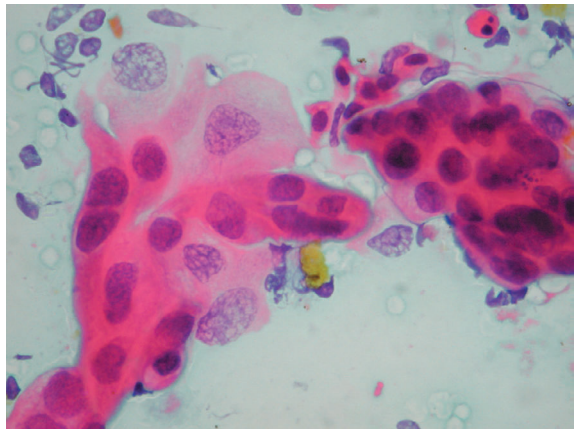

Figure 72.19 Adenocarcinoma cells identified in pancreatic juice collected at the time of endoscopic retrograde cholangiopancreatography (courtesy of Professor Roger Feakins).

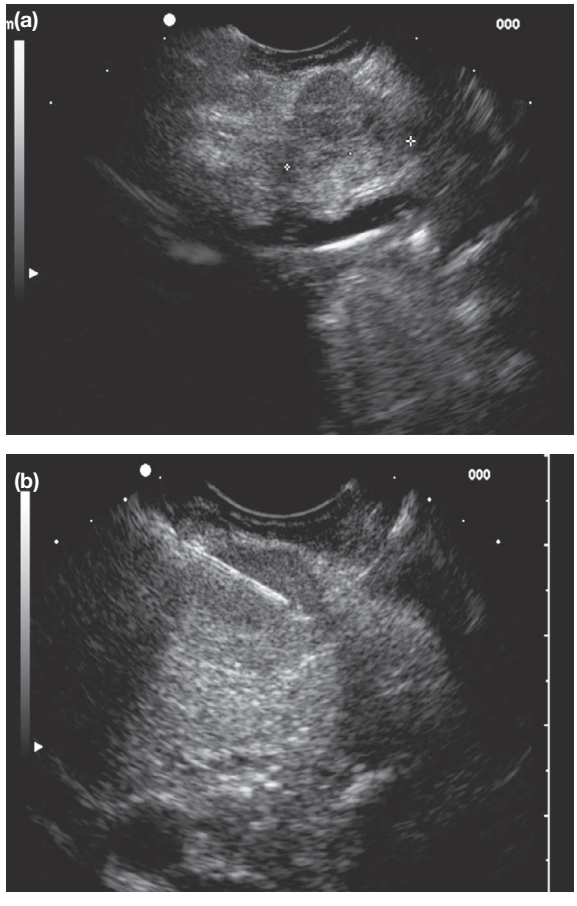

Figure 72.20 (a) Carcinoma of the pancreatic head as seen with endoscopic ultrasonography (EUS). **(b)** Aspiration biopsy carried out under EUS guidance: needle seen entering the tumour (courtesy of Dr Peter Fairclough).

This is particularly useful in identifying small tumours that may not show up well on CT or MRI, and in demonstrating the relationship of a pancreatic tumour to major vessels nearby. EUS can clarify the relationship of a neuroendocrine tumour to the main pancreatic duct (important if enucleation is being considered).

It helps to distinguish cystic tumours from pseudocysts. Transduodenal or transgastric fine-needle aspiration (FNA) or Trucut biopsy performed under endoscopic ultrasound guidance avoids spillage of tumour cells into the peritoneal cavity.

CONGENITAL ABNORMALITIES

Cystic fibrosis

This is inherited as an autosomal recessive condition. It occurs most frequently among white people, in whom it is the most common inherited disorder (incidence of 1:2000 live births in the UK). Cystic fibrosis (CF) develops when there is a mutation in the CFTR (cystic fibrosis transmembrane conductance regulator) gene on chromosome 7. This gene creates a cell membrane protein that helps to control the movement of chloride across the cell membrane.

CF is a multisystem disorder of exocrine glands that affects the lungs, intestines, pancreas and liver and is characterised by elevated sodium and chloride ion concentrations in sweat. The mother may notice that the child is salty when kissed.

Most of the organ damage is due to blockage of narrow passages by thickened secretions. Chronic pulmonary disease arises from plugging of bronchi and bronchioles. CF is the most common cause of chronic lung disease among children in resource-rich countries. Cor pulmonale may develop later. At birth, the meconium may set in a sticky mass and produce intestinal obstruction (meconium ileus) (see ***Chapter 18***). Secretions precipitate in the lumen of the pancreatic duct causing blockage, which results in duct ectasia and fatty replacement of exocrine acinar tissue. Pancreatic exocrine insufficiency leads to fat malabsorption. Steatorrhoea is usually present from birth, resulting in stools that are bulky, oily and offensive. The islets of Langerhans usually appear normal, but diabetes mellitus can occur in older patients. The liver may become cirrhotic as a result of bile duct plugging, and signs of portal hypertension may appear. Infertility is common owing to the absence of the vas deferens in men and thick cervical mucus in women.

Outside the newborn period, the earliest clinical signs of CF are poor growth, poor appetite, rancid greasy stools, abdominal distension, chronic respiratory disease and finger clubbing. The appearance of secondary sexual characteristics may be delayed. The diagnosis can be made by prenatal genetic testing, by the newborn blood spot (heel prick) test done on newborns in the UK and by the sweat test. Levels of sodium and chloride ions in the sweat above 90 mmol/L confirm the diagnosis.

Treatment is aimed at control of the secondary consequences of the disease. Pulmonary function is preserved with aggressive physiotherapy and antibiotics. Malabsorption is treated by administration of oral pancreatic enzyme preparations. The diet should be low in fat but contain added salt to replace the high losses in the sweat. With early diagnosis and optimal treatment, patients in resource-rich countries can now expect to survive to their mid-thirties. Those with end-stage lung disease may be considered for lung transplantation. Heterozygous carriers of the various gene mutations are asymptomatic but can be identified by DNA analysis. There is a suggestion that such patients may develop pancreatitis later in life.

Pancreas divisum

Pancreas divisum occurs when the embryological ventral and dorsal parts of the pancreas fail to fuse (***Figure 72.3***). The dorsal pancreatic duct becomes the main pancreatic duct and drains most of the pancreas through the minor or accessory papilla. The incidence of pancreas divisum ranges from 5% in autopsy series to 10% in some ERCP and MRCP series. Pancreas divisum found incidentally in an asymptomatic person does not warrant intervention; however, the incidence of pancreas divisum ranges from 25% to 50% in patients with recurrent acute pancreatitis, chronic pancreatitis and pancreatic pain. The minor papilla is substantially smaller than the major papilla, thus large volumes of secretions flowing through a narrow papilla leads to incomplete drainage, which may in turn cause obstructive pain or pancreatitis. Certainly, pancreas divisum should be excluded in patients with idiopathic recurrent pancreatitis. The diagnosis can be arrived at by MRCP, EUS or ERCP, augmented by injection of secretin if necessary. There may be changes indicative of obstruction or chronic inflammation in the dorsal duct system. Endoscopic sphincterotomy and stenting of the minor papilla may relieve the symptoms. Surgical intervention can take the form of sphincteroplasty, pancreatojejunostomy or even resection of the pancreatic head.

Annular pancreas

This is the result of failure of complete rotation of the ventral pancreatic bud during development, so that a ring of pancreatic tissue surrounds the second or third part of the duodenum. It is most often seen in association with congenital duodenal stenosis or atresia and is therefore more prevalent in children with Down syndrome. Duodenal obstruction typically causes vomiting in the neonate (see ***Chapter 18***). The usual treatment is bypass (duodenoduodenostomy). The diagnosis may be made in later life as a cause of pancreatitis, in which case resection of the head of the pancreas should be considered.

Ectopic pancreas

Islands of ectopic pancreatic tissue can be found in the submucosa in parts of the stomach, duodenum or small intestine (including Meckel's diverticulum), the gallbladder, adjoining the pancreas, in the hilum of the spleen and within the liver. Ectopic pancreas may also be found in the wall of an alimentary tract duplication cyst.

John Langdon Haydon Down (sometimes given as Haydon-Down), 1828–1896, physician, The London Hospital, London, and Superintendent, Earlswood Asylum for Idiots, Redhill, UK, described this syndrome in 1866.

Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the embryological origin of the eponymous diverticulum in 1809.

Congenital cystic disease of the pancreas

This sometimes accompanies congenital disease of the kidneys and liver and occurs as part of the von Hippel–Lindau syndrome.

INJURIES TO THE PANCREAS

External injury

Presentation and management

The pancreas is not frequently damaged in blunt abdominal trauma but when it occurs it is often associated with injuries to other viscera, especially the liver, the spleen and the duodenum. Occasionally, a forceful blow to the epigastrium (such as from the steering wheel in a car accident) may crush the body of the pancreas against the vertebral column. Penetrating trauma to the upper abdomen or the back carries a higher chance of pancreatic injury. Pancreatic injuries may range from a contusion or laceration of the parenchyma without duct disruption to major parenchymal destruction with duct disruption (sometimes complete transection) and, rarely, massive destruction of the pancreatic head. The most important factor that determines treatment is whether the pancreatic duct has been disrupted.

Blunt pancreatic trauma usually presents with epigastric pain, which may be minor at first, with the progressive development of more severe pain due to the sequelae of leakage of pancreatic fluid into the surrounding tissues. The clinical presentation can be quite deceptive; careful serial assessments and a high index of suspicion are required. A rise in serum amylase occurs in most cases. A CT scan of the pancreas will delineate the damage that has occurred to the pancreas (***Figure 72.21***). If there is doubt about duct disruption, an urgent ERCP should be sought. MRCP may also provide the answer, but the images can be difficult to interpret. Support with intravenous fluids and a 'nil by mouth' regimen should be instituted while these investigations are performed. There is no need to rush to a laparotomy if the patient is haemodynamically stable, without peritonitis. It is preferable to manage conservatively at first, investigate and, once the extent of the damage has been ascertained, undertake appropriate action. Operation is indicated if there is disruption of the main pancreatic duct; in almost all other cases, the patient will recover with conservative management.

In penetrating injuries, especially if other organs are injured and the patient's condition is unstable, there is a greater need to perform an urgent surgical exploration. Assessment of pancreatic damage and duct disruption at the time of surgery can be difficult because the bruising associated with the retroperitoneal damage prevents clear visualisation of the pancreas. A patient and thorough examination of the gland should be carried out. Haemostasis and closed drainage are adequate for minor parenchymal injuries. If the gland is transected in the body or tail, a distal pancreatectomy should be performed, with or without splenectomy. If damage is purely confined to the head of the pancreas, haemostasis and external drainage are normally effective. In the emergency setting, in an unstable patient with concomitant injuries, a surgeon unaccustomed to pancreatic surgery should refrain from trying to ascertain whether the duct in the pancreatic head is intact or embarking on a major resection. However, if there is severe injury to the pancreatic head and duodenum, then a pancreatoduodenectomy may be necessary.

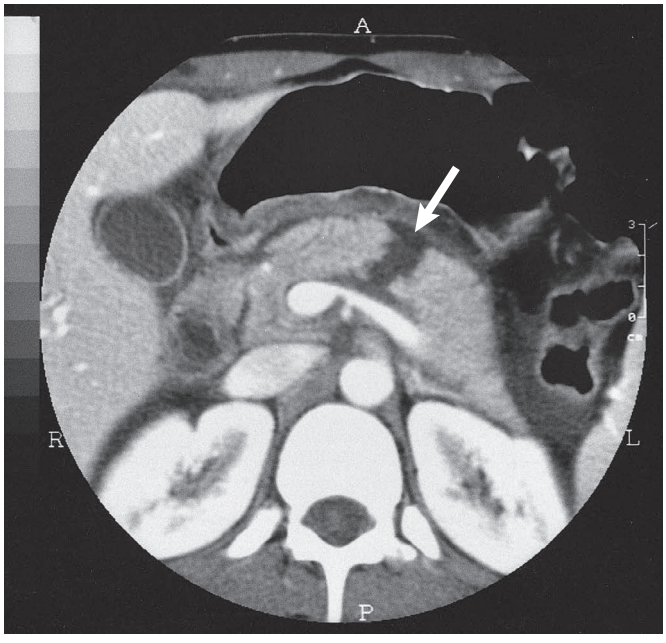

Figure 72.21 Computed tomography scan showing a pancreatic transection due to a bicycle handlebar injury. A distal pancreatectomy was performed.

Summary box 72.3

External injury to the pancreas

- Other organs are likely to be injured
- It is important to ascertain if the pancreatic duct has been disrupted
- CT and ERCP are the most useful tests
- Surgery is indicated if the main pancreatic duct is disrupted

Prognosis

The most common cause of death in the immediate period is bleeding, usually from associated injuries. Once the acute phase has passed, the morbidity related to the pancreatic injury itself is treatable, with a complete return to normal activity being the usual outcome.

Persistent drain output occurs in up to a third of patients (see ***Pancreatic fistula***). Sometimes, in the aftermath of trauma that has been treated conservatively, duct stricturing develops, leading to recurrent episodes of pancreatitis. The appropriate treatment in such cases is resection of the tail of the pancreas distal to the site of duct disruption.

A pancreatic pseudocyst may develop. If the main duct is intact, the cyst can be aspirated percutaneously in the first instance; it may not be necessary to undertake a cyst gastrostomy. If the cyst develops in the presence of complete disruption of the pancreas, there is no alternative but to undertake a distal resection or, occasionally, a pancreatojejunostomy with a Roux-en-Y loop. In a patient who presents with a peripancreatic cyst and a history of previous blunt abdominal trauma, do not assume that it is a post-traumatic pseudocyst. The possibility of a cystic neoplasm should be considered and excluded.

Iatrogenic injury

This can occur in several ways:

- Injury to the tail of the pancreas during splenectomy, resulting in a pancreatic fistula.
- Injury to the pancreatic head and the accessory pancreatic duct (Santorini), which is the main duct in 7% of patients, during Billroth II gastrectomy. A pancreatogram performed by cannulating the duct at the time of discovery of such an injury will demonstrate whether it is safe to ligate and divide the duct. If no alternative drainage duct can be demonstrated, then the duct should be reanastomosed to the duodenum or alternatively resection of the pancreatic head should be considered.
- Enucleation of islet cell tumours of the pancreas can result in fistulae.
- Duodenal or ampullary bleeding following sphincterotomy. This injury may require duodenotomy to control the bleeding.

Pancreatic fistula

Pancreatic fistula usually follows operative trauma to the gland or occurs as a complication of acute or chronic pancreatitis. It is important to define the site of the fistula and the epithelial structure with which it communicates (e.g. externally to skin or internally to bowel). If there is uncertainty about whether the fluid issuing from a drain site or a wound is pancreatic juice, measurement of the amylase content will be diagnostic.

Management includes correction of metabolic and electrolyte disturbances and adequate drainage of the fistula into a stoma bag with protection of the skin. Investigation of the cause of the fistula is required as the underlying cause must be treated before the fistula will close. Frequently, the cause is related to obstruction within the pancreatic duct, which can be overcome by endoscopic insertion of a stent or catheter into the pancreatic duct. While waiting for closure of the fistula, the patient should be given parenteral or nasojejunal nutritional support (as opposed to nasogastric or oral feeding; the rationale is that parenteral or nasojejunal feeding reduces the volume of pancreatic secretion). The use of octreotide will also suppress pancreatic secretion.

Summary box 72.4

Management of pancreatic fistulae

Tests

- Measure amylase level in fluid
- Determine the anatomy of the fistula
- Check if the main pancreatic duct is blocked or disrupted

Measures

- Correct fluid and electrolyte imbalances
- Protect the skin
- Drain adequately
- Parenteral or nasojejunal feeding
- Octreotide to suppress secretion
- Relieve pancreatic duct obstruction if possible (ERCP and stent)
- Treat underlying cause

PANCREATITIS

Pancreatitis is inflammation of the pancreatic parenchyma. For clinical purposes, it is useful to divide pancreatitis into acute, which presents as an emergency, and chronic, which is a prolonged and frequently lifelong disorder resulting from the development of fibrosis within the pancreas. It is possible that acute and chronic pancreatitis are different phases of the same process.

Acute pancreatitis is defined as an acute condition presenting with abdominal pain, a threefold or greater rise in the serum levels of the pancreatic enzymes amylase or lipase and/or characteristic findings of pancreatic inflammation on contrast-enhanced CT. Acute pancreatitis may recur.

The underlying mechanism of injury in pancreatitis is thought to be premature activation of pancreatic enzymes within the pancreas, leading to a process of autodigestion. Anything that injures the acinar cells and impairs the secretion of zymogen granules or damages the duct epithelium, and thus delays enzymatic secretion, can trigger acute pancreatitis. Once cellular injury has been initiated, the inflammatory process can lead to pancreatic oedema, haemorrhage and, eventually, necrosis. As inflammatory mediators are released into the circulation, systemic complications can arise, such as haemodynamic instability, bacteraemia (due to translocation of gut flora), acute respiratory distress syndrome and pleural effusions, gastrointestinal haemorrhage, renal failure and disseminated intravascular coagulation (DIC).

Acute pancreatitis may be categorised as mild (interstitial oedematous pancreatitis) or severe (necrotising pancreatitis). The former is characterised by interstitial oedema of the gland and minimal organ dysfunction. The majority of patients will have a mild attack of pancreatitis, the mortality from which is around 1%. Severe acute pancreatitis is seen in 5–10% of patients and is characterised by pancreatic necrosis, a severe

César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland.
Christian Albert Theodor Billroth, 1829–1894, Professor of Surgery, Vienna, Austria.

systemic inflammatory response and often multiorgan failure. In those who have a severe attack of pancreatitis, the mortality varies from 20% to 50%.

Acute pancreatitis has an early phase that usually lasts a week. It is characterised by a systemic inflammatory response syndrome (SIRS), which – if severe – can lead to transient or persistent organ failure (deemed persistent if it lasts for over 48 hours). About one-third of deaths occur in the early phase of the attack, from multiple organ failure. The late phase is seen typically in those who suffer a severe attack and can run from weeks to months. It is characterised by persistent systemic signs of inflammation and/or local complications, particularly fluid collections and peripancreatic sepsis. Deaths occurring after the first week of onset are often due to septic complications.

Chronic pancreatitis is defined as a continuing inflammatory disease of the pancreas characterised by irreversible morphological change typically causing pain and/or permanent loss of function. Many patients with chronic pancreatitis have painful exacerbations, but the condition may be completely painless.

Acute pancreatitis

Incidence

Acute pancreatitis accounts for 3% of all cases of abdominal pain among patients admitted to hospital in the UK. The hospital admission rate for acute pancreatitis is 9.8 per year per 100 000 population in the UK, although worldwide the annual incidence may range from 5 to 50 per 100 000. The disease may occur at any age, with a peak in young men and older women.

Summary box 72.5

Possible causes of acute pancreatitis

- Gallstones
- Alcoholism
- Post ERCP
- Abdominal trauma
- Following biliary, upper gastrointestinal or cardiothoracic surgery
- Ampullary tumour
- Drugs (corticosteroids, azathioprine, asparaginase, valproic acid, thiazides, oestrogens)
- Hyperparathyroidism
- Hypercalcaemia
- Hypertriglyceridaemia
- Pancreas divisum
- Sphincter of Oddi dysfunction
- Autoimmune pancreatitis
- Hereditary pancreatitis
- Viral infections (mumps, coxsackie B)
- Malnutrition
- Scorpion bite
- Idiopathic

Aetiology

The two major causes of acute pancreatitis are biliary calculi, which occur in 50–70% of patients, and alcohol abuse, which accounts for 25% of cases. Gallstone pancreatitis is thought to be triggered by the passage of gallstones down the common bile duct. If the biliary and pancreatic ducts join to share a common channel before ending at the ampulla, then obstruction of this passage may lead to reflux of bile or activated pancreatic enzymes into the pancreatic duct. Patients who have small gallstones and a wide cystic duct may be at a higher risk of passing stones. The proposed mechanisms for alcoholic pancreatitis include the effects of diet, malnutrition, direct toxicity of alcohol, concomitant tobacco smoking, hypersecretion, duct obstruction or reflux, and hyperlipidaemia. The remaining cases may be due to rare causes or may be idiopathic.

Among patients who undergo ERCP, 1–3% develop pancreatitis, probably as a consequence of duct disruption and enzyme extravasation. Patients with sphincter of Oddi dysfunction or a history of recurrent pancreatitis, and those who undergo sphincterotomy or balloon dilatation of the sphincter, carry a higher risk of developing post-ERCP pancreatitis. Patients who have undergone upper abdominal or cardiothoracic surgery may develop acute pancreatitis in the postoperative phase, as may those who have suffered blunt abdominal trauma.

Hereditary pancreatitis is a rare familial condition associated with mutations of the cationic trypsinogen gene. Patients have a tendency to suffer acute pancreatitis while in their teens, progress to chronic pancreatitis in the next two decades and have a high risk (possibly up to 40%) of developing pancreatic cancer by the age of 70 years. Hypertriglyceridaemia should be excluded.

Occasionally, tumours at the ampulla of Vater may cause acute pancreatitis. It is important to check the serum calcium level, a fasting lipid profile, autoimmune markers and viral titres in patients with so-called idiopathic acute pancreatitis. It is equally important to take a detailed drug history and remember the association of corticosteroids, azathioprine, asparaginase and valproic acid with acute pancreatitis. Statins (taken over a long time) and gliptins have been linked with pancreatitis, but the evidence is slim. It is essential to exclude tiny gallstones. A careful search for the aetiology must be made in all cases, and no more than 20% of cases should fall into the idiopathic category.

Summary box 72.6

Aetiology of acute pancreatitis

- It is essential to establish the aetiology
- Investigate thoroughly before labelling it as 'idiopathic'
- If due to gallstones, cholecystectomy is desirable during the same admission

Clinical presentation

Pain is the cardinal symptom. It characteristically develops quickly, reaching maximum intensity within minutes rather than hours and persists for hours or even days. The pain is

frequently severe, constant and refractory to the usual doses of analgesics. Pain is usually experienced first in the epigastrium but may be localised to either upper quadrant or felt diffusely throughout the abdomen. There is radiation to the back in about 50% of patients, and some patients may gain relief by sitting or leaning forwards. The suddenness of onset may simulate a perforated peptic ulcer, while biliary colic or acute cholecystitis can be mimicked if the pain is maximal in the right upper quadrant. Radiation to the chest can simulate myocardial infarction, pneumonia or pleuritic pain. In fact, acute pancreatitis can mimic most causes of the acute abdomen and should seldom be discounted in differential diagnosis.

Nausea, repeated vomiting and retching are usually marked. The retching may persist despite the stomach being kept empty by nasogastric aspiration. Hiccoughs can be troublesome and may be due to gastric distension or irritation of the diaphragm.

On examination, the appearance may be that of a patient who is well or, at the other extreme, one who is gravely ill with profound shock, toxicity and confusion. Tachypnoea is common, tachycardia is usual and hypotension may be present. The body temperature is often normal or even subnormal, but frequently rises as inflammation develops. It is useful to reiterate here that SIRS is defined by the presence of two or more of the following criteria: heart rate >90/min, core temperature <36°C or >38°C, respirations >20/min or PCO_2 <32 mmHg, and white blood cell count <4000 or >12 000/mm^3 (see also ***Chapter 2***). Mild icterus can be caused by biliary obstruction in gallstone pancreatitis, and an acute swinging pyrexia suggests cholangitis. Bleeding into the fascial planes can produce bluish discoloration of the flanks (Grey Turner's sign) or umbilicus (Cullen's sign). Subcutaneous fat necrosis may produce small, red, tender nodules on the skin of the legs.

Abdominal examination may reveal distension due to ileus or, more rarely, ascites with shifting dullness. A mass can develop in the epigastrium owing to inflammation. There is usually muscle guarding in the upper abdomen, although marked rigidity is unusual. A pleural effusion is present in 10–20% of patients. Pulmonary oedema and pneumonitis are also described and may give rise to the differential diagnosis of pneumonia or myocardial infarction. The patient may be confused and exhibit the signs of metabolic derangement together with hypoxaemia.

Investigations

Typically, the diagnosis is made on the basis of the clinical presentation and an elevated serum amylase level. A serum amylase level three times above normal is indicative of the disease. A normal serum amylase level does not exclude acute pancreatitis, particularly if there is delay in presentation. The serum lipase level provides a more sensitive and specific test than amylase. If there is doubt, and other causes of acute abdomen have to be excluded, contrast-enhanced CT is the best single imaging investigation.

Summary box 72.7

Investigations in acute pancreatitis should be aimed at answering three questions:

- Is a diagnosis of acute pancreatitis correct?
- How severe is the attack?
- What is the aetiology?

Assessment of severity

It is important to identify those patients who will develop severe pancreatitis as they require aggressive early management and possibly transfer to a specialist unit. A severe attack may be heralded by an initial clinical impression of a very ill patient and a worsening physiological state at 24–48 hours. Various prognostic scoring systems have been used, all aimed at predicting persistent organ failure, particularly respiratory, cardiac and renal. Severity stratification assessments should be performed in patients at 24 hours, 48 hours and 7 days after admission. The Ranson and Glasgow scoring systems are specific for acute pancreatitis, and a score of 3 or more at 48 hours indicates a severe attack (***Table 72.3***). Several other systems that are used in intensive care units can also be applied. These include the APACHE, SAPS, SOFA, MODS and modified Marshall scoring systems (the latter has the advantage of simplicity). Regardless of the system used, persisting organ failure indicates a severe attack. A serum C-reactive protein level >150 mg/L at 48 hours after the onset of symptoms is also an indicator of severity. Patients with a body mass index over 30 are at higher risk of developing complications. A revision in 2013 of the Atlanta classification of acute pancreatitis (1992) recommends that patients with acute pancreatitis be stratified into three groups:

- Mild acute pancreatitis:
  - no organ failure;
  - no local or systemic complications.
- Moderately severe acute pancreatitis:
  - organ failure that resolves within 48 hours (transient organ failure); and/or
  - local or systemic complications without persistent organ failure.
- Severe acute pancreatitis:
  - persistent organ failure (>48 hours);
  - single organ failure;
  - multiple organ failure.

John C Marshall, contemporary, trauma surgeon and intensivist, St Michael's Hospital, Toronto, Canada.

TABLE 72.3 The Ranson and Glasgow scoring systems to predict the severity of acute pancreatitis: in both systems, disease is classified as severe when three or more factors are present.

Ranson score	Glasgow score
On admission	**Within 48 hours**
Age >55 years	Age >55 years
White blood cell count >16 × 10^9/L	White blood cell count >15 × 10^9/L
Blood glucose >11 mmol/L (>200 mg/dL)	Blood glucose >10 mmol/L (no history of diabetes)
LDH >350 units/L	LDH >600 units/L or AST >200 units/L
AST >250 units/L	Serum urea >16 mmol/L (no response to intravenous fluids)
Within 48 hours	Arterial oxygen saturation (PaO_2) <8 kPa (60 mmHg)
Haematocrit fall of 10% or greater	Serum calcium <2.0 mmol/L
Blood urea nitrogen rise >5 mg/dL (1.8 mmol/L) despite fluids	Serum albumin <32 g/L
Arterial oxygen saturation (PaO_2) <8 kPa (60 mmHg)	
Serum calcium <8 mg/dL (2.0 mmol/L)	
Base deficit >4 mmol/L	
Fluid sequestration >6 litres	

AST, aspartate aminotransferase; LDH, lactate dehydrogenase; PaO_2, arterial oxygen tension.

Imaging

Plain erect chest and abdominal radiographs are not diagnostic of acute pancreatitis but are useful in the differential diagnosis. Non-specific findings in pancreatitis include a generalised or local ileus (sentinel loop), a colon cut-off sign and a renal halo sign. Occasionally, calcified gallstones or pancreatic calcification may be seen. A chest radiograph may show a pleural effusion and, in severe cases, a diffuse alveolar interstitial shadowing may suggest acute respiratory distress syndrome.

Ultrasonography does not establish a diagnosis of acute pancreatitis. The swollen pancreas may be seen, but ultrasonography should be performed within 24 hours in all patients to detect gallstones as a potential cause, rule out acute cholecystitis as a differential diagnosis and determine whether the common bile duct is dilated.

CT is not necessary for all patients, particularly those deemed to have a mild attack on prognostic criteria. But a contrast-enhanced CT is indicated in the following situations:

- If there is diagnostic uncertainty.
- In patients with severe acute pancreatitis to distinguish interstitial from necrotising pancreatitis (***Figure 72.22***). In the first 72 hours, CT may underestimate the extent of necrosis. The severity of pancreatitis detected on CT may be staged according to the Balthazar criteria.
- In patients with organ failure, signs of sepsis or progressive clinical deterioration.
- When a localised complication is suspected, such as fluid collection, pseudocyst or a pseudoaneurysm.

Cross-sectional MRI can yield similar information to that obtained by CT. EUS and MRCP can help in detecting stones in the common bile duct and directly assessing the pancreatic parenchyma but are not widely available. ERCP allows the identification and removal of stones in the common bile duct in gallstone pancreatitis. In patients with severe acute gallstone pancreatitis and signs of ongoing biliary obstruction and cholangitis, an urgent ERCP should be sought.

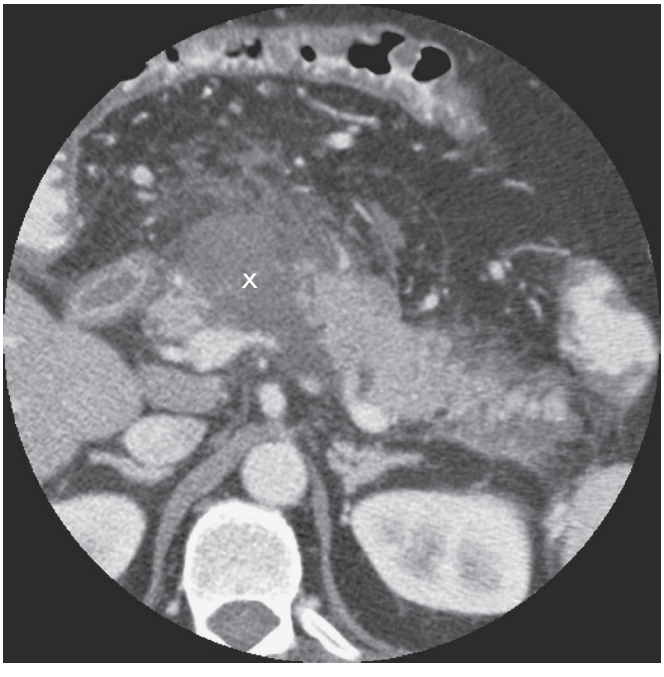

Figure 72.22 Contrast-enhanced computed tomography scan showing acute necrotising pancreatitis. Note the area of reduced enhancement in the pancreas (marked X), the peripancreatic oedema and stranding of the fatty tissues (courtesy of Dr Niall Power).

The presentation is so variable that sometimes even an experienced clinician can be mistaken. While this is not desirable, occasionally the diagnosis is only made at laparotomy. The appearances at laparotomy are characteristic (***Figure 72.23***).

Emil J Balthazar, contemporary, Professor Emeritus, Department of Radiology, New York University, New York, NY, USA.

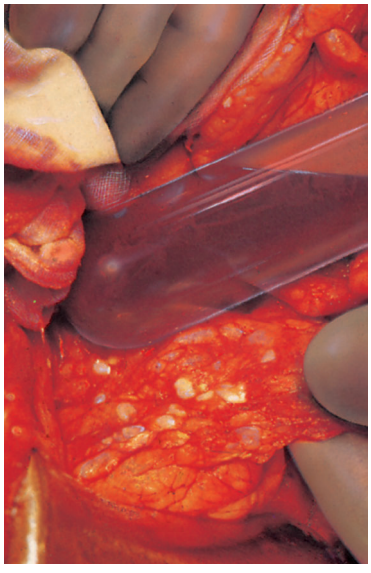

Figure 72.23 Widespread fat necrosis of the omentum. A test tube has been filled with blood-stained peritoneal fluid. This specimen was rich in amylase. Fat necroses are dull, opaque, yellow-white areas suggestive of drops of wax. They are most abundant in the vicinity of the pancreas but are widespread in the greater omentum and the mesentery. Fat necroses consist of small islands of saponification caused by the liberation of lipase, which splits into glycerol and fatty acids. Free fatty acids combine with calcium to form soaps (fatty necrosis) (courtesy of Dr GD Adhia, Mumbai, India).

TABLE 72.4 Early management of severe acute pancreatitis.

Admission to HDU/ICU
Analgesia
Aggressive fluid rehydration
Supplemental oxygen
Invasive monitoring of vital signs, central venous pressure, urine output, blood gases
Frequent monitoring of haematological and biochemical parameters (including liver and renal function, clotting, serum calcium, blood glucose)
Nasogastric drainage (only initially)
Antibiotics if cholangitis suspected; prophylactic antibiotics can be considered
CT scan essential if organ failure, clinical deterioration or signs of sepsis develop
ERCP within 72 hours for severe gallstone pancreatitis or signs of cholangitis
Supportive therapy for organ failure if it develops (inotropes, ventilatory support, haemofiltration, etc.)
If nutritional support is required, consider enteral (nasogastric) feeding

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; HDU, high-dependency unit; ICU, intensive care unit.

Management

If after initial assessment a patient is considered to have a mild attack of pancreatitis, a conservative approach is indicated with intravenous fluid administration and frequent, but non-invasive, observation. A brief period of fasting may be sensible in a patient who is nauseated and in pain, but there is little physiological justification for keeping patients on a prolonged 'nil by mouth' regimen. Antibiotics are not indicated. Apart from analgesics and antiemetics, no drugs or interventions are warranted, and CT scanning is unnecessary unless there is evidence of deterioration. However, if a stable patient meets the prognostic criteria for a severe attack of pancreatitis, then a more aggressive approach is required, with admission to a high-dependency or intensive care unit and invasive monitoring (***Table 72.4***).

Adequate analgesia should be administered. Aggressive fluid resuscitation is important, guided by frequent measurement of vital signs, urine output and central venous pressure. Supplemental oxygen should be administered and serial arterial blood gas analysis performed. The haematocrit, clotting profile, blood glucose and serum levels of calcium and magnesium should be closely monitored.

A nasogastric tube is not essential but may be of value in patients with vomiting. Specific treatments such as aprotinin, somatostatin analogues, platelet-activating factor inhibitors and selective gut decontamination have failed to improve outcome in numerous clinical trials. There are no data to support a practice of 'resting' the pancreas and feeding only by the parenteral or nasojejunal routes. If nutritional support is felt to be necessary, enteral nutrition (e.g. feeding via a nasogastric tube) should be used.

There is some evidence to support the use of prophylactic antibiotics in patients with severe acute pancreatitis but there is no consensus. The rationale is to prevent local and other septic complications. The regimens used include intravenous cefuroxime, or imipenem, or ciprofloxacin plus metronidazole. The duration of antibiotic prophylaxis should not exceed 14 days. Additional antibiotic use should be guided by microbiological cultures. If, however, there is evidence of cholangitis or concomitant respiratory or urinary infection then antibiotics should be given promptly.

If gallstones are the cause of an attack of predicted or proven severe pancreatitis, or if the patient has jaundice, cholangitis or a dilated common bile duct, ERCP should be carried out within 72 hours of the onset of symptoms as sphincterotomy and clearance of the bile duct can reduce the incidence of infective complications. In patients with cholangitis, sphincterotomy should be carried out or a biliary stent placed to drain the duct; however, ERCP is an invasive procedure and carries a small risk of worsening the pancreatitis.

Systemic complications

Pancreatitis may involve all organ systems (***Table 72.5***) and should be managed by a multidisciplinary team including intensive care specialists. When there is organ failure, appropriate supportive therapies may include inotropic support for haemodynamic instability, haemofiltration in the event of renal failure, ventilatory support for respiratory failure and

correction of coagulopathies (including DIC). Surgery has no role during the initial period of resuscitation and stabilisation and is reserved for the patient who deteriorates following successful stabilisation.

Local complications and their management

Once the patient survives the acute phase and major organ failure is controlled, local complications become pre-eminent as they carry a significant mortality. A CT scan should be performed if pain persists, signs of sepsis develop, organ dysfunction worsens or there is a further spike in the serum amylase level. The management is conservative with surgery only when conservative management has failed. Definitions are important. Terms such as 'phlegmon', which may refer to an abscess or to an inflammatory mass in the pancreas, are best avoided.

TABLE 72.5 Complications of acute pancreatitis.

Systemic	Local
(*More common in the first week*)	(*Usually develop after the first week*)
Cardiovascular	Peripancreatic fluid collection
Shock	Sterile pancreatic necrosis
Arrhythmias	Infected pancreatic necrosis
Pulmonary	Pancreatic abscess
ARDS	Pseudocyst
Renal failure	Pancreatic ascites
Haematological	Pleural effusion
DIC	Portal/splenic vein thrombosis
Metabolic	Pseudoaneurysm
Hypocalcaemia	
Hyperglycaemia	
Hyperlipidaemia	
Gastrointestinal	
Ileus	
Neurological	
Visual disturbances	
Confusion, irritability	
Encephalopathy	
Miscellaneous	
Subcutaneous fat necrosis	
Arthralgia	

ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.

Acute peripancreatic fluid collection

Acute peripancreatic fluid collection (APFC) occurs early in the course of mild pancreatitis without necrosis and is located adjacent to the pancreas. It has no encapsulating wall and is confined within normal fascial planes. The fluid is sterile and most such collections resolve. No intervention is necessary unless a large collection causes symptoms or pressure effects, in which case it can be percutaneously aspirated under ultrasound or CT guidance. Transgastric drainage under endoscopic ultrasound guidance is another option.

Sterile and infected pancreatic necrosis

The term 'pancreatic necrosis' refers to a diffuse or focal area of non-viable parenchyma. This can be identified by an absence of parenchymal enhancement on CT with intravenous contrast. Pancreatic necrosis is typically associated with lysis of peripancreatic fat. This may lead to an *acute necrotic collection* (ANC). This is typically an intra- or extrapancreatic collection containing fluid and necrotic material, with no definable wall. Gradually, over a period of over 4 weeks, this may develop a well-defined inflammatory capsule and evolve into *walled-off necrosis* (WON).

Collections associated with necrotising pancreatitis are sterile to begin with but often become subsequently infected, probably because of translocation of gut bacteria. Infected necrosis is associated with a mortality rate of up to 50%. Sterile necrotic material should not be drained or interfered with. However, if the patient shows signs of sepsis, then one should determine whether the collection is infected (***Figure 72.24***). Aspiration fluid with a fine needle, percutaneously under CT or ultrasound guidance, can provide the answer. If the aspirate is purulent, drainage of the infected fluid should be carried out. Internal drainage into the stomach under endoscopic ultrasound guidance should be considered first. A plastic or covered metal stent can be used to create a communication between the collection and the gastric lumen. The stent may be left in for weeks if necessary and may need to be changed if blocked. If endoscopic internal drainage is not possible, then percutaneous drainage should be considered. The tube drain inserted should have the *widest* bore possible. The aspirate should be sent for microbiological assessment and appropriate antibiotic therapy should be commenced as per the sensitivity report. The fluid can be quite viscous with particulate matter, and the drain may need regular flushing with full aseptic

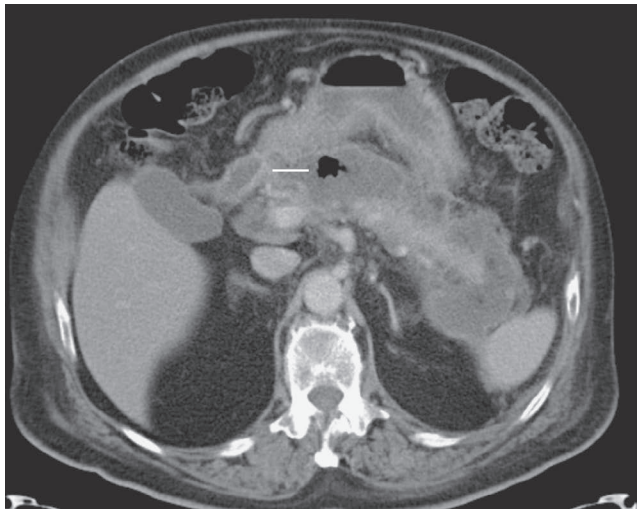

Figure 72.24 Infected pancreatic necrosis. Note the areas of reduced enhancement in the pancreas and the peripancreatic fluid collection with pockets of gas within it (arrow). This resolved after percutaneous drainage and antibiotic therapy.

precautions. Often, repeated imaging and repeated insertion of progressively wider drains is necessary.

Pancreatic necrosectomy should be considered if sepsis worsens despite conservative measures. This is a challenging operation that carries a high morbidity and mortality; it is best carried out in a specialist unit and is necessary only in a very small proportion of patients. The surgical approach may be through a midline laparotomy, especially if the area involved is around the pancreatic head. The duodenocolic and gastrocolic ligaments should be divided and the lesser sac opened. Thorough debridement of the dead tissue around the pancreas should be carried out. If the body and tail of the gland are primarily involved (***Figure 72.25***), a retroperitoneal approach through a left flank incision may be more appropriate. The tissues are inevitably friable, and one should be careful not to precipitate excessive bleeding or inadvertently breach the bowel wall. Blunt dissection is preferable to sharp dissection. A feeding jejunostomy may be a useful adjunct to the procedure. If gallstones are the precipitating factor of the pancreatitis, a cholecystectomy should be included. Some prefer a minimally invasive approach to a formal laparotomy. A rigid laparoscope is inserted into the peripancreatic area through a retroperitoneal approach, and vigorous irrigation and suction is combined with a gradual nibbling away of the necrotic debris.

Once a necrosectomy has been completed, further necrotic tissue may form. There are several possible ways of dealing with this (listed below), none of which has been proved to be more effective than the others. The last two approaches make greater logistic demands as one is committed to a re-exploration every 48–72 hours.

- **Closed continuous lavage.** Tube drains are left in and the raw area flushed (Beger) (***Figure 72.26***).
- **Closed drainage.** The incision is closed, but the cavity is packed with gauze-filled Penrose drains and closed suction drains. The Penrose drains are brought out through the flank and slowly pulled out and removed after 7 days.
- **Open packing.** The incision is left open, and the cavity is packed with the intention of returning to the operating room at regular intervals and repacking until there is a clean granulating cavity.
- **Closure and relaparotomy.** The incision is closed with drains with the intention of performing a series of planned relaparotomies every 48–72 hours until the raw area granulates (Bradley).

There is a subgroup of patients who respond initially to percutaneous treatment but then develop recurrent sepsis that requires repeated insertion of drains and fail to thrive. Necrosectomy should be considered in these patients, but it can be a difficult judgement call.

Patients with peripancreatic sepsis are ill for long periods of time and may require management in an intensive care unit. Nutritional support is essential. The parenteral and nasojejunal approaches are more popular (on the assumption that they rest the pancreas), although there is little evidence to show that nasogastric feeding, if tolerated, is harmful in any way.

Figure 72.25 Necrotic body and tail of the pancreas removed as an intact specimen rather than piecemeal. The patient had suffered severe necrotising gallstone pancreatitis complicated by persistent pancreatic sepsis. Necrosectomy was carried out through a left flank retroperitoneal approach.

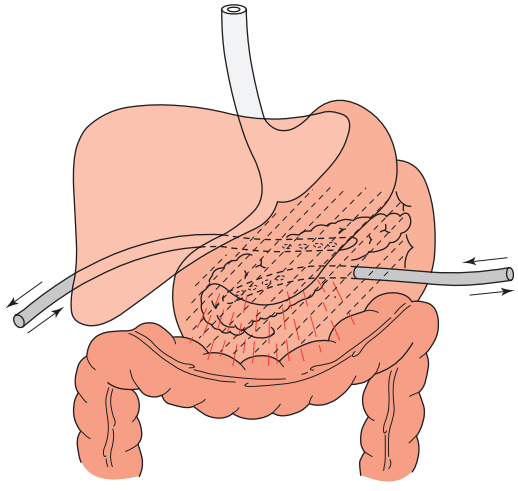

Figure 72.26 Continuous postoperative closed lavage of the lesser sac as advised by Beger. Lavage is carried out through several double-lumen and single-lumen catheters. Each time, 1 litre of saline is infused through and then drained over a period of hours, and the process is repeated.

Pancreatic abscess

This is a circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas. It may be an ANC or a WON that has become infected. The principles of diagnosis and management are as outlined above for infected pancreatic necrosis. Endoscopic internal drainage or, failing that, percutaneous drainage with the widest possible drains is the treatment, along with appropriate antibiotics and supportive care. Repeated scans may be required depending on the progress of the patient, and drains may need to be flushed, repositioned or reinserted. Very occasionally, open drainage of the abscess may be necessary.

Hans Günter Beger, b. 1936, Emeritus Professor of Surgery, Ulm, Germany.
Charles Bingham Penrose, 1862–1925, Professor of Gynecology, University of Pennsylvania, Philadelphia, PA, USA.
Edward Bradley III, contemporary, Emeritus Professor of Surgery, Florida State University College of Medicine, FL, USA.

Pancreatic ascites

This is a chronic, generalised, peritoneal, enzyme-rich effusion usually associated with pancreatic duct disruption. Paracentesis will reveal turbid fluid with a high amylase level. Adequate drainage with wide-bore drains placed under imaging guidance is essential. Measures that can be taken to suppress pancreatic secretion include parenteral or nasojejunal feeding and administration of octreotide. An ERCP may demonstrate duct disruption and allow placement of a pancreatic stent.

Pancreatic effusion

This is an encapsulated collection of fluid in the pleural cavity, arising as a consequence of acute pancreatitis. Concomitant pancreatic ascites may be present or there may be a communication with an intra-abdominal collection. Percutaneous drainage under imaging guidance is necessary.

Haemorrhage

Bleeding may occur into the gut, the retroperitoneum or peritoneal cavity. Possible causes include bleeding into a pseudocyst cavity, diffuse bleeding from a large raw surface or a pseudoaneurysm. The last is a false aneurysm of a major peripancreatic vessel confined as a clot by the surrounding tissues and often associated with infection. Recurrent bleeding is common, often culminating in fatal haemorrhage. CT, angiography or magnetic resonance angiography helps to make the diagnosis. Treatment involves embolisation or surgery.

Portal or splenic vein thrombosis

This may develop silently and is identified on a CT scan. A marked rise in the platelet count should raise suspicions. In the context of acute pancreatitis, treatment is usually conservative. The patient should be screened for procoagulant tendencies. If varices or other manifestations of portal hypertension develop, they will require treatment, such as endoscopic injection or banding, β-blockade, etc. Thrombocytosis may mandate the use of aspirin or other antiplatelet drugs for a period. Systemic anticoagulation, if instituted early in the process, may achieve recanalisation of the vein but it is not routinely used as it carries considerable risks in a patient with ongoing pancreatitis.

Pseudocyst

A pseudocyst is a collection of amylase-rich fluid enclosed in a well-defined wall of fibrous or granulation tissue. Pseudocysts typically arise following an attack of mild acute pancreatitis, lie outside the pancreas and represent an APFC that has not resolved and matured. Formation of a pseudocyst requires 4 weeks or more from the onset of acute pancreatitis. The term 'pseudocyst' is often used more loosely to include sterile WON that has failed to resolve or a collection that has developed in the context of chronic pancreatitis or after pancreatic trauma. (***Figure 72.27***; see also ***Figure 72.10***). More than half have a communication with the main pancreatic duct. Pseudocysts are often single but are occasionally multiple.

It is important to differentiate a pseudocyst from an APFC; the clinical scenario and radiological appearances should allow that distinction to be made. Occasionally, a cystic neoplasm may be confused with a chronic pseudocyst. EUS and aspiration of the cyst fluid are very useful in such a situation. The fluid should be sent for measurement of carcinoembryonic antigen (CEA) levels, amylase levels and cytology. Fluid from a pseudocyst typically has a low CEA level, and levels above 400 ng/mL are suggestive of a mucinous neoplasm. Pseudocyst fluid usually has a high amylase level, but that is not diagnostic as a tumour that communicates with the duct system may yield similar findings. Cytology typically reveals inflammatory cells in pseudocyst fluid. If there is no access to EUS, then percutaneous FNA is acceptable (just aspiration, *not* percutaneous insertion of a drain). ERCP and MRCP may demonstrate communication of the cyst with the pancreatic duct system, demonstrate ductal anomalies or diagnose chronic pancreatitis, and thus help in planning treatment.

Pseudocysts usually resolve spontaneously, but complications can develop (***Table 72.6***). Pseudocysts that are thick walled or large (>6 cm in diameter), have lasted for a long time (over 12 weeks) or have arisen in the context of chronic pancreatitis are less likely to resolve spontaneously. Therapeutic intervention is advised only if the pseudocyst causes symptoms, complications develop or distinction has to be made between a pseudocyst and a tumour.

There are three possible approaches to draining a pseudocyst: percutaneous, endoscopic and surgical. Percutaneous drainage to the exterior under radiological guidance should be avoided. It carries a very high likelihood of recurrence. Moreover, it is not advisable unless one is absolutely certain that the cyst is not neoplastic and that it has no communication with the pancreatic duct (or else a pancreaticocutaneous fistula will develop). A percutaneous transgastric cystgastrostomy can be performed under imaging guidance, and a double-pigtail drain placed with one end in the cyst cavity and the other end in the gastric lumen. In experienced hands, recurrence rates are no more than 15%. Endoscopic drainage usually involves

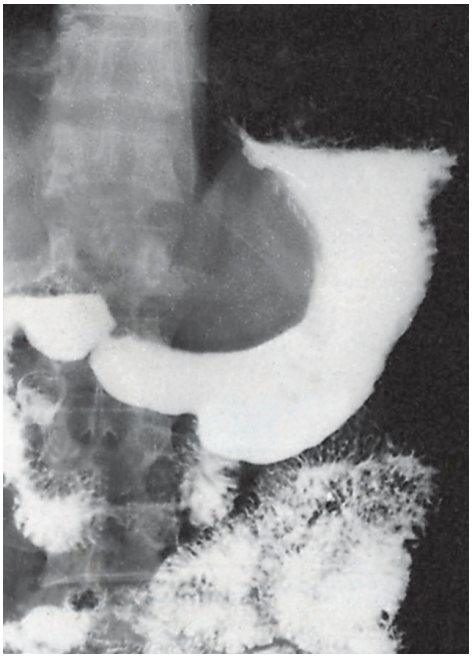

Figure 72.27 Barium meal. Pseudocyst displacing the stomach (courtesy of Professor VK Kapoor, Lucknow, India).

TABLE 72.6 Possible complications of a pancreatic pseudocyst.

Process	Outcomes
Infection	Abscess
	Systemic sepsis
Rupture	
Into the gut	Gastrointestinal bleeding
	Internal fistula
Into the peritoneum	Peritonitis
Enlargement	
Pressure effects	Obstructive jaundice from biliary compression
	Bowel obstruction
Pain	
Erosion into a vessel	Haemorrhage into the cyst
	Haemoperitoneum

puncture of the cyst through the stomach or duodenal wall under endoscopic ultrasound guidance, and placement of a tube drain with one end in the cyst cavity and the other end in the gastric lumen. The success rates depend on operator expertise. Occasionally, ERCP and placement of a pancreatic stent across the ampulla may help to drain a pseudocyst that is in communication with the duct. Surgical drainage involves internally draining the cyst into the gastric or jejunal lumen (***Figure 72.28***). Recurrence rates should be no more than 5%, and this still remains the standard against which the evolving radiological and endoscopic approaches are measured. The approach is conventionally through an open incision but laparoscopic cystgastrostomy is also feasible. Pseudocysts that have developed complications are best managed surgically.

There is a small group of patients who, having suffered an attack of necrotising pancreatitis with duct disruption, go on to suffer repeated complications in the form of recurrent fluid collections, pseudocysts, pleural effusions or pancreatic ascites. Very often disruption of the main pancreatic duct in the neck, body or tail is compounded by a stricture or a stone in the head that cannot be treated endoscopically. In such patients, some form of surgical resection and/or a drainage procedure – even though it may be technically challenging – may be the only way to achieve lasting resolution.

Summary box 72.8

Distinguishing a pseudocyst from a cystic neoplasm

- History
- Appearance on CT and ultrasonography
- FNA of fluid, preferably under endoscopic ultrasound guidance:
  - CEA (high level in mucinous tumours)
  - Amylase (level usually high in pseudocysts but occasionally in tumours)
  - Cytology

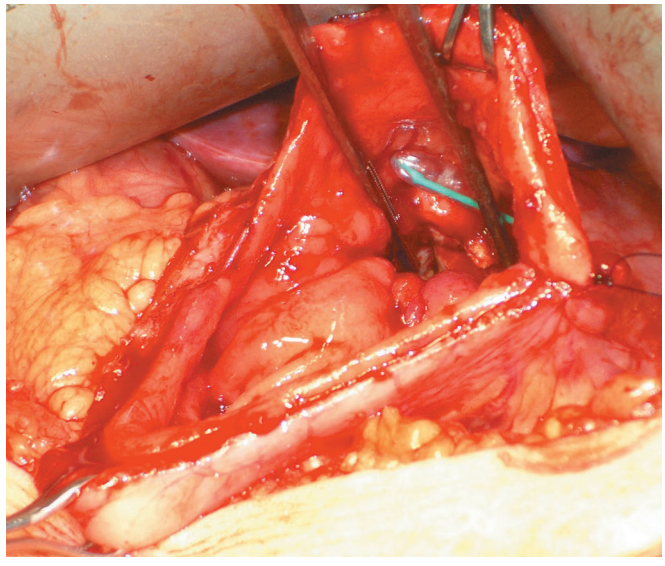

Figure 72.28 Cystgastrostomy for the pancreatic pseudocyst shown in ***Figure 72.10***. The anterior wall of the stomach has been opened and the edges drawn back, held by Babcock's forceps. An opening has been made through the posterior wall of the stomach into the pseudocyst and the tips of the dissecting forceps are in the cavity of the pseudocyst, which is lined by slough and granulation tissue. The tip of a nasogastric tube is visible. A running stitch will next be placed along the edges of this opening, suturing the full thickness of the posterior gastric wall to the capsule of the pseudocyst.

Outcomes and follow-up of acute pancreatitis

The overall mortality from acute pancreatitis has remained at 10–15% over the past 20 years. There is a clear responsibility before the patient is discharged to determine the aetiology of the attack of pancreatitis and the causes listed in ***Summary box 72.5*** must be looked for and excluded. Failure to remove a predisposing factor could lead to a second attack of pancreatitis, which could be fatal. A proportion of patients in the idiopathic group who suffer repeated attacks may prove to have biliary microlithiasis, which can be identified only by bile sampling at ERCP or by EUS. In a patient who has gallstone pancreatitis, the gallbladder and gallstones should be removed as soon as the patient is fit to undergo surgery and, preferably, before discharge from hospital.

Chronic pancreatitis

Chronic pancreatitis is a progressive inflammatory disease in which there is irreversible destruction of pancreatic tissue. Its clinical course is characterised by severe pain and, in the later stages, exocrine and endocrine pancreatic insufficiency. In the early stages of its evolution, it is frequently complicated by attacks of acute pancreatitis, which are responsible for the recurrent pain that may be the only clinical symptom. The incidence of chronic pancreatitis in several European, North American and Japanese studies ranges from 2 to 10 new cases per 100 000 population per year, with a prevalence of around 13 cases per 100 000, although there are suspicions that the prevalence is actually higher. In certain parts of the world, such

William Wayne Babcock, 1872–1963, surgeon, Philadelphia, PA, USA.

as southern India, the prevalence is much higher (100–200 per 100 000). The disease occurs more frequently in men (male-to-female ratio of 4:1) and the mean age of onset is about 40 years.

Aetiology and pathology

High alcohol consumption is the most frequent cause of chronic pancreatitis, accounting for 60–70% of cases, but only 5–10% of people with alcoholism develop chronic pancreatitis. The exact mechanism of how alcohol causes chronic inflammation in these patients is unclear; genetic and metabolic factors may be at play.

Other causes include pancreatic duct obstruction resulting from stricture formation after trauma, after acute pancreatitis or even occlusion of the duct by pancreatic cancer. Congenital abnormalities, such as pancreas divisum and annular pancreas, if associated with papillary stenosis, are rare causes of chronic pancreatitis.

Hereditary pancreatitis, CF, infantile malnutrition and a large unexplained idiopathic group make up the remainder. Normally, if trypsinogen becomes prematurely activated within the pancreas, it is inhibited by *SPINK1* and is destroyed. Hereditary pancreatitis is an autosomal dominant disorder with an 80% penetrance; it is associated with a gain-of-function mutation in the cationic trypsinogen gene (*PRSS1*) on chromosome 7, which leads to production of a degradation-resistant form of trypsin. A loss-of-function mutation in *SPINK1* also predisposes to idiopathic pancreatitis. Some patients with idiopathic chronic pancreatitis have mutations in the *CFTR* gene. Idiopathic chronic pancreatitis accounts for approximately 30% of cases and has been subdivided into early-onset and late-onset forms.

The importance of hereditary pancreatitis and pancreatitis occurring at a young age is that there is a markedly increased risk of developing pancreatic cancer, particularly if the patient smokes tobacco. Hyperlipidaemia and hypercalcaemia can lead to chronic pancreatitis.

Tropical pancreatitis is a form of idiopathic pancreatitis that begins at a young age and is associated with a high incidence of diabetes mellitus and stone formation. This has been described in resource-poor countries in Asia, Africa and central America. Malnutrition, ingestion of cyanogenic glycosides in cassava and exposure to hydrocarbons released by kerosene or paraffin lamps have been proposed as possible mechanisms for tropical pancreatitis.

Autoimmune pancreatitis has been described relatively recently. Features include diffuse enlargement of the pancreas and diffuse and irregular narrowing of the main pancreatic duct. It may occur in association with other autoimmune diseases, as a multisystem disorder, or may affect the pancreas alone. There may be changes in the biliary tree (autoimmune cholangiopathy) as well. The changes may be confused with neoplasia. Autoantibodies may be present and levels of the immunoglobulin subtype IgG4 are elevated.

At the onset of the disease when symptoms have developed, the pancreas may appear normal. Later, the pancreas enlarges and becomes hard as a result of fibrosis. The ducts become distorted and dilated with areas of both stricture formation and ectasia. Calcified stones weighing from a few milligrams to 200 mg may form within the ducts. The ducts may become occluded with a gelatinous proteinaceous fluid and debris and inflammatory cysts may form. Histologically, the lesions affect the lobules, producing ductular metaplasia and atrophy of acini, hyperplasia of duct epithelium and interlobular fibrosis.

Clinical features

Pain is the outstanding symptom in the majority of patients. The site of pain depends to some extent on the main focus of the disease. If the disease is mainly in the head of the pancreas then epigastric and right subcostal pain is common, whereas if it is limited to the left side of the pancreas left subcostal and back pain are the presenting symptoms. In some patients, the pain is more diffuse. Radiation to the shoulder can occur. Nausea is common during attacks and vomiting may occur. The pain is often dull and gnawing. Severe flare-ups of pain may be superimposed on background discomfort.

All the complications of acute pancreatitis can occur with chronic pancreatitis. Weight loss is common because the patient does not feel like eating. The pain prevents sleep and time off work is frequent. The number of hospital admissions for acute exacerbations is a pointer towards the severity of the disease. Analgesic use and abuse are frequent. This, too, gives an indication of the severity of the disability. The patient's lifestyle is gradually destroyed by pain, analgesic dependence, weight loss and inability to work. Loss of exocrine function leads to steatorrhoea in more than 30% of patients with chronic pancreatitis. Loss of endocrine function and the development of diabetes are not uncommon, and the incidence increases as the disease progresses. Complications frequently bring the patient to the attention of the surgeon. Infection is not infrequent, possibly related to the diabetes mellitus.

Investigations

Only in the early stages of the disease will there be a rise in serum amylase. Tests of pancreatic function merely confirm the presence of pancreatic insufficiency or that more than 70% of the gland has been destroyed.

Pancreatic calcifications may be seen on abdominal radiographs (***Figure 72.18***). CT or MRI scan will show the outline of the gland, the main area of damage and the possibilities for surgical correction (***Figure 72.29***; see also ***Figure 72.7***). Calcification is seen very well on CT but not on MRI. An MRCP will identify the presence of biliary obstruction and the state of the pancreatic duct (***Figure 72.30***). The use of intravenous secretin during the study may demonstrate a pancreatic duct stricture not apparent on standard MRCP, but a normal-looking pancreas on CT or MRI does not rule out chronic pancreatitis. ERCP is the most accurate way of elucidating the anatomy of the duct and, in conjunction with the whole organ morphology, can help to determine the type of operation required, if operative intervention is indicated. Histologically proven chronic pancreatitis can, however, occur in the setting of normal findings on pancreatography. Sonographic findings characteristic of chronic pancreatitis include the presence of stones, visible side branches, cysts, lobularity, an irregular main pancreatic duct, hyperechoic foci and strands, dilatation of the main pancreatic duct and hyperechoic margins of the main pancreatic duct. The

presence of four or more of these features is highly suggestive of chronic pancreatitis.

Treatment

Most patients can be managed with medical measures. There is no single therapeutic agent that has been shown to relieve symptoms (***Summary box 72.9***).

Endoscopic, radiological or surgical interventions are indicated mainly to relieve obstruction of the pancreatic duct, bile duct or the duodenum, or in dealing with complications (e.g. pseudocyst, abscess, fistula, ascites or variceal haemorrhage). Decompressing an obstructed pancreatic duct can provide pain relief in some patients (the assumption is that ductal hypertension causes the pain).

Endoscopic pancreatic sphincterotomy might be beneficial in patients with papillary stenosis and a high sphincter pressure and pancreatic ductal pressure. Patients with a dominant pancreatic duct stricture and upstream dilatation may benefit by placement of a stent across the stricture. The stent should be left in for no more than 4–6 weeks as it will block. The complication rate is high and less than two-thirds of patients experience pain relief, but those who do get relief may benefit from a surgical bypass. Pancreatic duct stones may be extracted at ERCP; this may sometimes be combined with extracorporeal shock wave lithotripsy. Pseudocysts may be drained internally under endoscopic ultrasound guidance. Percutaneous or transgastric drainage of pseudocysts under ultrasound or CT guidance may be performed.

The role of surgery is to overcome obstruction and remove mass lesions. Some patients have a mass in the head of the pancreas, for which either a pancreatoduodenectomy or a Beger procedure (duodenum-preserving resection of the pancreatic head) is appropriate. If the duct is markedly dilated, then a longitudinal pancreatojejunostomy or Frey procedure can be of value (***Figure 72.31***). The natural evolution of the disease may not be altered significantly, but around half the patients get long-term pain relief. The rare patient with disease limited to the tail will be cured by a distal pancreatectomy. Patients with intractable pain and diffuse disease may plead for a total pancreatectomy in the expectation that removing the

Summary box 72.9

Medical treatment of chronic pancreatitis

Treat the addiction

- Help the patient to stop alcohol consumption and tobacco smoking
- Involve a dependency counsellor or a psychologist

Alleviate abdominal pain

- Eliminate obstructive factors (duodenum, bile duct, pancreatic duct)
- Escalate analgesia in a stepwise fashion
- Refer to a pain management specialist
- For intractable pain, consider CT/EUS-guided coeliac axis block

Nutritional and pharmacological measures

- Diet: low in fat and high in protein and carbohydrates
- Pancreatic enzyme supplementation with meals
- Correct malabsorption of the fat-soluble vitamins and vitamin B12
- Micronutrient therapy with methionine, vitamins C and E, selenium (may reduce pain and slow disease progression)
- Steroids (only in autoimmune pancreatitis, for relief of symptoms)
- Medium-chain triglycerides in patients with severe fat malabsorption (they are directly absorbed by the small intestine without the need for digestion)
- Reducing gastric secretions may help

Treat diabetes mellitus

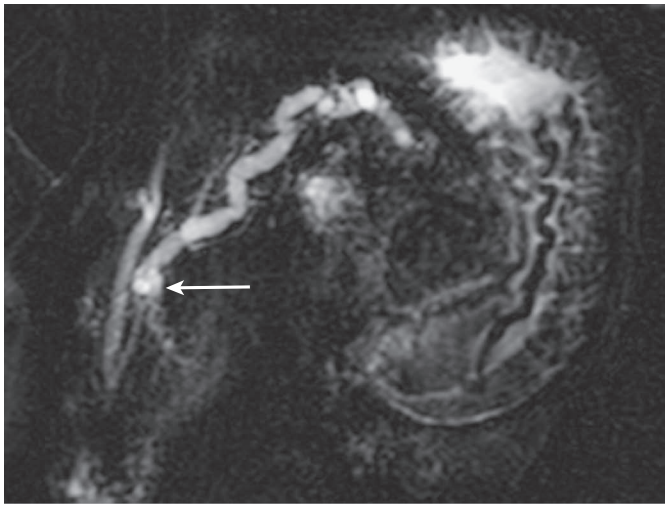

Figure 72.30 Magnetic resonance cholangiopancreatography in a patient with chronic pancreatitis, showing a stricture of the pancreatic duct in the body of the gland (arrow), with dilatation upstream.

Charles Frederick Frey, b. 1929, Professor of Surgery, University of California, Davis, CA, USA.

offending organ will relieve their pain. However, one should keep in mind that pancreatic function and quality of life are significantly impaired after this procedure, and the operative mortality rate is not trivial. Moreover, there is no guarantee of pain relief (approximately a third of patients get resolution, a third show some benefit and a third see no benefit at all). Total pancreatectomy and islet autotransplantation have been reported in selected patients, but it is difficult to demonstrate any overall benefit.

Prognosis

Chronic pancreatitis is a difficult condition to manage. Patients often suffer a gradual decline in their professional, social and personal lives. The pain may abate after a surgical or percutaneous intervention but tends to return over a period of time. In a proportion of patients, the inflammation may gradually burn out over a period of years, with disappearance of the pain, leaving only the exocrine and endocrine insufficiencies. Development of pancreatic cancer is a risk in those who have had the disease for more than 20 years. New symptoms or a change in the pattern of symptoms should be investigated and malignancy excluded.

Sphincter of Oddi dysfunction

Sphincter of Oddi dyskinesia or dysfunction (SOD) is a clinical syndrome in which pain, biochemical abnormalities and dilatation of the bile duct and/or pancreatic duct are attributed to abnormal function of the sphincter of Oddi. The true incidence of SOD is unknown. Females are more commonly affected than males. SOD may result from stenosis of the sphincter or from dysmotility. Scarring or stenosis of the sphincter can result from passage of stones, pancreatitis or prior endoscopic sphincterotomies.

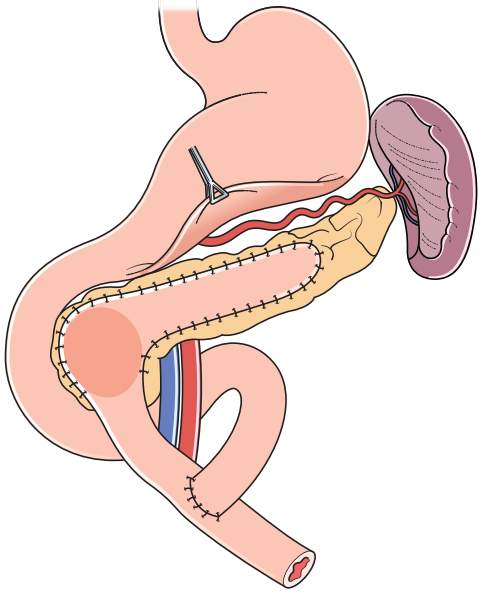

Figure 72.31 Pancreatojejunostomy. The pancreatic duct is opened longitudinally and a loop of jejunum is sutured to the duct. In the Frey procedure, the superficial part of the head of the pancreas is removed to achieve drainage.

There are two clinical types of SOD. Biliary-type SOD is characterised by biliary pain, which may be accompanied by abnormally raised liver enzymes and/or dilatation of the bile duct and/or evidence of delayed emptying on biliary scintigraphy. It may be a cause of persistent postcholecystectomy symptoms. A predominance of pancreatic problems, especially recurrent episodes of acute pancreatitis, is known as pancreatic-type SOD. Each type of SOD is further divided into types I, II and III (***Table 72.7***). This classification helps to predict the underlying pathology and the likelihood of successful treatment. Type I disease is thought to result from a fixed stenosis and responds best to therapy. An episodic dysmotility is the presumed underlying abnormality in the other types and often does not respond as well to treatment.

Biliary-type SOD should be considered and excluded in patients with the postcholecystectomy syndrome. Pancreatic-type SOD should be excluded in patients with recurrent acute pancreatitis of unexplained aetiology. The role of SOD in chronic pancreatitis is unclear. A careful history is essential. CT and MRCP can demonstrate dilatation of the biliary and pancreatic ducts. MRCP with intravenous secretin injection can particularly demonstrate pancreatic duct dilatation due to raised sphincter pressures. EUS may achieve the same end. Quantitative cholescintigraphy (hepatobiliary iminodiacetic acid [HIDA] scan) may demonstrate delayed biliary transit. ERCP with manometry is indicated to confirm the diagnosis if the pain is disabling, non-invasive investigations have not shown structural abnormalities and conservative therapy has

TABLE 72.7 Milwaukee classification of sphincter of Oddi (SOD) dysfunction.

1. Biliary-type SOD
Type I: Typical biliary-type pain Liver enzymes (AST, ALT or ALP) >2 times normal limit documented on at least two occasions during episodes of pain Dilated CBD >12 mm in diameter Prolonged biliary drainage time (>45 min)[a]
Type II: Biliary-type pain, and One or two of the above criteria
Type III: Biliary-type pain only
2. Pancreatic-type SOD
Type I: Pancreatic-type pain Amylase and/or lipase >2 times upper normal limit on at least two occasions during episodes of pain Dilated pancreatic duct (head >6 mm, body >5 mm) Prolonged pancreatic drainage time (>9 min)[a]
Type II: Pancreatic-type pain, and one or two of the above criteria
Type III: Pancreatic-type pain only

AST, aspartate aminotransferase; ALT, alanine aminotransferase; ALP, alkaline phosphatase; CBD, common bile duct.

[a]Difficult to measure and often eschewed in clinical practice.

not helped. A basal sphincter pressure higher than 40 mmHg is the manometric criterion used to diagnose SOD.

Endoscopic sphincterotomy is the treatment of choice for type I SOD. The question of whether dual sphincterotomies (biliary and pancreatic) should be carried out remains unanswered. There is however a particularly high risk of post-ERCP pancreatitis (30% or more), though placement of a pancreatic stent at the time of the procedure appears to reduce this risk. For patients with type II SOD, manometry should be done before considering sphincterotomy, and the results of sphincterotomy are less consistent. Patients with type III SOD are even more difficult, with response rates to sphincterotomy ranging from 8% to 65%. Medical therapy should be tried before proceeding to manometry. Proton pump inhibitors, spasmolytic drugs, calcium blockers (nifedipine) and psychotropic agents have all been tried with varying degrees of success. Injection of botulinum toxin (which can cause a chemical sphincterotomy for up to 3 months) or placement of a pancreatic stent (these are usually removed after 6 weeks) do not provide lasting relief but can be used to identify patients who may benefit from a sphincterotomy.

In a small subgroup of patients who have experienced significant but short-lived relief with sphincterotomy or stenting, surgical transduodenal sphincteroplasty may be considered but the long-term results are often poor. In exceptional circumstances, where the pancreatic head is badly scarred after repeated stenting and numerous attacks of pancreatitis and sphincteroplasty has failed or is unlikely to succeed, one should consider surgical resection of the pancreatic head.

TABLE 72.8 Risk factors for the development of pancreatic cancer.

Demographic factors
Age (peak incidence 65–75 years)
Male gender
Black ethnicity
Environment/lifestyle
Cigarette smoking
Genetic factors and medical conditions
Family history
Two first-degree relatives with pancreatic cancer: relative risk increases 18- to 57-fold
Germline *BRCA2* mutations in some rare high-risk families
Hereditary pancreatitis (50- to 70-fold increased risk)
Chronic pancreatitis (5- to 15-fold increased risk)
Lynch syndrome (HNPCC)
Ataxia telangiectasia
Peutz–Jeghers syndrome
Familial breast–ovarian cancer syndrome
Familial atypical multiple mole melanoma
Familial adenomatous polyposis – risk of ampullary/duodenal carcinoma
Diabetes mellitus
Obesity

HNPCC, hereditary non-polyposis colorectal cancer.

CARCINOMA OF THE PANCREAS

Pancreatic cancer is the seventh leading cause of cancer deaths in men and women worldwide. In the USA it follows lung cancer and colorectal cancer as the third most common cause of cancer death. In the UK, it is the tenth most common cancer and its incidence has increased slightly over the last 10 years. Nearly 85% of patients present with unresectable or metastatic disease. Even among those who undergo surgery, 5-year survival is around 20%. There is no simple screening test. Patients with an increased inherited risk of pancreatic cancer (***Table 72.8***) should be referred to specialist units for screening and counselling.

Pathology

More than 85% of pancreatic cancers are ductal adenocarcinomas. The remaining tumours constitute a variety of pathologies with individual characteristics. Endocrine tumours of the pancreas are rare. These are covered in ***Chapter 57***.

Ductal adenocarcinomas arise most commonly in the head of the gland. They are solid, scirrhous tumours, characterised by neoplastic tubular glands within a markedly desmoplastic fibrous stroma. Fibrosis is also a characteristic of chronic pancreatitis, and histological differentiation between tumour and pancreatitis can cause diagnostic difficulties. Ductal adenocarcinomas infiltrate locally, typically along nerve sheaths, along lymphatics and into blood vessels. Liver and peritoneal metastases are common. Proliferative lesions in the pancreatic ducts can precede invasive ductal adenocarcinoma. These are termed pancreatic intraepithelial neoplasia or PanIN, and can demonstrate a range of structural complexity and cellular atypia.

Cystic tumours of the pancreas may be serous or mucinous. Serous cystadenomas are typically found in older women and are large aggregations of multiple small cysts, almost like bubble wrap. They are benign. Mucinous tumours, on the other hand, have the potential for malignant transformation. They include mucinous cystic neoplasms (MCNs) and intraductal papillary mucinous neoplasms (IPMNs). MCNs are seen in perimenopausal women, show up as multilocular thick-walled cysts in the pancreatic body or tail and, histologically, contain an ovarian-type stroma. IPMNs are more common in the pancreatic head and in older men, but an IPMN arising from a branch duct can be difficult to distinguish from an MCN. IPMNs arising within the main duct are often multifocal and have a greater tendency to prove malignant. Thick mucus seen extruding from the ampulla at ERCP is diagnostic of a main duct IPMN. Mucinous tumours can be confused with pseudo-

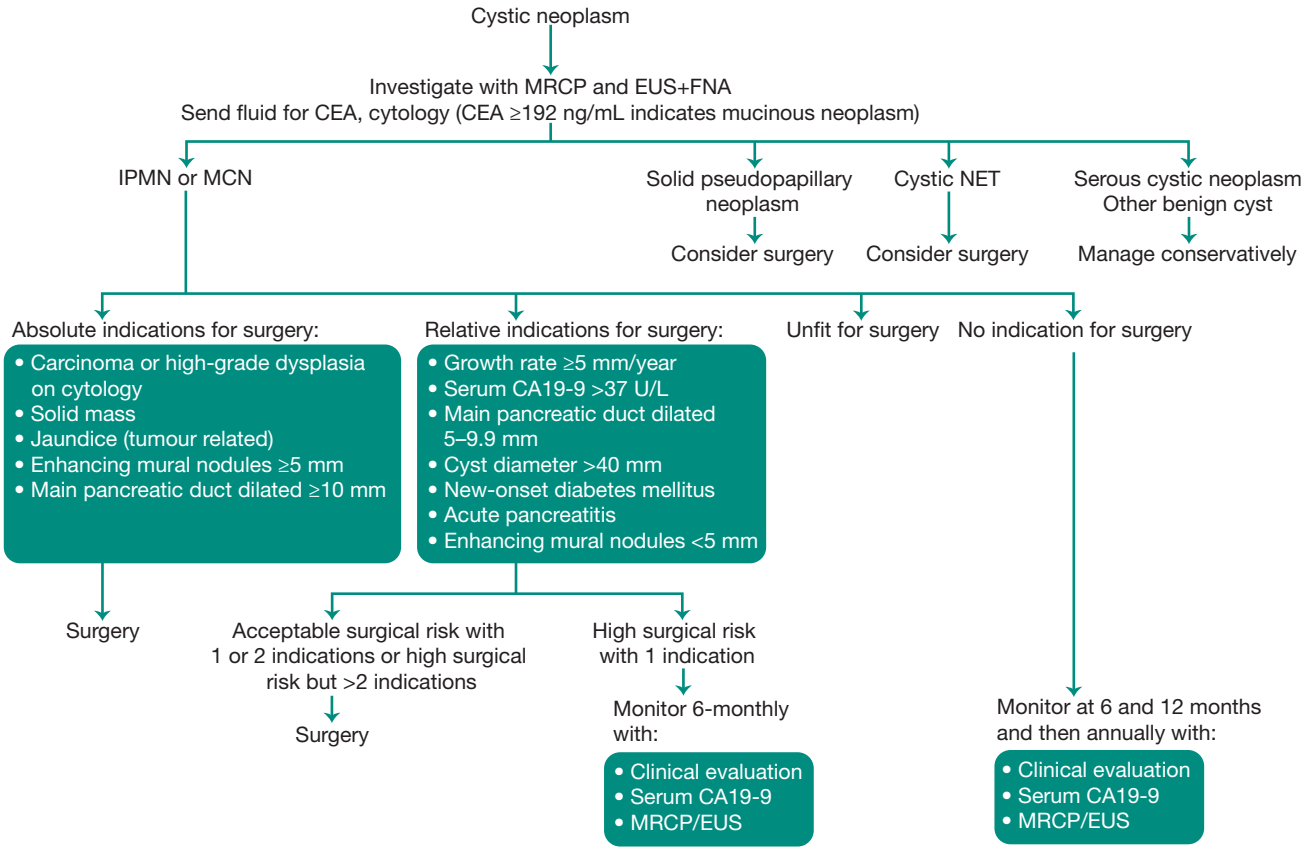

Figure 72.32 Management algorithm for cystic neoplasms of the pancreas. CA19-9, carbohydrate antigen 19-9; CEA, carcinoembryonic antigen; EUS, endoscopic ultrasonography; FNA, fine-needle aspiration; IPMN, intraductal papillary mucinous neoplasm; MCN, mucinous cystic neoplasm; MRCP, magnetic resonance cholangiography and pancreatography; NET, neuroendocrine tumour. (Adapted from The European Study Group on Cystic Tumours of the Pancreas. European evidence-based guidelines on pancreatic cystic neoplasms. *Gut* 2018; **67**: 789–804.)

cysts (***Summary box 72.8 and Figure 72.32***). Occasionally, lymphoepithelial cysts, lymphangiomas, dermoid cysts and intestinal duplication cysts can show up in the pancreas. Solid pseudopapillary neoplasms are rare, slowly progressive but malignant lesions seen in women of childbearing age, and manifest as large, part-solid, part-cystic tumours.

Tumours arising from the ampulla or from the distal common bile duct can present as a mass in the head of the pancreas and constitute around a third of all tumours in that area. Adenomas of the ampulla of Vater are diagnosed at endoscopy as polypoid submucosal masses covered by a smooth epithelium. They can harbour foci of invasive carcinoma; the larger the adenoma, the greater the risk. Biopsies taken at endoscopy may not always include the malignant focus. Endoscopic surveillance, endoscopic resection or even surgical transduodenal ampullary excision should be considered (***Figure 72.33***). Patients with familial adenomatous polyposis (FAP) can present with multiple duodenal polyps. Malignant transformation in a duodenal polyp is a significant cause of mortality in these patients, mandating endoscopic follow-up and pancreatoduodenectomy in selected patients with high-grade dysplasia within the polyp.

Ampullary adenocarcinomas often present early with biliary obstruction. Their natural history is distinctly more favourable than that of pancreatic ductal adenocarcinoma. Ampullary carcinomas are relatively small when diagnosed, which may account for their better prognosis. Occasionally, other malignant neoplasms can arise at the ampulla, such as carcinoid tumours and high-grade neuroendocrine carcinomas.

Clinical features

Jaundice secondary to obstruction of the distal bile duct is the most common symptom that draws attention to ampullary and pancreatic head tumours. It is characteristically painless jaundice but may be associated with nausea and epigastric discomfort. Pruritus, dark urine and pale stools with steatorrhoea are common accompaniments of jaundice. In the absence of jaundice, symptoms are often non-specific, namely vague discomfort, anorexia and weight loss, and are frequently dismissed by both patient and doctor. Upper abdominal symptoms in a patient recently diagnosed with diabetes, especially in one above 50 years of age with no family history or obesity, should raise suspicion. Occasionally, a patient will present with an unexplained attack of pancreatitis; all such patients should have follow-up imaging of the pancreas. Tumours of the body and tail of the gland often grow silently and present at an advanced unresectable stage.

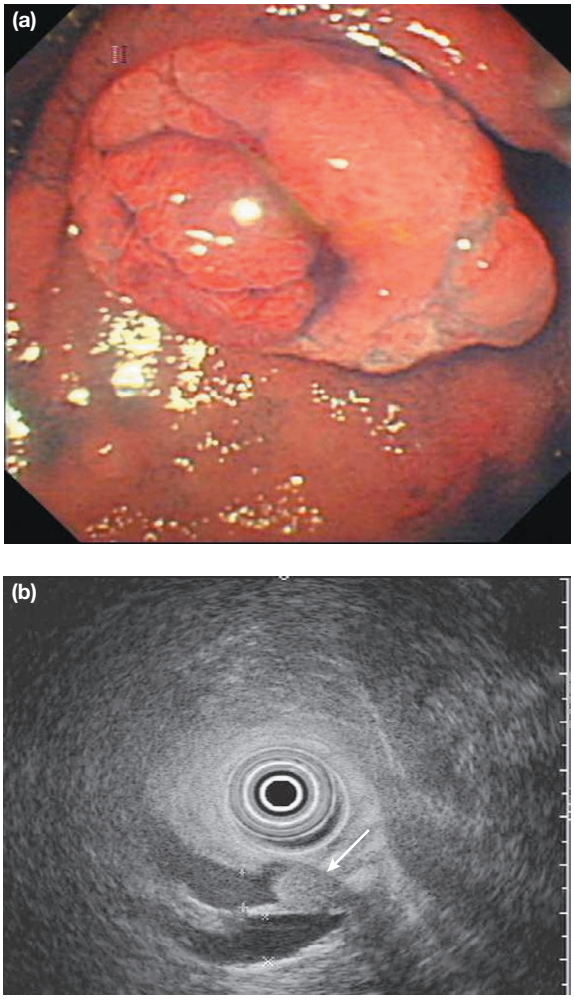

Figure 72.33 (a) Carcinoma of the ampulla as seen at endoscopy. **(b)** Appearance of the same tumour (arrow) on endoscopic ultrasonography (courtesy of Dr Peter Fairclough).

Back pain is a worrying symptom, raising the possibility of retroperitoneal infiltration.

On examination, there may be evidence of jaundice, weight loss, a palpable liver and a palpable gallbladder. Courvoisier first drew attention to the association of an enlarged gallbladder and a pancreatic tumour in 1890, when he noted that, when the common duct is obstructed by a stone, distension of the gallbladder (which is likely to be chronically inflamed) is rare; when the duct is obstructed in some other way, such as a neoplasm, distension of the normal gallbladder is common. Other signs of intra-abdominal malignancy should be looked for with care, such as a palpable mass, ascites, supraclavicular nodes and tumour deposits in the pelvis; when present, they indicate a grim prognosis.

Investigations

In a jaundiced patient, the usual blood tests and ultrasound scan should be performed. Ultrasonography will determine if the bile duct is dilated. If it is, and there is a genuine suspicion of a tumour in the head of the pancreas, the preferred test is a contrast-enhanced CT scan (***Figure 72.8***). In the majority of instances, this should establish if there is a tumour in the pancreas and if it is resectable. The presence of hepatic or peritoneal metastases, lymph node metastases distant from the pancreatic head or encasement of the superior mesenteric, hepatic or coeliac artery by tumour are clear contraindications to surgical resection. Tumour size, continuous invasion of the duodenum, stomach or colon and lymph node metastases within the operative field are not contraindications. If the tumour abuts or minimally invades the portal or superior mesenteric vein, this is not a contraindication to surgery (as part of the vein can be resected if necessary); however, complete encasement and occlusion of the vein and any degree of arterial involvement remain contraindications to surgical resection. MRI and magnetic resonance angiography can provide information comparable to CT.

ERCP and biliary stenting should be carried out if there is any suggestion of cholangitis, if there is diagnostic doubt or if there is likely to be a delay between diagnosis and surgery in a deeply jaundiced patient with distressing pruritus. It relieves the jaundice and can also provide a brush cytology or biopsy specimen to confirm the diagnosis (***Figures 72.13, 72.14 and 72.19***). Otherwise, preoperative ERCP and biliary stenting is not routine in patients with resectable disease as it is associated with a higher incidence of infective complications after surgery.

The prothrombin time should be checked, and clotting abnormalities should be corrected with vitamin K or fresh-frozen plasma prior to ERCP. If a stent is placed in a patient who may undergo resection, it should be a plastic stent or a covered metal stent, as these can be easily removed during surgery.

EUS is useful if CT fails to demonstrate a tumour, if tissue diagnosis is required prior to surgery (e.g. a mass has developed on a background of chronic pancreatitis and a distinction needs to be made between inflammation and neoplasia), if vascular invasion needs to be confirmed or if separating cystic tumours from pseudocysts (***Figure 72.33***; see also ***Figure 72.20***). Transduodenal or transgastric FNA or Trucut biopsy performed under endoscopic ultrasound guidance avoids spillage of tumour cells into the peritoneal cavity. Percutaneous transperitoneal biopsy of potentially resectable pancreatic tumours should be avoided as far as possible. Histological confirmation of malignancy is desirable but not essential, particularly if the imaging clearly demonstrates a resectable tumour. The lack of a tissue diagnosis should not delay appropriate surgical therapy. In patients judged to have unresectable disease, tissue diagnosis should be obtained prior to starting palliative therapy. A CT scan of the chest and a fluorodeoxyglucose–positron emission tomography (FDG-PET) scan are routinely used to complete the staging.

Diagnostic laparoscopy prior to an attempt at resection can spare a proportion of patients an unnecessary laparotomy by identifying small peritoneal and liver metastases. It can be combined with laparoscopic ultrasonography. The tumour marker carbohydrate antigen 19-9 (CA19-9) is not highly specific or sensitive, but a baseline level should be

Ludwig Courvoisier, 1843–1918, surgeon, Basel, Switzerland, was one of the first surgeons to remove stones from the common bile duct.

established; if it is initially raised, it can be useful later in identifying recurrence.

Management

At presentation, more than 85% of patients with ductal adenocarcinoma are unsuitable for resection because of advanced disease. If imaging shows that the tumour is potentially resectable, the patient should be considered for surgical resection, as that offers the only (albeit small) chance of a cure. Every patient with pancreatic cancer should ideally be discussed in a multidisciplinary forum. Comorbidities should be taken carefully into account. Biological rather than chronological age should be the consideration. In patients with locally advanced or metastatic disease the primary objective should be to relieve symptoms, improve quality of life and extend survival, rather than achieve a cure. Patients will broadly fall into four categories.

1. Resectable: these patients should be offered surgery, to be followed by adjuvant chemotherapy. Some centres have begun to suggest that neoadjuvant chemotherapy be used prior to resection, but the evidence is not strong.
2. Borderline resectable (usually because of significant venous occlusion or arterial abutment): these patients may be offered neoadjuvant chemotherapy with/without chemoradiotherapy, to be followed by surgical resection if the disease has been downstaged. Adjuvant therapy should follow.
3. Locally advanced and unresectable: offer systemic chemotherapy. Surgery may subsequently be possible in a small cohort who get downstaged.
4. Metastatic: offer systemic chemotherapy

If a cystic tumour is encountered, no matter how large, surgical resection should be considered as it carries a reasonable chance of cure. Tumours of the ampulla have a good prognosis and should, if at all possible, be resected. Some of the rare tumours and the neuroendocrine lesions should also be resected if at all possible.

Surgical resection

The standard resection for a tumour of the pancreatic head or the ampulla is a pylorus-preserving pancreatoduodenectomy (PPPD). This involves removal of the duodenum and the pancreatic head, including the distal part of the bile duct. The original pancreatoduodenectomy as proposed by Whipple included resection of the gastric antrum. Preserving the antrum and the pylorus is thought to result in a more physiological outcome with no difference in survival or recurrence rates. The Whipple procedure is now reserved for situations in which the entire duodenum has to be removed (e.g. in FAP) or in which the tumour encroaches on the first part of the duodenum or the distal stomach and a PPPD would not achieve a clear resection margin. Total pancreatectomy is warranted only in situations where one is dealing with a multifocal tumour (e.g. a main duct IPMN) or the body and tail of the gland are too inflamed or too friable to achieve a safe anastomosis with the bowel. The PPPD procedure includes a local lymphadenectomy. Extended lymphadenectomy has not been shown to be beneficial in improving survival and is associated with increased morbidity. If the tumour is adherent to the portal or superior mesenteric vein but can still be removed by including a patch or a short segment of vein in the resection, with an appropriate reconstruction of the vessel, then that should be done. This is not associated with an increase in the morbidity or mortality of the procedure and the outcomes are similar. Arterial resections are not recommended unless carried out within the context of a trial. If performed outside a trial, they should be preceded by multidisciplinary discussion and careful counselling of the patient, and be carried out in a specialist unit.

For tumours of the body and tail, distal pancreatectomy with splenectomy is the standard. Infiltration of the splenic artery or vein by the tumour is not a contraindication to resection. When resecting the pancreatic tail for a benign lesion, one may attempt to preserve the spleen if possible. When removing the spleen, prior vaccinations against pneumococci, meningococci and *Haemophilus influenzae* B should be administered, and subsequent antibiotic prophylaxis given (see ***Chapter 70***).

While the majority of pancreatic resections continue to be performed via an open approach, minimally invasive approaches – laparoscopic and robotic – are feasible and may yield comparable results. Minimally invasive pancreatic resections are technically challenging, pose additional demands on operating room time and equipment and involve a significant learning curve for the surgeon and the entire team. They should be restricted to specialist centres and surgeons who have experience in doing them. Distal pancreatectomy, especially for smaller tumours, lends itself more easily to the laparoscopic or robotic approach than a pancreatic head resection. Robotic surgery may carry greater ergonomic benefit for the surgeon (see ***Chapter 10***).

Pancreatoduodenectomy

The patient's coagulation screen should be checked preoperatively and adequate hydration ensured. The patient should be aware of the diagnosis, the gravity of the operation and the risks involved. The operation has three distinct phases:

- exploration and assessment;
- resection;
- reconstruction.

A cholecystectomy is performed. The bile duct and hepatic artery are exposed, removing the lymphatic tissue in this area. Exposure of the hepatic artery enables division of the gastroduodenal artery and visualisation of the portal vein. The distal part of the gastric antrum is mobilised. The duodenum and right colon are mobilised from the retroperitoneal tissues. The superior mesenteric vein is exposed inferior to the pancreatic

Allen Oldfather Whipple, 1881–1963, Director of Surgical Services, The Presbyterian Hospital, and Professor of Surgery, Columbia University, New York, NY, USA, began to perform two-stage pancreatoduodenectomies in 1934 and shortened the procedure into a one-stage process in 1940. **Alessandro Codivilla** (1861–1912) and **Walter Kausch** (1867–1928) had performed the operation before him, but Whipple was the surgeon who established pancreatoduodenectomy as an operation.

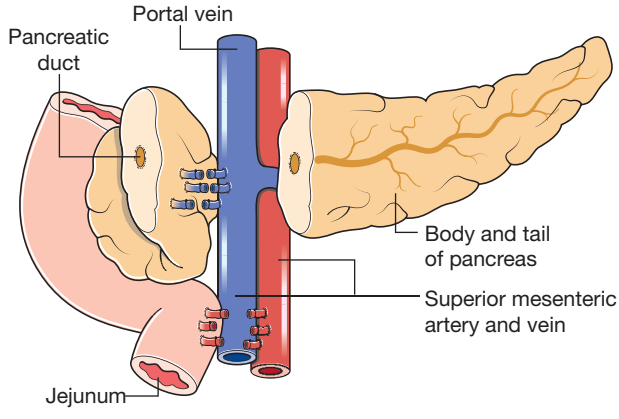

Figure 72.34 Resection of the head of the pancreas in a pylorus-preserving pancreatoduodenectomy.

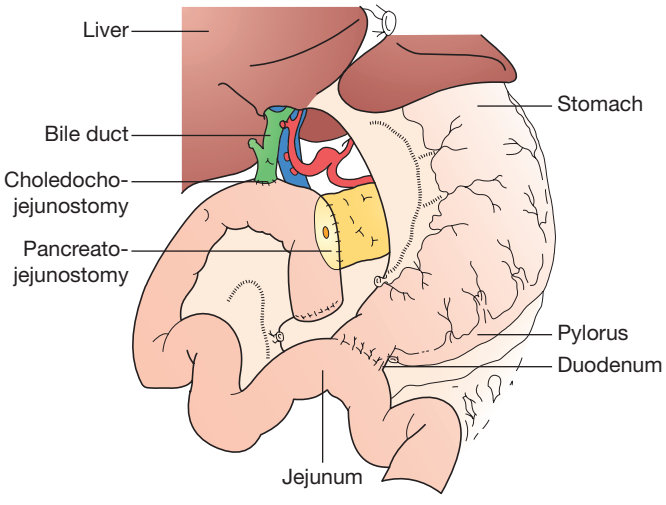

Figure 72.35 Reconstruction after a pylorus-preserving pancreatoduodenectomy.

neck. Careful dissection into the plane between the vein and the pancreatic substance (***Figure 72.2***) will reveal whether the tumour is adherent to the vein. At this juncture, a decision has to be made whether to proceed to the next phase of resection or not. If resection is to be performed, the fourth part of the duodenum is dissected and freed from the ligament of Treitz so that the upper jejunum can be brought into the supracolic compartment. The jejunum is divided 20–30 cm downstream from the duodenojejunal flexure, and the mesentery of the proximal jejunum is detached. The first part of the duodenum is divided. The neck of the pancreas is divided, and then the uncinate process is separated from the superior mesenteric vein and artery working up towards the upper bile duct, which is divided, releasing the specimen (***Figure 72.34***). Retroperitoneal lymph nodes within the operative field are completely removed with the specimen. Reconstruction is carried out as in ***Figure 72.35***. The pancreatic stump, the divided bile duct and the duodenal stump are anastomosed onto the jejunum, in that order. Some surgeons prefer to anastomose the pancreas to the posterior wall of the stomach instead; others prefer to create a separate Roux loop of the jejunum and anastomose the pancreas to that. The operation should take between 3 and 6 hours. Blood loss should be low and transfusion is often not necessary. Patients are usually nursed in a high-dependency area for the first 24–48 hours after surgery. Prolonged nasogastric drainage is unnecessary and early feeding can be commenced. Enhanced recovery after surgery (ERAS) protocols should be applied to pancreatic resections as with other types of gastrointestinal surgery.

Resection for pancreatic cancer should be carried out in specialist units. There is a clear correlation between higher caseload volume and lower hospital mortality and morbidity. PPPD should carry a mortality of no more than 3–5%. The morbidity remains high, with some 30–40% of patients developing a complication in the postoperative period. These complications are usually infective, but a leak from the anastomosis between the pancreas and the bowel is known to occur in at least 10% of patients, and this may give rise to the major complication of a postoperative pancreatic fistula (POPF). Octreotide may be administered in the perioperative period to suppress secretion and reduce the likelihood of a leak, but the evidence for its efficacy is still debatable. Following surgical resection, the pathological tumour–node–metastasis stage should be documented.

Adjuvant therapy

At the beginning of this century, the reported 5-year survival following resection of a pancreatic adenocarcinoma ranged from 7% to 25% (around 10% for most centres). The median survival was 11–20 months. Considering that, at best, 15% of patients had resectable disease to begin with, this meant only two or three out of 100 patients with this disease could expect to survive to 5 years. Moreover, recurrences could and did show up even beyond the 5-year cut-off. The high recurrence rate following resection inevitably led to the consideration of adjuvant treatments to improve outcome. Starting with the large multicentre European study (ESPAC-1) in 2004, which showed an improvement in median survival after adjuvant chemotherapy with 5-fluorouracil (5-FU) but no advantage with adjuvant radiotherapy, there have been several further studies that have looked at gemcitabine alone, gemcitabine with capecitabine and most recently modified fluorouracil plus leucovorin, oxaliplatin and irinotecan (mFOLFIRINOX). The latter has been associated with disease-free survival of over 21 months and median overall survival of over 54 months. Most patients with resected ductal adenocarcinoma are now offered 6 months of adjuvant chemotherapy with mFOLFIRINOX. Those with a poor functional status or a contraindication to mFOLFIRINOX are offered gemcitabine with/without capecitabine. Some centres continue to offer chemoradiotherapy, particularly in patients with involved (R1) resection margins, and further trials of adjuvant chemoradiation are in progress.

Wenzel Treitz, 1819–1872, Professor of Anatomy and Pathology, at Kraków, Poland, and later at Prague, Czech Republic.

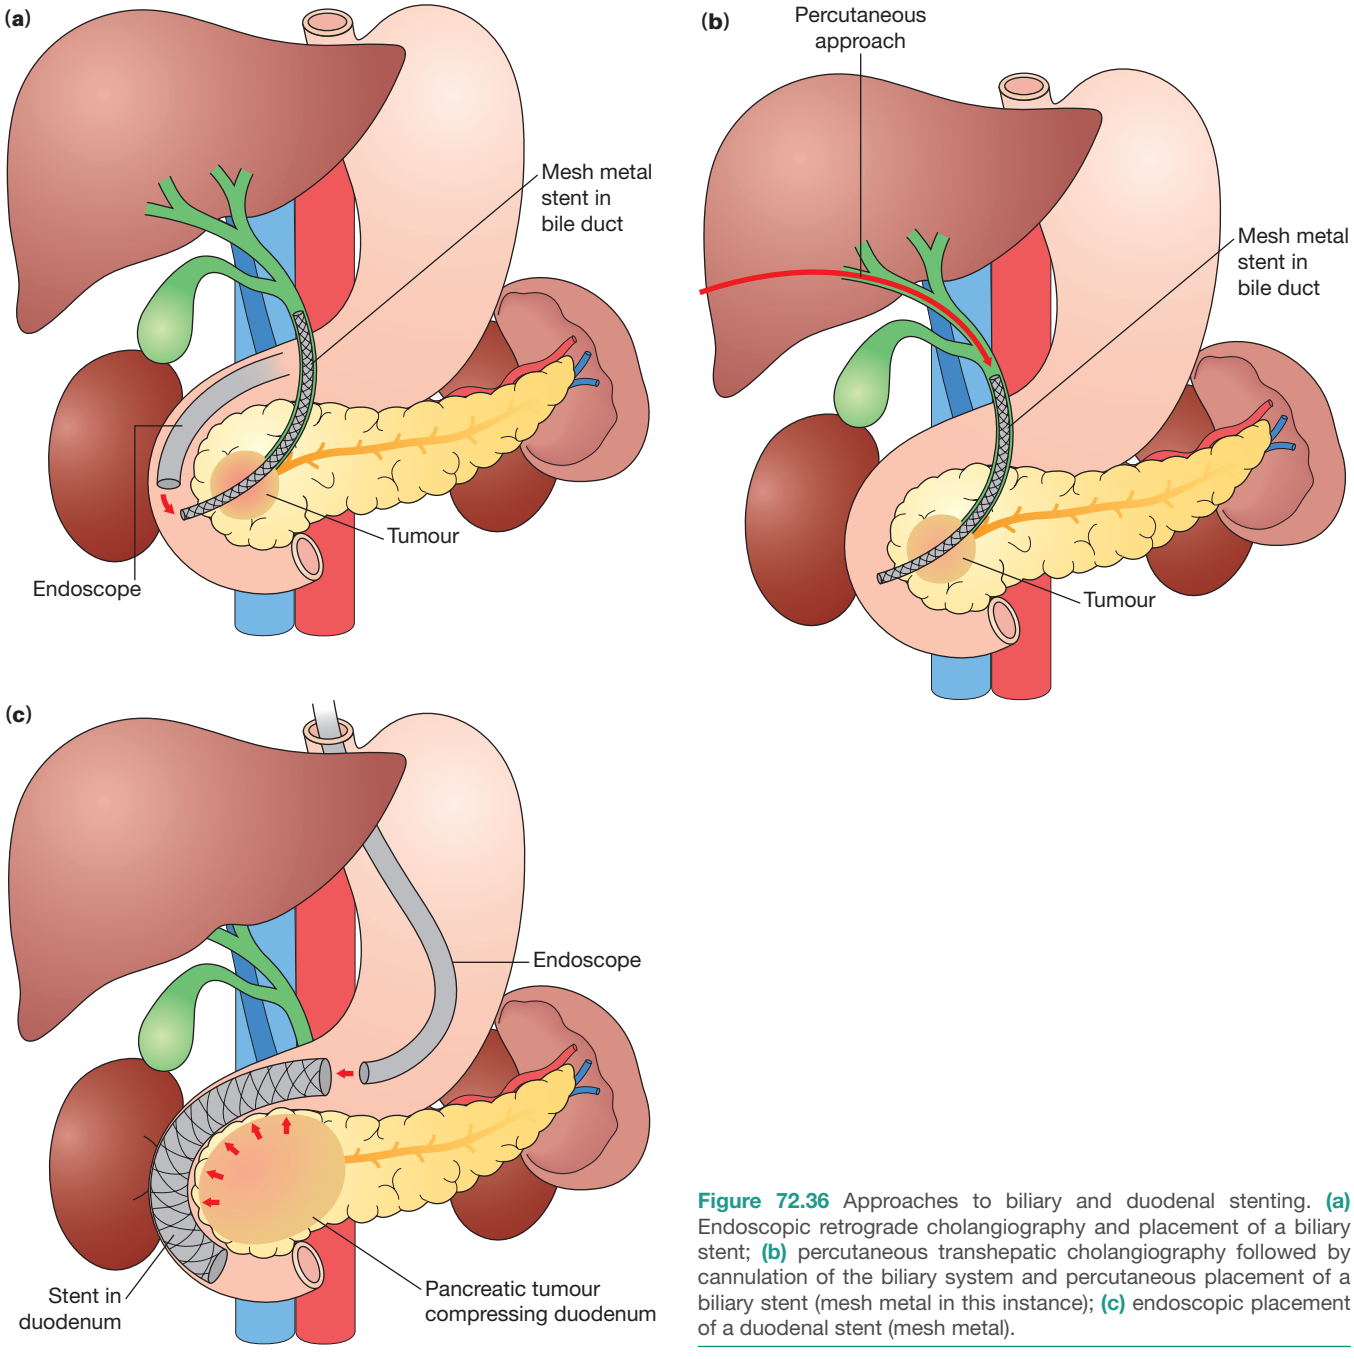

Figure 72.36 Approaches to biliary and duodenal stenting. **(a)** Endoscopic retrograde cholangiography and placement of a biliary stent; **(b)** percutaneous transhepatic cholangiography followed by cannulation of the biliary system and percutaneous placement of a biliary stent (mesh metal in this instance); **(c)** endoscopic placement of a duodenal stent (mesh metal).

It should be emphasised, however, that these depressing statistics apply to ductal adenocarcinomas. Patients with resected ampullary tumours have a 5-year survival of 40%, and cystic tumours and neuroendocrine tumours can often be cured by surgical resection.

Palliation

The median survival of patients with unresectable, locally advanced, non-metastatic pancreatic cancer is 6–10 months and, in patients with metastatic disease, it is 2–6 months.

If unresectable disease is found in the course of a laparotomy that was commenced with the intent to resect, a choledochoenterostomy and a gastroenterostomy should be carried out to relieve (or pre-empt) jaundice and duodenal obstruction. The bile duct may be anastomosed to the duodenum or to a loop of jejunum. It is preferable to use the bile duct rather than the gallbladder. Cholecystojejunostomy is easier to perform, but the bile must then drain through the cystic duct, which is narrow and, if inserted low into the bile duct, is vulnerable to occlusion by tumour growth. A coeliac plexus block can also be administered. A transduodenal Trucut biopsy of the tumour should be obtained.

In patients found to have unresectable disease on imaging, jaundice is relieved by stenting at ERCP (***Figure 72.36a***).

Stents may be made of plastic or self-expanding metal mesh. Plastic stents are cheaper but tend to occlude faster and, if the patient is likely to have a longer life expectancy, a metal stent can be used. If the patient is not a suitable candidate for endoscopic biliary stenting, a percutaneous transhepatic stent can be placed (***Figure 72.36b***). Obstruction of the duodenum occurs in approximately 15% of cases. If this occurs early in the course of the disease, surgical bypass by gastrojejunostomy is appropriate but, if it is late in the course of the disease, then the use of expanding metal stents inserted endoscopically is preferable, as many of these patients have prolonged delayed gastric emptying following surgery (***Figure 72.36c***). If both biliary and duodenal metal stents are to be placed endoscopically, the biliary one should be placed first.

If no operative procedure is undertaken, an EUS-guided or percutaneous biopsy of the tumour should be performed before consideration of chemotherapy or chemoradiation. Lymphomas of the pancreas are rare and constitute less than 3% of all pancreatic cancers. These respond to chemoradiotherapy and surgical resection is not indicated. For patients with ductal adenocarcinoma who have locally advanced or metastatic disease, mFOLFIRINOX or alternatively gemcitabine plus albumin-bound paclitaxel particles (nab-paclitaxel) should be considered if the functional status is good. However, the 2–5 months' increase in median survival with these regimens has to be offset against the higher toxicity and cost. No long-term cures have been described with chemotherapy or radiotherapy.

There is no role for surgical resection if metastases are present at the time of the initial presentation. In a very small proportion of patients who have been deemed unresectable owing to major vascular involvement and do not have metastatic disease, attempts have been made to downstage the tumour with one of the newer combination chemotherapy regimens, sometimes with chemoradiation added in, to try to render them resectable. Such neoadjuvant therapies are only very occasionally successful and should ideally be considered within a clinical trial.

Steatorrhoea is treated with enzyme supplementation. Diabetes mellitus, if it develops, is treated with oral hypoglycaemics or insulin as appropriate, and pain with either analgesics or an appropriate nerve block.

Summary box 72.10

Palliation of pancreatic cancer

Relieve jaundice and treat biliary sepsis

- Surgical biliary bypass
- Stent placed at ERCP or percutaneous transhepatic cholangiography

Improve gastric emptying

- Surgical gastroenterostomy
- Duodenal stent

Pain relief

- Stepwise escalation of analgesia
- Coeliac plexus block
- Transthoracic splanchnicectomy

Symptom relief and quality of life

- Encourage normal activities
- Enzyme replacement for steatorrhoea
- Treat diabetes

Consider chemotherapy

PART 11 | Abdominal

CHAPTER 73

Functional disorders of the intestine

Learning objectives

To recognise and understand:

- The spectrum of intestinal disorders resulting from abnormal neuromuscular functions
- The management of relatively common acute motility disturbances
- The management of common chronic disorders that present to surgeons such as chronic constipation and irritable bowel syndrome
- The existence of several rare neuromuscular diseases that may affect the intestine
- The limited role of surgery in the treatment of most of these disorders

APPLIED ANATOMY AND PHYSIOLOGY

The intestine must subserve basic functions of moving contents from proximal to distal in a rhythmical fashion to allow mixing, digestion and absorption of contents. The motility of the intestine has been studied for more than a century and all readers should know of the seminal experiments of Bayliss and Starling in their 1899 paper 'The movements and innervation of the small intestine', which led to adoption of the term 'peristalsis'. In the small intestine, fasting motility can be described by the three phases of the migrating motor complex (MMC), with fed activity resembling phase II. Colonic motility is much more complicated and still poorly understood with some features akin to the MMC but also specific phenomena such as retrograde movements (presumed to allow greater resident time and therefore fluid and electrolyte absorption). The main characteristics of intestinal motility are shown in ***Table 73.1***.

The intestine, like the heart, is autonomous in generating its own rhythmical electrical, and therefore local motor, activity by intrinsic pacemaker activity generated by small fibroblast-like cells called the interstitial cells of Cajal. These cells, which are mainly resident within the muscularis propria, have several key functions, including setting the membrane potential of smooth muscle cells so that they are primed to contract and connecting smooth muscle cells electrically so that synchronous

TABLE 73.1 Contractile activity of the intestine.

Region	Broad category	
Small intestine	Phase I	Quiescence (40–60% of total time)
	Phase II	High-frequency contractions allowing mixing and absorption (20–30% of total time)
	Phase III	High-amplitude propagated activity (5–10 minutes)
Large intestine	Phasic contractions	Low-amplitude propagated pressure waves
		High-amplitude propagated pressure waves[a]
		Retrograde pressure waves
		Simultaneous pressure waves
		Periodic colonic and rectal motor activity (localised bursts)
	Tonic contractions	Sustained activity responsible for tone

[a]Most akin to phase III of the migrating motor complex and responsible for mass movements of faecal content.

Sir William Bayliss, 1860–1924, physiologist, and **Ernest Henry Starling**, 1866–1927, University College London, London, UK. Starling's contributions to medicine also included Starling's principle (capillary pressures) and filling of the heart (Frank–Starling law).
Santiago Ramon y Cajal, 1852–1934, Spanish neuroscientist, pathologist and Nobel prize winner (1906) for studies of cellular anatomy of the nervous system.

contraction occurs. Also akin to the heart, this activity is affected by a hierarchy of external control systems but mainly by the enteric nervous system (ENS) via the myenteric plexus. The myenteric plexus is one of the two intramural plexuses of the ENS (the other being the submucosal plexus). The former has the major role in motor functions while the latter has roles in sensing, mucosal blood flow regulation and secretion. Both are composed of small groups of enteric neurones that congregate with glial cells to form ganglia, these being connected in a lattice-type network of axons (***Figure 73.1***). The ENS has a neurochemical complexity and number of neurones (five times the number in the spinal cord) that has led to it being called the 'little brain' (***Summary box 73.1***). Thus, although higher control mechanisms including the autonomic nervous system (ANS) and brain allow the intestinal motility to respond to wider environmental cues, e.g. waking, exercise, the smell and taste of food and stress, the intestine can initiate and sustain peristalsis without any external inputs.

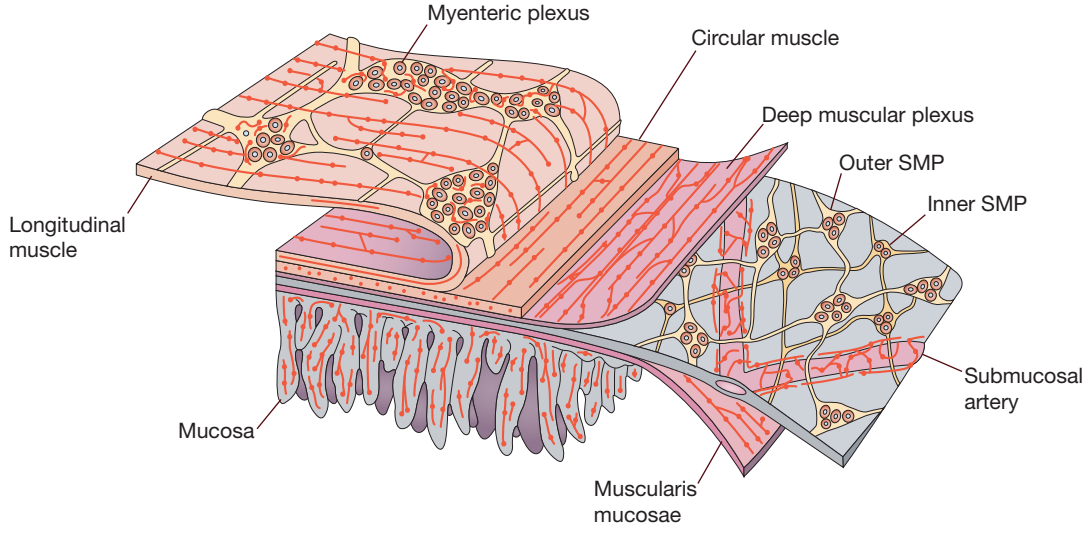

Figure 73.1 Schematic diagram of the enteric nervous system. SMP, submucosal plexus. (Reproduced by permission from Springer Nature. Furness JB. The enteric nervous system and neurogastroenterology. *Nat Rev Gastroenterol Hepatol* 2012; **9**: 286–94. © 2012.)

Summary box 73.1

Regulation of intestinal contractile activity

Myogenic control mechanisms

- Interstitial cells of Cajal generating slow wave activity

Neurogenic control mechanisms

- ENS (a variety of cells in myenteric and submucosal ganglia)
- ANS (sympathetic and parasympathetic mainly via ENS ganglia)
- Central nervous system (CNS) (brain–gut interactions)

Chemical control mechanisms

- Local paracrine (especially from mucosal enteroendocrine cells)
- Endocrine

The rectum constitutes a final and specialised end to the intestine. Its role is mainly for temporary storage of faeces prior to defecation. This role permits both further water absorption and the ability of higher mammals to socially defecate (an ability shared with small rodents as well as many larger species). To this end, the wall of the rectum is specialised in terms of compliance and of having nerve endings that provide conscious perception of filling. In concert with the upper anal canal, the rectum is also capable of distinguishing solid, liquid and gas by the 'sampling' reflex. Together the act of defecation requires complex neuromuscular functions and it is no surprise that it goes wrong with sufficient regularity to cause much human misery in the form of constipation and incontinence (see ***Chapter 80***).

TESTS OF INTESTINAL FUNCTION

Subsequent chapters address diagnostic tests specific to the rectum (see ***Chapter 79***) and anus (see ***Chapter 80***). Here the focus is on tests that may be relevant to studying the motility of the small intestine and colon. A general proviso in reading this section is that our current ability to understand the physiology of the intestine in humans is limited by both access and understanding. In general, we measure what can be measured and all tests have inherent limitations to interpretation. ***Summary box 73.2*** provides an overview of all tests, denoting those that have general clinical application versus those that are the preserve of highly specialised units or research studies.

Summary box 73.2 makes clear that few tests are in general use. Small bowel contrast studies, e.g. barium follow-through, although available, have poor sensitivity for detecting much other than visceral distension (superseded by axial imaging with computed tomography [CT] or MRI) or grossly retarded transit. Breath hydrogen testing assesses the presence

Summary box 73.2

Tests of small intestinal function

Transit

- Small bowel barium contrast study[a]
- Breath hydrogen small bowel transit tests (lactulose or lactose ^{13}C-ureide)[a]
- Wireless motility capsule small bowel transit study[b]

Contractile activity

- Antroduodenal manometry (ideally prolonged [24 hours] ambulatory study)
- Dynamic magnetic resonance imaging (MRI) studies

Tests of colonic function

Transit

- Radio-opaque marker studies[a]
- Isotope scintigraphy
- Wireless motility capsule whole-gut transit study[b]

Contractile activity

- Colonic manometry
- Dynamic MRI studies

[a]Denotes general availability.
[b]Adopted by some highly funded health systems.

of carbohydrate malabsorption and is an indirect measure of transit because stagnated content allows some degree of bacterial overgrowth and fermentation products (hydrogen, methane and carbon dioxide). Although frequently used in patients with unexplained chronic abdominal symptoms such as irritable bowel syndrome (IBS), its utility in reliably measuring transit or detecting bacterial overgrowth is limited by issues of reproducibility.

The wireless motility capsule measures pH, temperature and pressure as it traverses the whole gastrointestinal tract; changes in these variables can be used to determine timings as it migrates from stomach to small bowel and large bowel. While it offers a number of advantages over and above current techniques, especially with respect to patient tolerability, safety and standardisation, it is not widely available owing to cost.

Prolonged measurement of small bowel contractile activity can be performed using multichannel pressure recordings called manometry that show phases of the MMC. Some findings may be indicative of underlying small bowel neuromuscular diseases such as myopathies and neuropathies (see ***Chronic impairment of intestinal motility with dilatation of the small intestine: intestinal pseudo-obstruction***) but these findings have issues of specificity and the technology itself is only available in a small number of centres worldwide. Dynamic MRI (long sequences of image acquisition with computer analysis) is currently a research tool but may well represent the future.

The radio-opaque marker study is the mainstay of evaluation of colonic transit. Though variations in technique exist in terms of the number of markers, interval to radiograph and definition of slow transit, the basic premise is that a number of markers (small pieces of plastic tubing, prepackaged in gelatin capsules) are ingested and an abdominal radiograph (which includes the pelvis) taken at an interval. The patient abstains from laxatives for the duration of the study. In patients with significant numbers of retained markers (based on control data), slow-transit constipation is diagnosed (***Figure 73.2***). Other studies of colonic transit, e.g. isotope scintigraphy and direct measurements of colonic contractile activity, are restricted to a very small number of specialist centres worldwide.

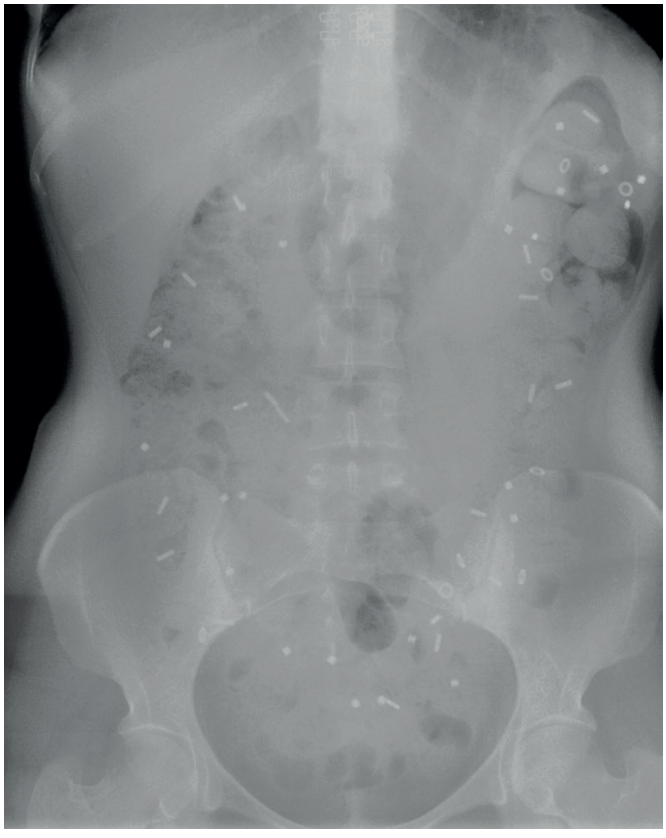

Figure 73.2 Radio-opaque marker transit study in a woman. All 50 markers are retained, indicating slow-transit constipation.

SCOPE OF DISEASE

A functional diagnosis is usually made when *routine* investigations fail to find an easy explanation (e.g. a structural or biochemical cause) for a combination of typical symptoms. For instance, in a patient with lower abdominal pain, constipation and bloating if routine investigation finds a morphological abnormality, e.g. sigmoid diverticulosis, then the patient will be given a diagnosis of diverticular disease. However, if all usual tests, including colonoscopy, yield no findings then the same patient might be described as having IBS – a functional intestinal disorder. Like much of medicine, there are however grey areas. Further, understanding is not aided by historic nomenclature where terms such as pseudo-obstruction describe different entities in the small and large intestine (***Table 73.2***). This chapter considers the main disorders using this classification with a focus on those most pertinent to the surgical reader.

TABLE 73.2 Scope of functional intestinal diseases.

History of onset	Visceral diameter	Region predominantly affected	Nomenclature
Acute	Dilated	Small intestine	Ileus (including postoperative ileus)
		Large intestine	Acute colonic pseudo-obstruction
Chronic	Dilated	Small intestine	Intestinal pseudo-obstruction
		Large intestine	Megacolon
Chronic	Normal	Intestine	Constipation and irritable bowel syndrome

ACUTE ADYNAMIC NEUROMUSCULAR STATES OF THE SMALL INTESTINE WITH DILATATION: ILEUS

Definition

Ileus can be defined as:

> ***a disruption of the normal propulsive ability of the intestine due to a malfunction of contractile activity in the absence of mechanical obstruction.***

This definition excepts certain older terms such as 'meconium ileus' and 'gallstone ileus' (see ***Chapters 17 and 78***) that persist in usage, although they are technically misnomers (i.e. there is mechanical obstruction). The term 'paralytic ileus', although descriptive for the student, is outdated and not entirely correct since studies show that motor activity is not abolished but rather dysregulated.

Causes and risk factors

The risk factors for ileus are listed in ***Summary box 73.3***. Postoperative ileus (POI) occurs in 10–20% of patients undergoing elective major abdominal surgery and is usually defined by a failure to tolerate oral intake or pass stool 72 hours after surgery.

Summary box 73.3

Risk factors for ileus

- Recent surgery: POI
- Local inflammation (peritonitis, severe acute pancreatitis)
- Systemic inflammation by any cause, e.g. sepsis, trauma
- Electrolyte disturbance (especially hypokalaemia and hypercalcaemia)
- Acute endocrine disturbance (hypothyroidism, diabetic ketoacidosis)
- Medications, e.g. opioids
- Acute CNS disease (especially high spinal transections)
- Intestinal ischaemia (mesenteric vascular disease)

Pathophysiology

Classic teaching points to a reflex inhibition of intestinal motility caused by deranged ANS inputs. This teaching, which fits nicely with basic 'fight and flight' concepts of increased sympathetic signalling and parasympathetic withdrawal during trauma (including surgery), has been superseded by the concept of a two-phase response. First, an immediate stress response, mediated by spinal reflexes and activation of the hypothalamic–pituitary–adrenal axis (HPA) axis, leads to a decrease or abolition of motility. This is then followed very rapidly by evolution of a more prolonged inflammatory response in the bowel wall itself, mediated first by mast cell activation and thence recruitment and activation of macrophages and neutrophils (***Figure 73.3***). These lead to inhibition of enteric neuronal and smooth muscle function as well as further effects on spinal reflexes.

Clinical features

Symptoms include abdominal distension and vomiting akin to mechanical small bowel obstruction (see ***Chapter 78***); however, colicky pain is less of a feature. On examination, other than evidence of the cause, e.g. recent surgery, the abdomen will be distended, tympanic and have reduced or absent bowel sounds.

Diagnosis

CT scanning is frequently required to exclude both mechanical obstruction and any local driver of ileus in the peritoneum such as inflammation or infection (***Figure 73.4***). In instances of POI this is required to exclude local complications of surgery. Blood tests should be used to detect any drivers of ileus such as metabolic abnormalities (especially hypokalaemia).

Management

Ileus may be managed by nasogastric drainage and restriction of oral intake until there is evidence of improvement. Supportive care such as attention to fluid and electrolyte balance and nutrition is also important, especially if ileus persists. Underlying drivers of ileus, e.g. abscess or peritonitis, should be managed on their merits. Regrettably, despite improved knowledge of the pathophysiology, specific drugs aimed at blocking inflammation or stimulating local neuromuscular function, e.g. prokinetics, have not proved sufficiently effective yet to be adopted for routine use.

In patients with POI, if prolonged, CT scanning is the most effective investigation; it will demonstrate any intra-abdominal sepsis or mechanical obstruction and therefore guide any

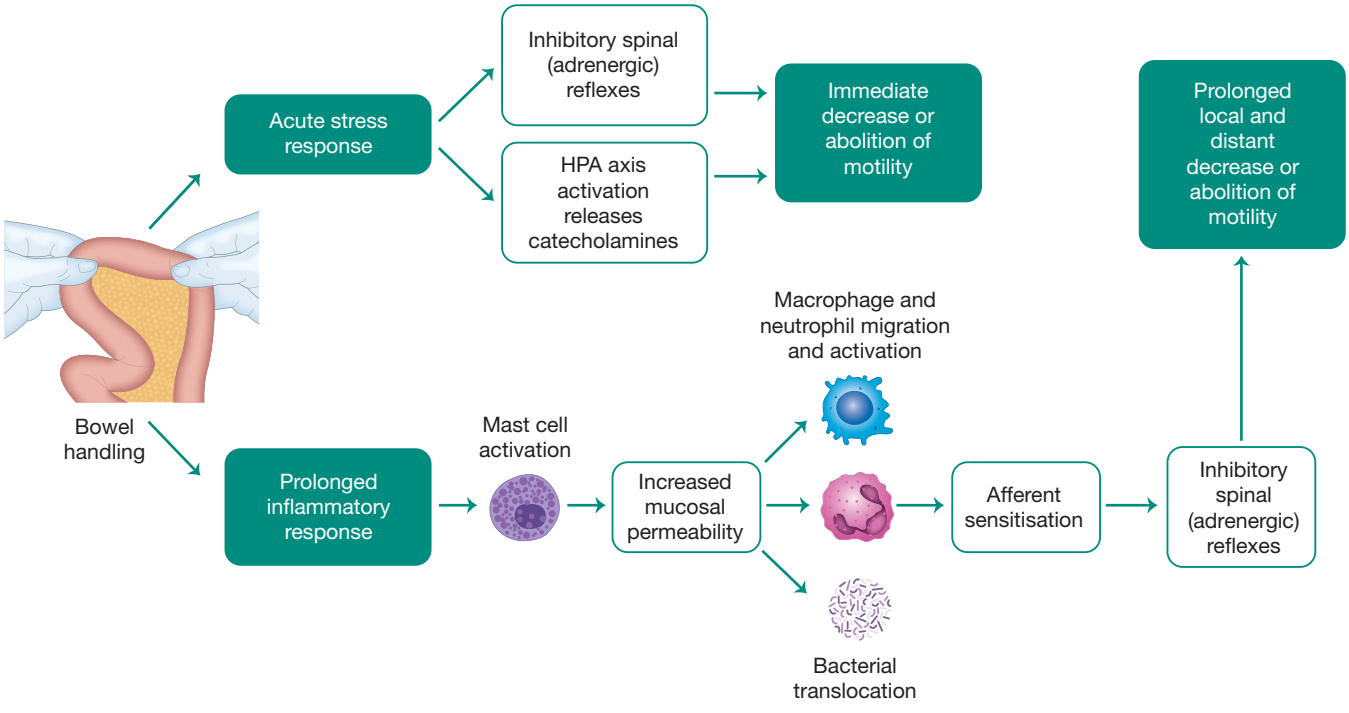

Figure 73.3 Pathophysiology of postoperative ileus. HPA, hypothalamic–pituitary–adrenal axis.

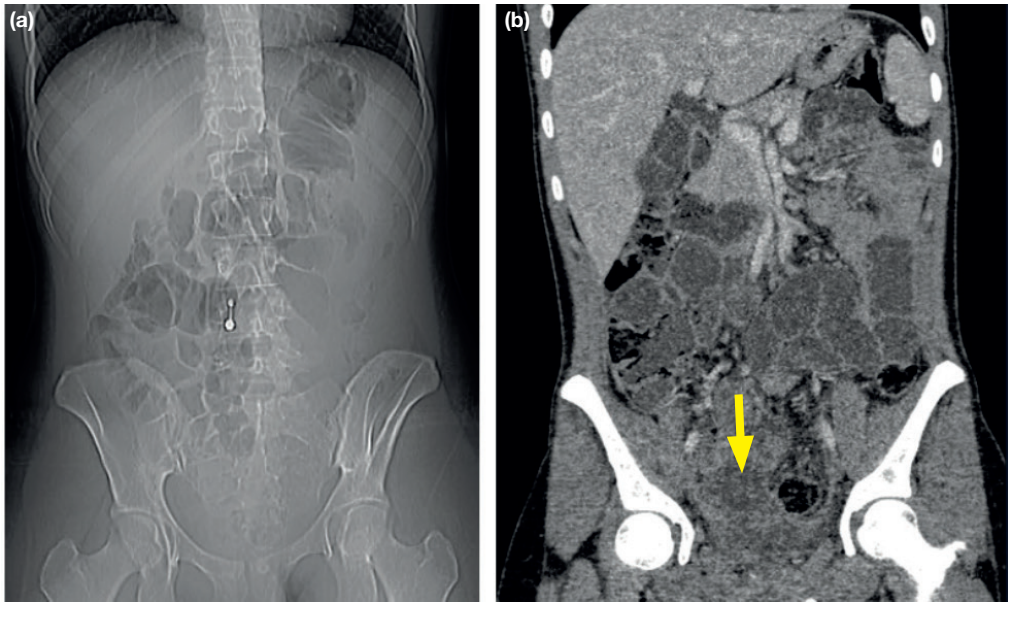

Figure 73.4 Computed tomography abdomen scout film **(a)** and representative coronal image **(b)** of a 22-year-old woman showing widespread dilatation of the small intestine (ileus) secondary to a driving inflammatory focus (pelvic collection, arrow) (courtesy of Dr Arman Parsai, Barts Health NHS Trust, London, UK).

requirement for laparotomy. Otherwise the decision to take a patient back to theatre in these circumstances is always difficult. The need for a laparotomy becomes increasingly likely the longer the bowel inactivity persists, particularly if it lasts for more than 7 days or if bowel activity recommences following surgery and then stops again.

Prevention

Minimally invasive surgical approaches have reduced risks of POI for many operations. The enhanced recovery programme (see ***Chapter 74***) seeks to further reduce risk of POI by avoidance of opioid-containing drugs and suppression of the inflammatory response.

ACUTE ADYNAMIC NEUROMUSCULAR STATES OF THE LARGE INTESTINE WITH DILATATION: ACUTE COLONIC PSEUDO-OBSTRUCTION

Definition

The term acute colonic pseudo-obstruction (ACPO) is defined as:

> ***Acute massive dilatation of the colon with obstructive symptoms but in the absence of mechanical obstruction.***

ACPO was first described by Sir William Ogilvie, who in 1948 recognised this syndrome in two patients with sudden onset of abdominal pain, constipation and large bowel dilatation (hence the eponym Ogilvie's syndrome). It is one of the three common diagnoses in patients evaluated for a clinical presentation of large bowel obstruction (see ***Chapter 78***), the other two being colorectal cancer and volvulus (remember the three Ts: tumour, torsion and 'tired out'). Toxic megacolon (see ***Chapter 75***), although conveniently being a fourth 'T', should be considered as a different condition entirely although the end point is also one of acute dilatation.

Risk factors

In Ogilvie's original report, the clinical picture was associated with a retroperitoneal neoplasm infiltrating and destroying prevertebral ganglia. This is actually a very rare cause. The main risks are shown in ***Summary box 73.4***.

Summary box 73.4

Risk factors for acute colonic pseudo-obstruction

- Frailty and senility
  - Neurological
  - Neurodegenerative diseases
  - Stroke
  - Spinal cord injury
  - Retroperitoneum tumour infiltration
- Trauma/surgical
  - Major orthopaedic injuries or surgery, e.g. vertebral, pelvic and femoral
  - Major gynaecological surgery
  - Obstetrics, including caesarean section
- Systemic inflammation by any cause, e.g. sepsis, trauma, especially with multiorgan failure
- Localised infective conditions, e.g. respiratory, urinary
- Myocardial infarction
- Metabolic and electrolyte disturbances
- Medications, e.g. opioids and any with anticholinergic actions (e.g. psychiatric and Parkinson's), calcium channel antagonists

The majority of patients fall into two categories: those that have a high background risk and a small acute event (e.g. the elderly patient with Parkinson's disease and a urinary tract infection [UTI]) – the colon has little 'reserve' and a small insult tips the balance into one of progressive abolition of motility and tone with consequent gaseous dilatation; and those with little background risk and a large acute event, e.g. major surgery/trauma.

Pathophysiology

This is poorly understood. It can however be appreciated that, like ileus, risk factors reflect both 'imbalanced' extrinsic autonomic innervation and an 'inflammatory' state. Evidence to support the former is provided by the response to anticholinesterase pharmacological therapy.

Clinical features

Symptoms include abdominal distension, absolute constipation and, as a later feature, vomiting akin to mechanical large bowel obstruction (see ***Chapter 78***); however, colicky pain is less of a feature. The history is very important to establish risk factors, some of which may be modifiable. On abdominal examination, the abdomen is usually grossly distended and tympanic. In uncomplicated cases, the abdomen should not be tender. Tenderness and especially any evidence of peritonism indicate that massive colonic dilatation may have led to ischaemia with/without perforation – a surgical emergency. Such complications occur in 3–15% of patients with advanced age and increased caecal diameter, with a delay in decompression increasing risk.

Diagnosis relies upon accurate clinical observation and plain abdominal radiography showing degrees of colonic dilatation, mainly involving the proximal colon. CT is however the definitive investigation (***Figure 73.5***) to differentiate mechanical from pseudo-obstruction, to provide a caecal diameter and to show any evidence of complications (e.g. perforation). A CT scan will also differentiate pseudomembranous colitis with toxic dilatation, which is a further differential diagnosis in hospitalised or institutionalised patients due to *Clostridium difficile* infection.

Management

The management of ACPO depends on whether complications are evident or considered imminent. In patients with clinical and radiological features of caecal ischaemia or perforation, emergency surgery will be required and usually necessitates a subtotal colectomy and end ileostomy (with high levels of morbidity and mortality). The majority of patients can however follow a more stepwise approach, starting with conservative measures (***Table 73.3***). Clearly the underlying cause where relevant, e.g. UTI, respiratory tract infection or myocardial infarction, should also be managed in parallel. It is reasonable to wait before progressing from one stage to the

The entire colon and rectum is variably distended with fluid and gas. **(c)** Plain abdominal radiograph (courtesy of James Hill) and **(d)** intraoperative photograph of the colon during surgery for acute colonic pseudo-obstruction (courtesy of James Hill).

TABLE 73.3 Management of acute colonic pseudo-obstruction.

Reversal of risk factors	Correct fluid and electrolyte imbalances
	Stop or reduce offending drugs, e.g. opioids, anticholinergics, calcium channel blockers (where possible)
	Empty the rectum by enemas and/or flatus tube
Endoscopic decompression	Colonoscopy +/– flatus tube
Pharmacological decompression	Intravenous neostigmine unless contraindicated (risk of arrhythmia and bronchospasm[a])
Surgery	Subtotal colectomy (usually with ileostomy)
	Venting stoma, e.g. caecostomy, in very unfit patients

[a]Requires high-dependency unit-level monitoring and support on hand for cardiorespiratory complications.

next but caecal diameters of 12 cm or above warrant rapid decompression to reduce perforation risk.

The decision of whether to use intravenous neostigmine is difficult and is usually reserved for patients in whom supportive measures and colonic decompression have failed. Treatment is associated with profound autonomic effects (salivation, bradycardia, bronchospasm and hypotension) as well as abdominal cramps, followed often by a massive evacuation of flatus and faeces. Cardiac monitoring and a health professional competent in the emergency administration of resuscitative drugs (especially atropine) are essential. Contraindications to the use of neostigmine include renal insufficiency, recent myocardial infarct, arrhythmias and asthma.

Surgery is associated with high morbidity and mortality and should be reserved for those with impending perforation when other treatments have failed or perforation has occurred.

Prognosis

ACPO is a life-threatening condition in which prompt diagnosis and appropriate management can limit the occurrence of complications (e.g. ischaemia or perforation). Such complications occur in about 5–10% of patients and require emergency surgery with mortality rates between 30% and 60%. Recurrence is an issue in some patients with unmodifiable risk factors, e.g. senility and neurological disease. Such patients should have chronic modification of polypharmacy to avoid offending drugs and keep the rectum empty by regular enemas. Prokinetic medications, such as those used for chronic constipation, may have a role in such patients, although none are licensed for this indication.

CHRONIC IMPAIRMENT OF INTESTINAL MOTILITY WITH DILATATION OF THE SMALL INTESTINE: INTESTINAL PSEUDO-OBSTRUCTION

Definition

Intestinal pseudo-obstruction (IPO) is defined as:

> ***A clinical syndrome caused by severe impairment of intestinal motility leading to small intestinal dilatation in the absence of a mechanical cause.***

The term 'chronic' is sometimes added for clarity.

Causes

IPO is a rare disease. Approximately half of cases arise shortly after birth or in infancy, caused by a number of very rare enteric neuropathies and myopathies, including genetic and familial, inflammatory and degenerative forms. Other cases arise later in life when a secondary aetiology is more common. In some patients, a cause is not found and these are termed idiopathic. The full list of causes is given in ***Summary box 73.5***.

Summary box 73.5

Causes of intestinal pseudo-obstruction

Primary

- Several very rare enteric myopathies and neuropathies
- Unknown (termed 'idiopathic')

Secondary

- Connective tissue disease, especially scleroderma
- Radiation injury
- Amyloidosis
- Autonomic neuropathies including diabetes and paraneoplasia
- Infections: Chagas' disease (South American trypanosomiasis)

Diagnosis

IPO presents clinically with the symptoms and signs of small bowel obstruction with pain, distension and vomiting. After clinical evaluation and plain radiology, a degree of suspicion is helpful to avoid unnecessary and potentially harmful surgery. Such suspicion is merited when there is no obvious cause for mechanical obstruction, i.e. no known bowel disease, previous surgery or hernia, and on the length of history. Here, knowing the list of secondary causes becomes helpful. For instance, in someone who is a smoker with finger clubbing, a small cell carcinoma of the lung may be the cause of paraneoplastic pseudo-obstruction; alternatively, the patient may have clinical signs of scleroderma. Axial imaging is essential to exclude mechanical obstruction. Adjunctive blood and imaging tests may help define a cause and these can include MRI of the brain and skeletal muscle biopsy for rare diagnoses such as mitochondrial myopathies.

Primary neuropathies and myopathies can be diagnosed histologically, but this requires full-thickness tissue and a variety of special stains (available only in specialist centres). Since laparotomy and bowel resections are best avoided, a laparoscopic or minilaparotomy full-thickness biopsy may be warranted for diagnosis (***Figures 73.6 and 73.7***).

Management

The main lines of management are shown in ***Summary box 73.6***, noting that for most patients there is no cure. Surgery, with the exception of placing feeding tubes or formation of a venting stoma, is impotent for a condition that is a diffuse neuromuscular disease. Further, surgery worsens the prognosis by adding the risk of adhesions into the diagnosis and, if resections or complications occur, speeding the patient towards intestinal failure. Small bowel (or multivisceral) transplantation is an option in selected patients.

Figure 73.6 Intestinal pseudo-obstruction in a young male patient. A full-thickness biopsy was undertaken from the proximal jejunum at minilaparotomy.

Carlos Justiniano Ribeiro Chagas, 1879–1934, Director of the Oswaldo Cruz Institute and Professor of Tropical Medicine, University of Rio de Janeiro, Brazil.

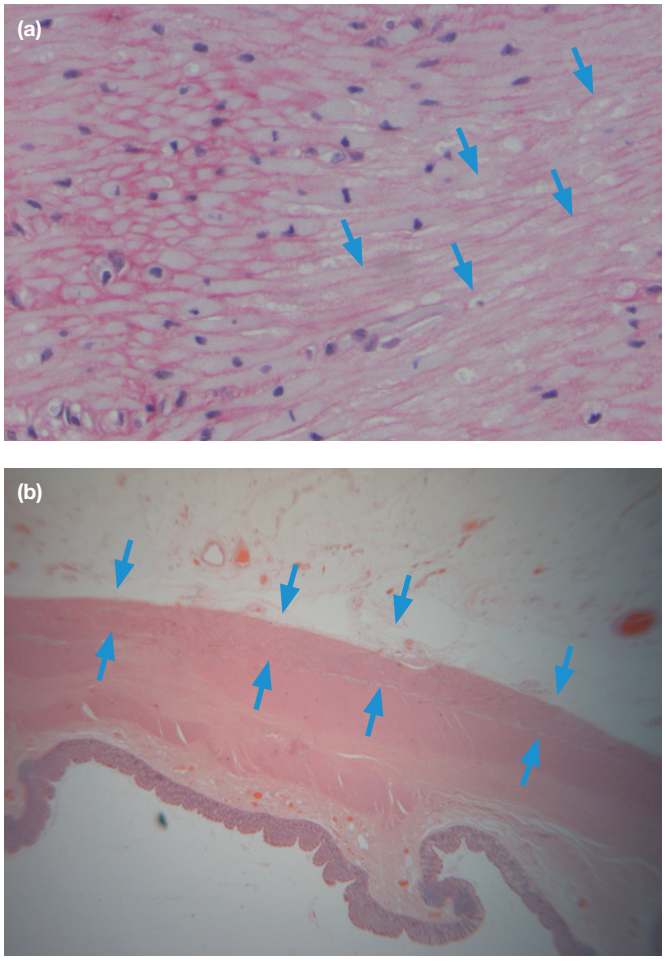

Figure 73.7 Two examples of myopathy: **(a)** hollow visceral myopathy (note the vacuolation of the smooth muscle, arrows); **(b)** extra muscle layer in the muscularis propria (arrows).

Summary box 73.6

Management of intestinal pseudo-obstruction

- Nutrition (enteral/parenteral)
- Analgesia (but try to avoid opioids)
- Prokinetics (generally disappointing)
- Antibiotics (overgrowth)
- Immunotherapy – specific inflammatory cases (limited data)
- Psychological support, including specific patient support groups
- Palliative care
- Surgery (very selected cases)

Prognosis

Prognosis is poor – sometimes considered the 'motor neurone disease' of the gut. Infantile forms have a mortality of approximately 50%. This is generally lower in adult forms depending on cause and avoiding repeated surgery and overuse of opioid drugs. Together these cause a vicious spiral of declining motility and progression to type II/III intestinal failure with the need for lifelong parenteral nutrition.

CHRONIC IMPAIRMENT OF INTESTINAL MOTILITY WITH DILATATION OF THE LARGE INTESTINE: MEGACOLON AND MEGARECTUM

Definition

Chronic dilatation in the absence of a mechanically obstructing cause can be focused in the colon (megacolon) or rectum (megarectum), although in practice these commonly overlap (***Figure 73.8***). Megacolon may also accompany some forms of IPO in patients found to have chronic small and large intestinal dilatation. Toxic megacolon refers to an acute condition in which acute inflammation leads to a loss of compliance and rapid dilatation (it has nothing in common other than the name).

Causes of megacolon and megarectum

Primary and secondary causes (***Table 73.4***) vary between megarectum and megacolon. The most common disease to use the term megacolon is Hirschsprung's disease (occurring in 1 in 5000 live births) (see ***Chapter 17***). Actually, in this instance, it can be argued that the so-called 'congenital megacolon' does in fact reflect a degree of distal obstruction from the distal contracted aganglionic segment. This leads to the absence of passage of meconium at birth and is generally incompatible with life without urgent surgery. Adult Hirschsprung's disease is a very rare disease and leads to a megarectum because the affected segment is 'ultrashort', affecting only the transition zone of the anus. Histologically, this is very difficult to diagnose with certainty and some challenge its existence at all.

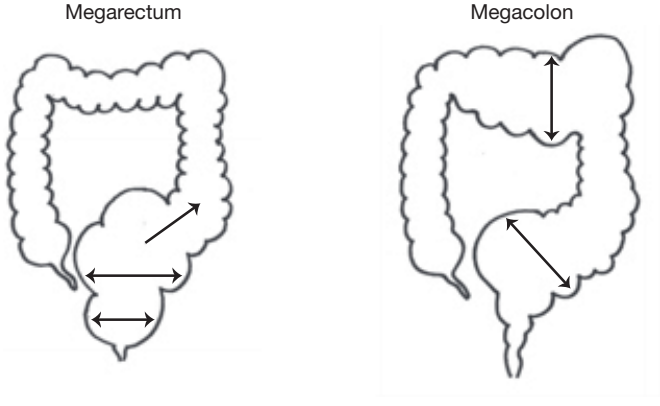

Figure 73.8 Schematic drawing of the distribution of bowel dilatation in megacolon and megarectum.

Harald Hirschsprung, 1830–1916, physician, The Queen Louise Hospital for Children, Copenhagen, Denmark, described congenital megacolon in 1887.

TABLE 73.4 Causes of megacolon and megarectum.

Megacolon	*Primary*	Congenital	Classic (rectosigmoid) Hirschsprung's disease
			Rare early-onset (some genetic) myopathies and neuropathies
		Acquired	Rare late-onset (some genetic mitochondrial) myopathies and neuropathies
			Unknown (termed 'idiopathic')
	Secondary	Genetic	Muscular dystrophy and other rare genetic muscle diseases
			MEN type 2B with ganglioneuromatosis
			Rare genetic autonomic neuropathies
		Acquired	CNS diseases, including senility, Parkinson's, dementias, amyloid and spinal cord injury
			Connective tissue disease, especially scleroderma
			Infections: Chagas' disease (South American trypanosomiasis)
			Autonomic neuropathies secondary to diabetes and paraneoplasia
Megarectum	*Primary*	Congenital	Ultrashort-segment Hirschsprung's disease (congenital megarectum)
			Inadequately resected Hirschsprung's disease (post reconstruction)
			Anorectal malformations (post reconstruction)
	Secondary	Congenital	Severe psychobehavioural + cognitive impairment (+ genetic)
		Acquired	Later-onset behavioural (autistic spectrum) disorders
			Sexual abuse; neglect; parental negativism

CNS, central nervous system; MEN, multiple endocrine neoplasia.

More common causes of megacolon include extreme senility and CNS neurodegenerative disease, resembling an attenuated form of ACPO. Others are denoted 'idiopathic' to reflect that no cause is established; this group, who are predominantly female, phenotypically resemble a severe form of slow-transit constipation (see ***Constipation***). All are rare.

Patients with megarectum are usually divided into two groups by clinicians. The first are those who have had previous surgery for Hirschsprung's disease or anorectal malformations in whom ongoing problems are common – due perhaps to surgical reconstruction or an as yet undetermined neuromuscular disease. The second, predominantly male, group are sometimes described as 'idiopathic'; however, nearly all, if assessed carefully, will have some form of psychobehavioural disorder. The pathogenesis is considered to be stool withholding in infancy or childhood, leading to chronic distension and loss of compliance.

Diagnosis and management

Megarectum may present with a mass the size of a full-term baby (***Figure 73.9***) but diagnosis is mainly radiological. The mainstay of management of both (in brief) requires getting the rectum empty. In some patients with megarectum this may require manual disimpaction under anaesthesia. Thereafter, high doses of regular osmotic and simulant laxatives orally as well as regular enemas (or high-volume transanal irrigation (TAI); see ***Constipation***) are required to keep it empty. Prokinetics may also have a role. Compliance with medication is often an issue in young patients with psychobehavioural problems. Surgery has an important role in patients who fail medical management. Colectomy or subtotal colectomy is generally required for megacolon. A variety of options exist for megarectum. A first step may be an anterograde colonic enema (ACE) procedure (see ***Constipation***). If this fails, definitive surgery includes pull-through procedures, low anterior resection, restorative proctocolectomy and rectum-reducing procedures, e.g. vertical reduction rectoplasty. All should be undertaken with covering loop ileostomy and many advocate performing an ileostomy for 6 months to 1 year prior to surgery. This allows the rectum to shrink and reduce in vascularity, making eventual surgery safer; some patients may also simply

Figure 73.9 Plain abdominal radiograph of a teenage male with megarectum.

choose to live with the ileostomy rather than risk pelvic surgery. The hazard of operating on a rectum that occupies the whole pelvis with serosal veins that sometimes resemble the iliac veins cannot be underestimated and surgery should be performed in specialist centres.

CHRONIC IMPAIRMENT OF INTESTINAL MOTILITY WITHOUT DILATATION

Constipation and IBS are very common conditions and collectively represent about a third of patients presenting to the average colorectal clinic in the Western world. They are presented here as separate entities to reflect the general approach of most physicians; however, the reader should be aware that there is very considerable overlap, especially between constipation and the constipation-predominant form of IBS (C-IBS). Patients can fulfil the criteria for both diagnoses concurrently or move between diagnoses over time.

Constipation

Definitions

'Constipation' is not a disease but rather a term often used by patients to describe dissatisfaction with their bowel function or their ability to defecate. As such it means different things to different patients (and different doctors) and can describe symptoms that directly relate to defecation, e.g. straining, or those considered consequent in the abdomen, e.g. pain and bloating. More formal definitions such as that of the American College of Gastroenterologists – 'unsatisfactory defecation, characterized by infrequent stools, difficult stool passage or both for at least 3 months' – cover most symptoms and introduce a time criterion to exclude patients with transient symptoms (sometimes called 'simple constipation'). Stricter definitions of 'chronic constipation' include a measure of resistance to treatment – 'unsatisfactory defecation characterized by infrequent stools, difficult stool passage or both for at least 6 months where this has proven unresponsive to lifestyle alterations and basic laxative therapy'.

Epidemiology

Self-reported constipation is very common, with a worldwide prevalence of about 10% (making it one of the commonest ailments in humans). Fortunately, patients with chronic constipation (based on 6 months of symptoms and failure of at least two laxatives) are much less common (approximately 0.5%). Most studies report a higher prevalence of self-reported constipation in women than in men with a ratio of 2:1. The ratio is much higher for chronic constipation at approximately 9:1 female to male.

Risk factors

The vast majority of patients with chronic constipation lack a single unifying cause for their problems. The main associated medical conditions and diseases within the gastrointestinal tract itself are listed in ***Table 73.5***.

Diagnosis

Clinical history

A thorough history will determine whether constipation represents a new complaint, i.e. one indicative of a change

TABLE 73.5 Risk factors for constipation.

Gastrointestinal causes	
Mechanical obstruction	Benign and malignant strictures
Functional obstruction	Pelvic organ prolapse syndromes (dynamic obstruction at the level of the anorectum)
	Megarectum
	Anal pain, e.g. chronic fissure
Medical causes	
Metabolic disorders	Hypercalcaemia, uraemia, hypokalaemia, hypomagnesaemia
Endocrine disorders	Hypothyroidism, diabetes, pregnancy
Neurological disorders	Degenerative CNS diseases, e.g. multiple sclerosis, Parkinson's, cerebrovascular disease, spinal or pelvic nerve lesions, autonomic neuropathies, cognitive impairment
Drugs	Opioids
	Anticholinergics
	Calcium channel blockers
Psychological	Severe endogenous depression
	Eating disorders
	Cognitive behavioural disorders
Other	Connective tissue diseases
	Joint hypermobility
	Causes of immobility, e.g. degenerative joint disease

CNS, central nervous system.

in bowel habit. The patient should be asked specifically about the frequency and consistency of bowel movements and the progress of such changes over time (as well as other alarm symptoms such as rectal bleeding and weight loss). With additional information regarding family history, previous colon cancer screening and other gastrointestinal investigations, an informed decision can be made whether intraluminal investigation of the colon is required. Other organic causes of constipation may be deduced by appropriate history taking and biochemical investigation. With the exclusion of treatable secondary causes, if the history is short and multiple previous therapies have not already been tried, the patient may be first considered to have 'simple' constipation that can be managed with reassurance and lifestyle advice (fibre, fluids and exercise) with/without simple laxative therapy.

In patients with chronic symptoms, after exclusion of a secondary cause, the focus should shift to the investigation and management of chronic constipation. Many patients may attribute the start of symptoms to a major life event. Common among these are hysterectomy and childbirth, other abdominal surgeries or trauma. Constipation can also be associated with previous abuse and it may sometimes be necessary to tactfully seek a history of physical or sexual abuse. Other patients will have no such triggers, having had symptoms from childhood and on occasion from infancy. Such patients are overwhelmingly female (>95%) and on investigation are often found to have generalised slow-transit constipation as opposed to other pathophysiological findings (this group, who represent 5–10% of patients with chronic constipation, are variably referred to in the literature are 'idiopathic slow-transit constipation' or 'colonic inertia'). It is helpful to systematically document the main symptoms that in the patient's mind constitute a problem since this has some bearing on treatment decisions and subsequent monitoring of effectiveness. Several questions form detailed scoring systems to systematically facilitate this in a research context. However, in routine practice it is sufficient to list in the patient's record the presence or absence of several common symptoms (***Summary box 73.7***). The presence of prolapse symptoms reflects the overlap between diagnoses in patients with pelvic floor disorders (see ***Chapter 80***). The remaining history should document prescribed and self-administered laxatives (and therapeutic benefit thereof) and also gain an impression of the quality of diet in respect of fibre and fluid intake.

Clinical examination

Poor nutritional status should prompt a search for a secondary cause, including occult carcinoma, more widespread intestinal motility disorders such as IPO (see ***Chronic impairment of intestinal motility with dilatation of the small intestine: intestinal pseudo-obstruction***) and eating disorders. An abdominal examination should be conducted to look for scars, any significant abdominal distension, tenderness or masses. Bloating is a common and expected finding with chronic constipation, but significant distension, tenderness or masses should prompt a full investigation.

All patients presenting with constipation should undergo a rectal examination. The perineum and anus should be examined for evidence of faecal incontinence that may indicate impaction and overflow. Some degree of faecal incontinence and chronic constipation coexists in 40% of patients; marked soiling of the underwear is especially associated with the rarer diagnosis of megarectum. Scarring, e.g. from episiotomy, sentinel pile formation secondary to an underlying anal fissure, external haemorrhoids or prolapse, may also be present. The degree of perineal descent on straining, indicative of pelvic floor weakness, should also be determined visually (>3 cm is usually considered abnormal). A digital rectal examination will diagnose impaction, gain a rough measure of anal tone at rest and on squeeze and ascertain obvious sphincter defects. An effort should be made to look for any anterior defect in the rectovaginal septum leading to a rectocele. Anoscopy and proctoscopy should be performed if there is any history of rectal bleeding and may indicate fissure or internal piles. A urogynaecological examination is desirable in all patients with suspected pelvic multi-organ prolapse.

Summary box 73.7

Symptoms to directly question in patients with constipation

Abdominal symptoms
- Abdominal pain
- Bloating

Defecatory symptoms
- Frequency of spontaneous or assisted bowel opening
- Painful defecation
- Stool consistency (can use Bristol stool scale)
- Digitation (vaginal or anal)
- Straining
- Incomplete/unsuccessful evacuation
- Leakage/incontinence
- Prolapse

Other pelvic symptoms
- Vaginal bulging or prolapse
- Urinary incontinence

Investigations

While findings from history or physical examination may indicate a secondary cause of constipation, making further investigation mandatory, it is also typical practice in patients with chronic constipation to exclude certain secondary causes by investigation even though the diagnostic utility of such investigations is acknowledged to be low (the commonest undiagnosed systemic disease is hypothyroidism). Thus, serum electrolyte, creatinine, calcium, glucose, haemoglobin levels and thyroid function tests are usually performed. The approach taken to structural investigation of the colon when patients have no suspected intraluminal pathology varies on the basis of available resource and may include colonoscopy.

In patients with chronic constipation in whom basic laxatives have failed, further specialist investigative tests may be warranted. Colonic transit can be investigated by a radio-opaque marker study (***Figure 73.2***). In addition, rectal

sensory testing and evacuation proctography will determine if the patient has a functional or dynamic structural cause of evacuation disorder. Problems such as dyssynergic defecation (functional) and intussusception/rectocele (structural) may occur in isolation or coexist with transit disturbances (*Figure 73.10*).

Management

The treatment of chronic constipation follows a stepwise progression from lifestyle changes through potentially to major surgery in a small minority of patients. *Table 73.6* lists the main available approaches, noting where some apply only to certain diagnoses derived from the results of specialist tests of colonic and anorectal function. *Figure 73.11* provides a basic algorithm to accompany *Table 73.6*.

Patients with chronic constipation have generally had symptoms for many years and will have tried a number of remedies and prescribed laxatives. They will also usually have tried to address lifestyle modifications. Before resorting to specialist tests, it is possible to try and rationalise laxative therapy and provide a programme of nurse-led behavioural interventions. In regard to laxatives, current advice is to stop current laxatives (unless these are working well) and then titrate an oral osmotic laxative, e.g. polyethylene glycol (PEG), until the stool form is soft or liquid. If this is insufficient then a stimulant laxative such as bisacodyl may be added. If symptoms of obstructed defecation predominate then rectal laxatives in the form of suppositories or enemas may be tried with or without continuation of oral laxatives. The failure of such drugs should then prompt a trial of one of the newer prokinetic or secretagogue

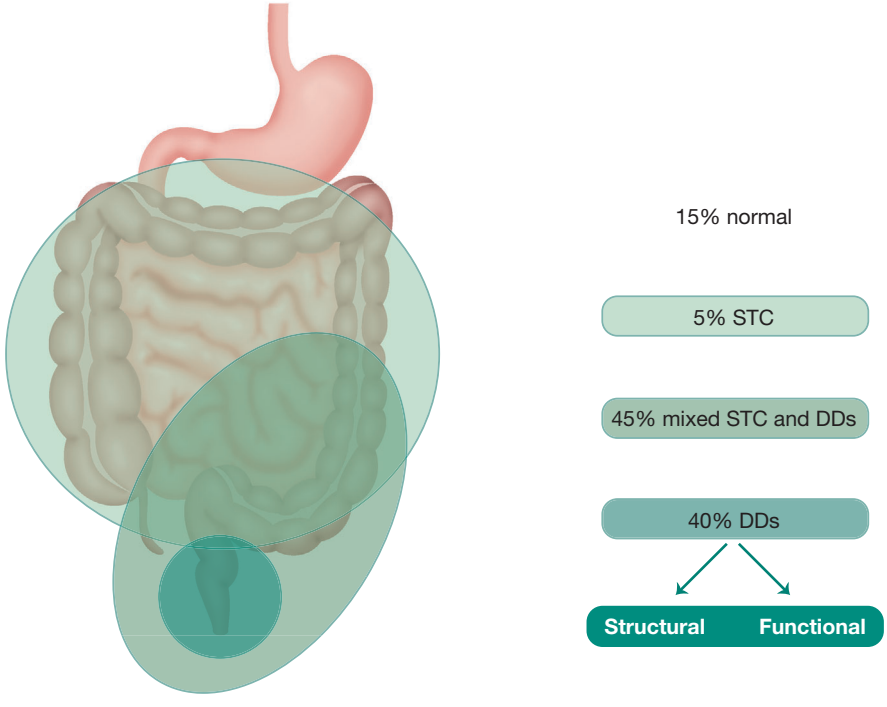

Figure 73.10 Schematic overview of pathophysiology of chronic constipation. DD, defecation disorder; STC, slow-transit constipation.

TABLE 73.6 Treatment options in patients with chronic constipation.

Lifestyle	Increase fluid intake
	Dietary modification, e.g. increased fibre
	Increase exercise
	Reduce body mass (pelvic floor prolapse syndromes)
Drugs	Oral laxatives (favoured for slow transit)
	Rectal laxatives (favoured for rectal evacuation disorders)
	Prokinetics, e.g. prucalopride
	Secretagogues, e.g. linaclotide
Behavioural therapies	Habit training
	Habit training with direct visual biofeedback (favoured for dyssynergic defecation)
	Pelvic floor muscle training (favoured for pelvic floor prolapse syndromes)
Transanal irrigation	High- or low-volume systems available
Surgery	See *Summary box 73.8*

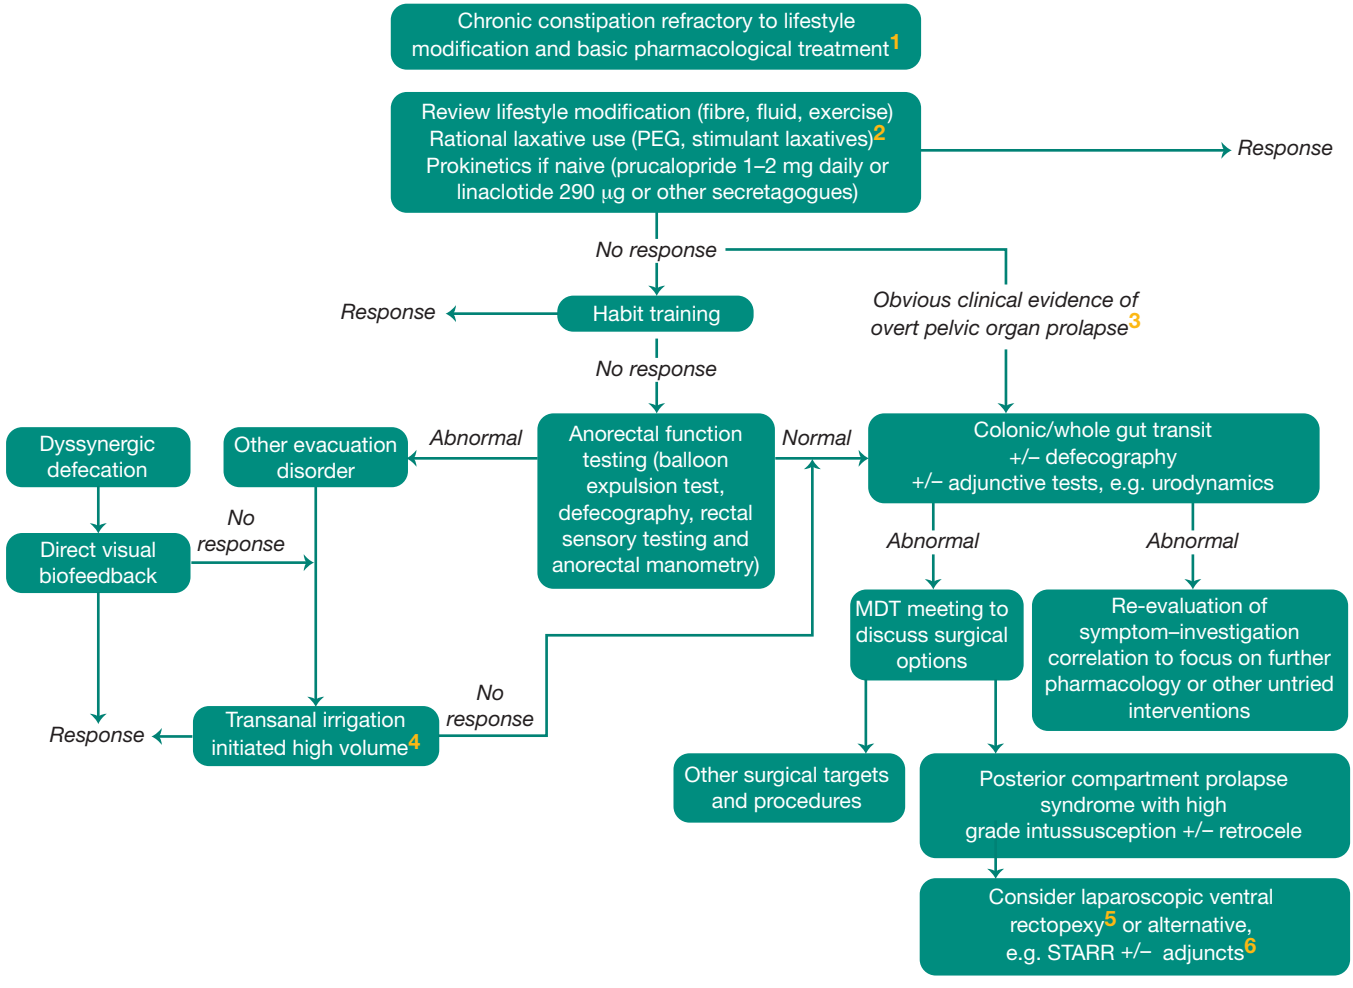

Figure 73.11 Algorithm of chronic constipation management. MDT, multidisciplinary team; PEG, polyethylene glycol. 1, alarm features excluded and secondary causes treated appropriately; 2, in constipation-predominant irritable bowel syndrome, consider antispasmodics or neuromodulators in case constipation improves but abdominal pain persists and is dominant symptom; 3, examples of overt prolapse include anterior (stage 3 cystocele), middle (stage 3 rectocele, uterovaginal prolapse) and posterior compartments (grade IV/V intussusception); 4, unless patient preference for low volume or specific contraindications to high volume; 5, may reduce specific symptoms but not have overall effect on quality of life; 6, common adjuncts include sacrocolpopexy, hysterectomy, transvaginal tape and cystocele repair.

drugs. These drugs are successful in a proportion of patients but do have some unwanted side effects (that the patient should be warned about). All drugs should be tried daily for a minimum of 4 weeks before concluding that they are ineffective and the reactionary use of laxatives, i.e. in response to being constipated, rather than their preventative use, should be strongly discouraged.

The most common form of behavioural intervention is often described by the term 'habit training'. This involves optimising dietary patterns to maximise gastrocolic response and the morning clustering of colonic high-amplitude propagated contractions that propel contents towards the rectum for subsequent evacuation. Dietary advice to optimise intake of liquid and fibre is given as well as advice about frequency and length of toilet visits and posture (***Figure 73.12***). Patients are also instructed on basic gut anatomy and function and gain an appreciation of how psychological and social stresses may influence gut functioning. Simple pelvic floor and balloon expulsion exercises are often included. Such appointments also

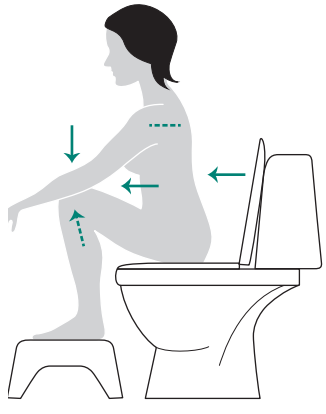

Figure 73.12 Correct posture for defecation.

offer an opportunity to further rationalise and monitor laxative therapy.

If this fails, there may be recourse to the specialist tests to assess colonic transit and also anorectal function (see ***Chapter 80***). Armed with the results of these tests, the patient may have a more targeted approach relative to their observed pathophysiology. One example of this approach is for patients with a condition termed 'dyssynergic defecation', where there is a failure to relax, or even paradoxical contraction of the pelvic floor muscles (especially puborectalis) during defecatory efforts. In such patients, instrument-based biofeedback learning techniques provide direct visual computer-based biofeedback of pelvic floor activity. The aim is to retrain the patient to appropriately contract abdominal and relax pelvic floor muscles during defecation with the patient receiving feedback of anal and pelvic floor muscle activity as recorded by surface electromyographic anal pressure sensors or digital examination by the therapist.

Transanal irrigation (TAI) may be used for any patient with an evacuation disorder when habit training and/or biofeedback have failed. A number of devices are available that administer a low (approximately 50–100 mL) or high volume (approximately 500 mL) of irrigant fluid into the rectum. The patient sits on the toilet to evacuate the fluid and faecal material.

Some patients with chronic refractory symptoms may seek a surgical solution to their problem. Surgical procedures can be broadly divided into those addressing dynamic structural problems of the pelvic floor (prolapse procedures), those that seek specifically to address slow-transit constipation and those that may have a role for both (***Summary box 73.8***).

Summary box 73.8

Surgical options in patients with chronic constipation

Prolapse procedures for dynamic structural causes of obstructed defecation

- Hitching procedures, e.g. rectopexy
- Rectal wall excisional procedures, e.g. stapled transanal rectal resection (STARR)
- Rectovaginal reinforcement procedures, e.g. posterior vaginal repair, intra-anal Delorme's procedure

Procedures for slow-transit constipation

- Colectomy and ileorectal anastomosis
- Other variants of subtotal colectomy

Procedures for refractory chronic constipation in general

- Stoma: ileostomy or colostomy
- ACE procedures
- Neuromodulation

All surgery should be undertaken in the knowledge that none of the above-listed operations is perfect. All represent a trade-off between benefits and short-term harms and poor long-term functional outcomes. On this basis, the following are essential requirements before surgery is undertaken:

- pathophysiological findings from specialist tests concur with the symptomatology and findings on clinical examination;
- conservative (non-surgical) treatment options have been tried;
- the patient's case has been reviewed at a multidisciplinary team (MDT) meeting and surgery recommended;
- the patient has been consented in the very clear knowledge of the range of possible outcomes;
- surgery is undertaken in a centre with expertise in managing functional conditions.

The range of procedures for rectal prolapse are covered in detail in ***Chapter 79***. Those primarily targeting the intestine are covered briefly here.

Colectomy

Colectomy is a radical and clearly irreversible final solution for patients with refractory slow-transit constipation. Its use should be very highly selective, not least because it is not actually a solution for many patients even when the surgery itself passes without complication. Removal of the whole colon with ileorectal anastomosis (as performed for inflammatory bowel disease) is best studied; subtotal resections with ileosigmoid or caecorectal anastomosis are alternatives. Outcomes vary greatly and are often compromised by early problems of ileus and a higher than expected rate of adhesional small bowel obstruction. Later problems include ongoing constipation and obstructive symptoms, diarrhoea and urgency, abdominal pain and bloating. Embarking on this procedure requires very careful MDT review, documentation of generalised slow-transit constipation and exclusion of a long list of relative contraindications.

Stoma

A stoma may be used as a definitive procedure, as a guide to further treatment or as salvage from a failed or complicated prior surgical intervention. There are few published data to support evidence-based use; however, an ileostomy may be employed as a guide to colectomy with subsequent resection avoided if ileostomy output is unsatisfactorily high or symptoms such as pain and bloating are untouched by diversion. As a definitive procedure, there is little evidence in adults to guide the choice of ileostomy or colostomy; however, it is generally considered that slow-transit constipation is unsatisfactorily treated by colostomy.

Anterograde colonic enema procedures

The formation of a conduit to introduce irrigant into the colon is best established in children and in patients with neurological disease. A variety of methods have been proposed to access the caecum either directly, e.g. with a Chait tube caecostomy, or indirectly via the appendix (appendicostomy). The latter is almost certainly preferable although only possible when the

Edmond Delorme, 1847–1929, French military surgeon and Professor of Surgery, Val-de-Grace Military Hospital, Paris, France.
Peter Graham Chait, contemporary, radiologist, Toronto, Canada.

native appendix is still present and the patient is not obese. The appendix can be reversed (Malone anterograde continent enema technique) or used in its native orientation (much simpler). Outcomes in adults with chronic constipation are variable but generally this is a good option in patients considering colectomy or stoma as the only alternative.

Neuromodulation

The attraction of being able to treat chronic constipation with a minimally invasive and safe approach such as sacral neuromodulation is supported by research data showing that stimulation improves motility and also some observational data. It is now clear from randomised trials that it has no role for slow-transit constipation but it may yet have a place in modifying anorectal function in some patients with severe functional syndromes leading to obstructed defecation (as it does for the bladder).

Irritable bowel syndrome

Surgery has no role in treating IBS. Nevertheless, patients with chronic abdominal pain and a change in their bowels are very common in surgical clinics and all surgeons should at least have a passing familiarity with a disorder that is a source of misery to millions of people worldwide.

Definitions

IBS is a functional bowel disorder characterised by abdominal pain or discomfort, stool irregularities and bloating. The term replaced nineteenth century descriptions such as 'irritable' or 'spastic' colon in 1979 to reflect the fact that the colon is not the only site of the problem. Diagnostic criteria have evolved to the now used Rome IV Foundation definition:

> ***Recurrent abdominal pain on average at least 1 day/week in the last 3 months, associated with two or more of three criteria: (1). related to defecation; (2). associated with a change in the frequency of stool and (3). associated with a change in the form (appearance) of stool. These criteria should be fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.***

The change in frequency and form of the stool dictates subdivisions of IBS into constipation-predominant (IBS-C), diarrhoea-predominant (IBS-D) and mixed (IBS-M) subclasses (***Figure 73.13***).

Aetiology and risk factors

Regardless of exact definition, the cardinal symptoms of chronic abdominal pain and 'deranged digestion' favour a 'biopsychosocial model' (***Figure 73.14***) that encompasses the role of stressful life events and brain–gut interactions in symptom generation. Several common life events are particularly well documented; these include postinfective IBS, where a seemingly discrete attack of gastroenteritis (viral, bacterial or otherwise) is followed by chronic ongoing symptoms; physical and/or sexual abuse (and neglect); surgery; and trauma. One implication of the model is that IBS has much overlap with other medical conditions that have similar or nearly identical biopsychosocial determinants (***Summary box 73.9***).

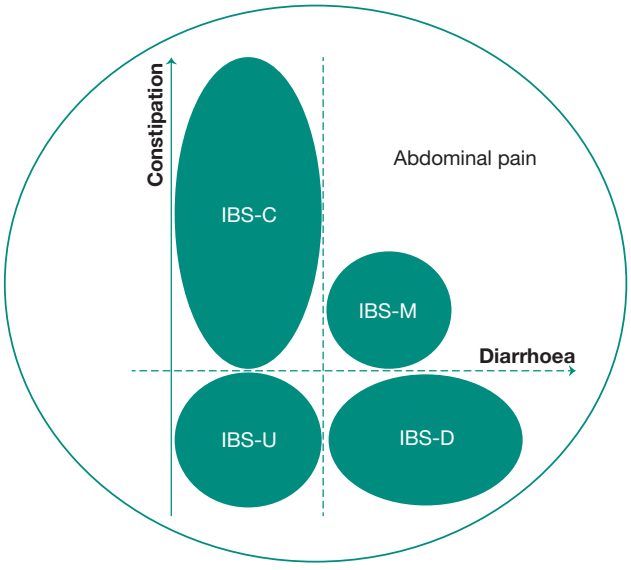

Figure 73.13 Irritable bowel syndrome (IBS) subtypes according to the Rome criteria. All patients have abdominal pain but subtypes vary according to bowel form at presentation such as to meet criteria for IBS with constipation (IBS-C), IBS with diarrhoea (IBS-D), mixed-type IBS (IBS-M) and unsubtyped (IBS-U).

Summary box 73.9

IBS-associated comorbidities

General

- Fibromyalgia syndrome
- Chronic fatigue syndrome
- Chronic pelvic pain, chronic prostatitis and bladder pain syndromes
- Chronic back pain
- Migraines
- Depression
- Anxiety
- Somatisation
- Sleep disturbance

Gastrointestinal disorders[a]

- Eating disorders
- Dyssynergic defecation
- Levator ani syndrome and proctalgia fugax
- Food intolerances

[a]The overlap of IBS with other Rome-defined functional gastrointestinal disorders should also be noted, including functional dyspepsia and functional constipation.

Patrick Malone, contemporary, surgeon, Southampton, UK.

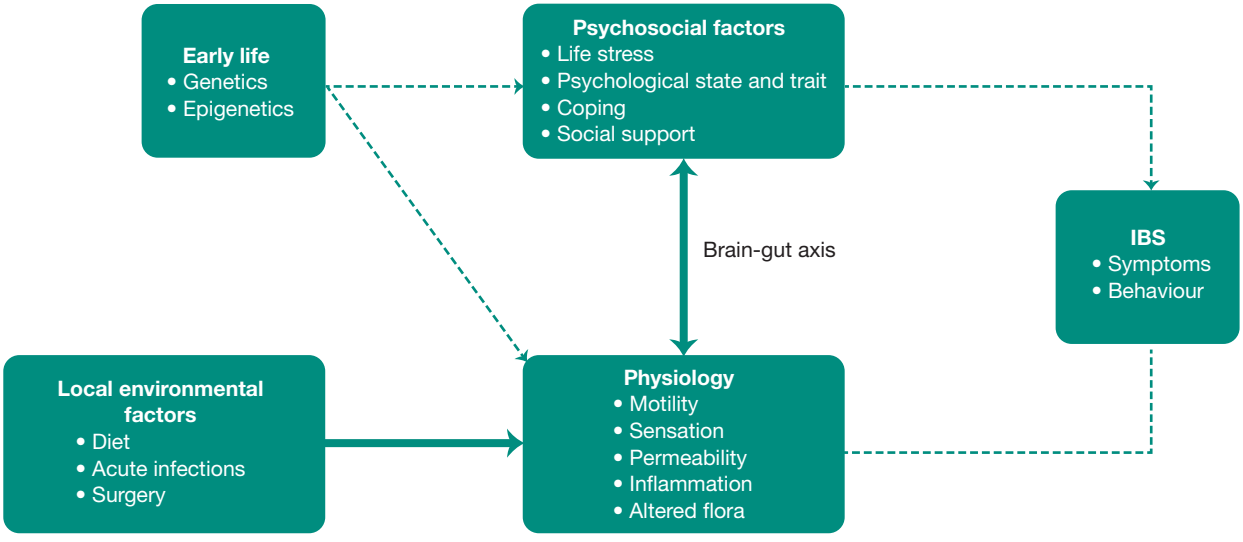

Figure 73.14 Biopsychosocial model of irritable bowel syndrome (IBS). The scheme is a conceptualisation of the pathogenesis and clinical expression of IBS showing interrelationships between various risk factors and changes in physiology.

Diagnosis

Clinical history

Besides symptoms required by the diagnostic criteria, other symptoms may be present. Common associated symptoms include bloating (very common), straining at defecation, excessive flatulence and postprandial indigestion. A history of precipitating events (as per the model) and of comorbidities (***Summary box 73.7***) should also be sought to support the diagnosis. The patient may also have a history of multiple operations, which on reflection may have been directed to chronic abdominal pain, e.g. appendicectomy, cholecystectomy or hysterectomy.

Clinical examination

Physical examination helps to reassure patients and also to exclude another organic cause for symptoms. However, abdominal examination rarely discloses a specific diagnosis (abdominal tenderness is often present but non-specific); the absence of objective findings supports a diagnosis of IBS. A digital rectal examination may identify patients with dyssynergic defecation and other causes of constipation.

Investigations

There are no valid laboratory biomarkers of IBS. Routine blood panels, including inflammatory markers, are generally

TABLE 73.7 Treatments for irritable bowel syndrome.

Nutrition	Increased (constipation) or reduced (bloating) fibre
	Gluten-free diet (especially if equivocal diagnosis of coeliac disease)
	FODMAP diet
	Probiotics
	Consider dietary supplements, prebiotics
Drugs	Antispasmodics: peppermint oil, hyoscine butylbromide (Buscopan)
	Laxatives, e.g. stool softeners, osmotic and stimulant (avoid lactulose because of bloating and pain)
	Antidiarrhoeals: loperamide (μ-opioid receptor agonist); 5-HT_3 receptor antagonists, such as alosetron, ondansetron
	Motility accelerants, e.g. linaclotide (guanylyl cyclase C agonist), prucalopride (5-HT_4 receptor agonist)
	Low-dose antidepressants: tricyclics and selective serotonin reuptake inhibitors
	Manipulation of the microbiota by non-absorbable antibiotics, e.g. rifaximin
	Neuromodulators, e.g. gabapentin and pregabalin
Psychotherapy	Cognitive–behavioural therapy
	Gut-directed hypnosis
	Guided self-help interventions

5-HT, 5-hydroxytryptamine; FODMAP, fermentable oligosaccharides, disaccharides, monosaccharides and polyols.

performed to reassure that there are no indicators of organic disease, e.g. cancer, inflammatory bowel disease or diverticular disease. Specific tests include serological tests for coeliac disease, faecal calprotectin and stool microbiology in cases of diarrhoea predominance. Invasive procedures are generally not warranted unless alarm features are present that mandate endoscopy. That noted, it is quite common practice to perform colonoscopy, not least to reassure the patient that their chronic symptoms do not have an organic basis. In patients with IBS-D, colonoscopy with random biopsies is warranted to exclude microscopic colitis. Other tests that may be relevant include (75Se-homocholic acid taurine [^{75}SeHCAT] test or serum serum 7-α-hydroxy-4-cholesten-3-one (C4) levels) for bile salt malabsorption, breath testing for carbohydrate malabsorption, gastrointestinal physiology for constipation and upper gastrointestinal endoscopy for associated dyspeptic symptoms.

Management

Only a fraction of patients with IBS-like symptoms seek medical care and most will initially consult primary care physicians for their symptoms. The factors that drive this consultation are symptom severity, especially pain, and concerns that symptoms might indicate an underlying severe disease, e.g. cancer. Therefore, in many cases, the doctor's role is to exclude diseases that can mimic IBS symptoms by relevant investigations such as endoscopy.

When a positive diagnosis of IBS has been made, management requires an integrated approach, including education, reassurance, dietary alterations, pharmacotherapy and behavioural or psychological interventions/support. The initial treatment strategy should be based on predominant symptoms and includes antispasmodics for abdominal pain, antidiarrhoeals for IBS-D and laxatives for IBS-C, whereas nutritional interventions and psychotherapy can be used in all subtypes. ***Table 73.7*** provides a list of potential management strategies for IBS. This list is not all encompassing, nor does it provide weighting to one treatment over another in terms of effectiveness in clinical trials. Some treatments are popular, e.g. low-dose antidepressants but such use is off-label; others may be tried over the counter by patients, e.g. prebiotics, although there is no trial evidence.

A key point in the management of IBS rests with notable exclusions from ***Table 73.7***. Thus the table makes no reference to standard analgesics and surgery. Opioid analgesia should be avoided in IBS because the further disturbance to motility worsens the prognosis and in extreme use can lead to narcotic bowel syndrome (an opioid-induced state of hyperalgesia whose main driver is the activation of glial cells). Surgery has a well-documented association with symptom onset of IBS (cholecystectomy, appendicectomy, hysterectomy and back surgery); further surgery leads not only to greater potential visceral sensitisation (via injury) but also serves to confuse subsequent diagnosis, e.g. adhesional versus functional cause for symptoms. There is also a body of evidence to suggest that surgery perpetuates a search for an 'organic' diagnosis that hinders patient acceptance and adaption to their chronic problem. For the surgeon, the key is to exclude any surgical cause of pain and then prevent further harm by avoiding surgery.

SUMMARY

Functional intestinal disorders range from the very common – constipation and IBS – through to the very rare, e.g. various genetic and familial neuropathies and myopathies causing IPO. The surgeon will almost certainly encounter acute problems such as POI and ACPO. This chapter provides an overview that can be supplemented by the recommended further reading.

PART 11 | Abdominal

CHAPTER 74

The small intestine

Learning objectives

To appreciate:
- The basic anatomy and physiology of the small intestine
- The range of conditions that may affect the small intestine

To understand:
- The aetiology and pathology of common small intestinal conditions
- The principles of investigation of small intestinal symptoms
- The importance of non-surgical management of small intestinal problems
- The principles of small intestinal surgery
- That complex intestinal problems are best managed by a multidisciplinary team

ANATOMY OF THE SMALL INTESTINE

Although the duodenum is anatomically indistinguishable from the rest of the small intestine, in surgical terms it may be regarded as a distinct structure and is discussed in ***Chapter 67***. The small intestine lies between the duodenojejunal (DJ) flexure and the ileocaecal valve (***Figure 74.1***). It is difficult to establish the length of the small intestine. It varies widely between subjects (it is said to be longer in men) and estimates gathered at surgery, at postmortem and during radiological investigations have been noted to vary widely, even in the same individual. Most studies however describe a range between 300 and 850 cm.

The proximal 40% of the small intestine is referred to as the jejunum and the remainder is the ileum. There is no clear demarcation between jejunum and ileum, as the character of the small intestine changes gradually from proximal to distal. The jejunum tends to have a wider diameter and a thicker wall, with more prominent mucosal folds (valvulae conniventes), while the ileum has a thicker, more fatty mesentery with more complex arterial arcades. The ileum also contains larger aggregates of lymph nodes (Peyer's patches), which can occasionally become the lead points in childhood intussusception.

The small intestine has a rich blood supply, derived from the superior mesenteric artery (SMA), while venous drainage is via the portal venous system. The superior mesenteric vein joins the splenic vein to form the portal vein, which drains into the liver, carrying absorbed nutrients from the bowel for processing. The lymphatic drainage of the small intestine follows the arterial supply.

The small intestine has a rich autonomic innervation arising from the splanchnic nerves, which contribute a dense network of sympathetic fibres around the SMA and its branches. Referred pain from the small intestine is usually felt in the periumbilical region (T10). The blood and nerve supplies to the small intestine run in its mesentery, which is attached to the posterior abdominal wall and runs obliquely downwards to the right between the DJ flexure to the left of the second lumbar vertebra and the right sacroiliac joint (***Summary box 74.1***; see ***Chapter 65***).

Summary box 74.1

Important features of small bowel anatomy
- Comprises jejunum and ileum
- Has valvulae conniventes
- Blood supply from SMA

PHYSIOLOGY OF THE SMALL INTESTINE

The principal function of the small intestine is the digestion of food and absorption of nutrients, water and electrolytes. Carbohydrates and proteins are broken down in the intestinal lumen by pancreatic enzymes, but the final hydrolysis takes place at the brush border of the jejunum, after which these nutrients are absorbed. Fats are digested chiefly by the actions of pancreatic lipase and bile salts. The products of fat digestion, fatty acids and monoglycerides, separate from bile salts in the jejunum and are absorbed for further processing. The jejunum is the principal site for digestion and absorption of fluid, electrolytes, iron, folate, fat, protein and carbohydrate,

Valvulae conniventes describes a fold of mucous membrane that passes across two-thirds of the bowel circumference.
Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

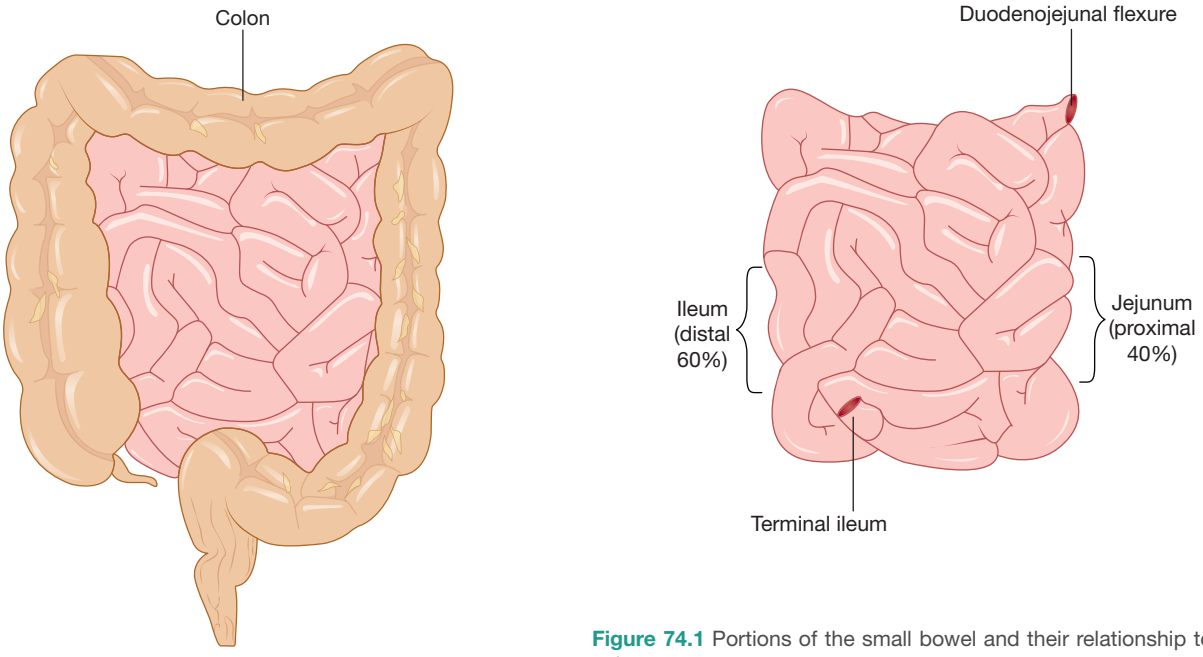

Figure 74.1 Portions of the small bowel and their relationship to the colon.

but the absorption of bile salts and vitamin B12 only occurs in the terminal ileum, where there are specific transporters. If the jejunum is resected, the ileum can assume all the required absorptive functions, but resection of the terminal ileum will result in a diminished bile salt pool, vitamin B12 deficiency and may lead to deficiency of the fat-soluble vitamins A, D, E and K. The ileum also plays an important role in water absorption, possibly because the tightness of the intercellular junctions supports a concentration gradient across its lumen. Significant ileal resection therefore commonly results in very troublesome diarrhoea.

The small intestine plays an important role in the metabolism of plasma lipoproteins, as it is the main site of synthesis of high-density, low-density and very low-density lipoproteins (HDL, LDL, VLDL). These particles transport most of the absorbed dietary fat to the systemic circulation via the lymph. The small bowel also synthesises intestinal hormones such as glucagon-like peptides GLP-1 and 2, peptide YY and motilin, which interact with the enteric nervous system to modulate intestinal function, growth and differentiation.

INFLAMMATORY BOWEL DISEASE

The term 'inflammatory bowel disease' is reserved for conditions characterised by the presence of idiopathic intestinal inflammation; conditions such as infective or ischaemic enteritis are, by definition, excluded. Crohn's disease (CD) is the only known 'inflammatory bowel disease' that affects the small intestine and is covered in detail in ***Chapter 75***.

INFECTIVE ENTERITIS

Campylobacter

Infection with *Campylobacter jejuni* (a Gram-negative rod with a distinctive spiral shape) is the most common form of bacterial gastroenteritis in the UK, typically acquired from eating infected poultry. It causes diarrhoea and abdominal pain and may mimic an acute abdomen. Severe cases may resemble ulcerative colitis, with rectal bleeding and colorectal ulceration, causing diagnostic difficulty. The organism is fastidious in culture and may take several days to isolate in the laboratory. Toxic dilatation and even disintegrative colitis have rarely been reported to occur. Treatment is generally supportive as the condition usually resolves without antibiotics. It is a notifiable disease.

Yersinia

Yersinia enterocolitica is a Gram-negative rod that can infect the terminal ileum, appendix, ascending colon and mesenteric lymph nodes, and can cause a granulomatous inflammatory process that may mimic CD. *Yersinia* typically causes a fever and gastroenteritis, but may persist and cause a terminal ileitis, which, on occasion, may perforate. The diagnosis may be made on stool culture, but is more often confirmed serologically. If discovered at laparotomy, the terminal ileum and mesenteric nodes will look thickened and inflamed and a lymph node biopsy can be taken for diagnostic purposes. The disease is normally self-limiting, but responds to treatment with co-trimoxazole or chloramphenicol antibiotics.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, along with Leon Ginzburg and Gordon Oppenheimer, described regional ileitis in 1932.

Salmonella, typhoid and paratyphoid

Salmonella are a family of Gram-negative rods that can cause a range of enteric infections. *Salmonella* gastroenteritis is typically caused by *Salmonella enteritidis* from poultry and is most often a self-limiting illness comprising headache, fever and watery diarrhoea. When severe, antibiotics and hospitalisation and intravenous fluids may be needed. The diagnosis is based on stool culture. *Shigella* and enteropathogenic strains of *Escherichia coli* may cause similar diarrhoeal illnesses.

Typhoid fever is caused by *Salmonella enterica* and presents with fever and abdominal pain after an incubation period of 10–20 days. Over the next week, the patient can develop distension, diarrhoea, splenomegaly and characteristic 'rose spots' on the abdomen caused by a vasculitis. Typhoid is a systemic infection and diagnosis of typhoid is confirmed by culture of blood or stool. Treatment is by antibiotics, usually chloramphenicol. A number of surgical complications can result, including paralytic ileus, intestinal haemorrhage, free ileal perforation and cholecystitis.

Invasion of the systemic circulation, which is a characteristic feature of salmonellosis, may cause severe Gram-negative sepsis, resulting in septic shock. Some patients develop metastatic sepsis, including septic arthritis and osteomyelitis, meningitis, encephalitis, disseminated intravascular coagulation and pancreatitis.

Perforation of a typhoid ulcer characteristically occurs during the third week of the illness, although it is sometimes the first clinical sign of the disease. The ulcer is parallel to the long axis of the gut and is usually situated in the distal ileum. Perforation requires surgery to wash out and close the ulcer and intestinal resection is usually avoided. In unstable patients, notably with evidence of septic shock, the bowel should be exteriorised and the perforation closed after recovery. Paratyphoid infection (with *Salmonella* Paratyphi A) resembles typhoid fever and is treated in a similar manner (see ***Chapter 6***).

Tuberculosis of the intestine

Tuberculosis, like CD, can affect any part of the gastrointestinal tract. The sites affected most often are the ileum, proximal colon and peritoneum. There are two principal disease presentations.

Ulcerative tuberculosis

Ulcerative tuberculosis develops secondary to pulmonary tuberculosis and arises as a result of swallowing tubercle bacilli. Multiple ulcers, lying transversely, develop in the terminal ileum and the overlying serosa is thickened, reddened and covered in tubercles. Patients typically present with diarrhoea and weight loss, although subacute obstruction and even local perforation and fistula formation can occur. A barium follow-through or computed tomography (CT) examination fails to show filling of the distal ileum, caecum and the ascending colon as a result of narrowing of the ulcerated segment (***Figure 74.2***).

A course of antituberculous chemotherapy usually leads to cure, provided the pulmonary tuberculosis is adequately treated. Surgery is usually undertaken only in the rare event of a perforation or complete intestinal obstruction.

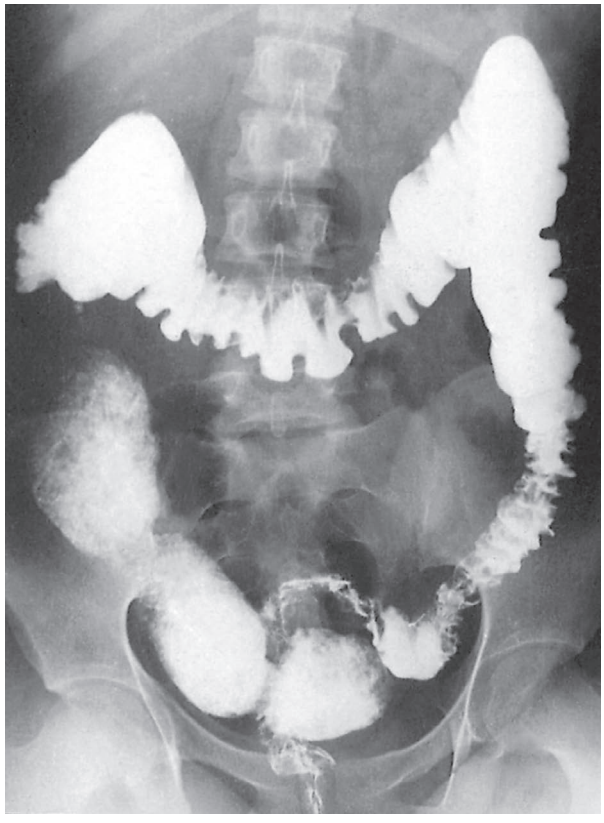

Figure 74.2 Ileocaecal tuberculosis showing dilatation of the distal ileum and stricturing of the terminal ileum and caecum (courtesy of Dr. VK Kapoor, Delhi, India).

Hyperplastic tuberculosis

This is caused by the ingestion of *Mycobacterium tuberculosis* by patients with a high resistance to the organism. The infection usually occurs in the ileocaecal region, although solitary and multiple lesions in the distal ileum are also sometimes seen. The infection establishes itself in lymphoid follicles, and the resulting chronic inflammation causes thickening of the intestinal wall and narrowing of the lumen. There is early involvement of the regional lymph nodes, which may caseate. Unlike in CD, abscess and fistula formation are uncommon.

Patients usually present with attacks of abdominal pain and intermittent diarrhoea. There is incomplete ileal obstruction, leading to stasis and bacterial overgrowth. This in turn causes steatorrhoea, anaemia and loss of weight. Patients may present with a mass in the right iliac fossa and vague ill health. The differential diagnosis is that of an appendix mass, lymphoma, carcinoma of the caecum, CD, tuberculosis or actinomycosis. A barium follow-through or small bowel enema will show a long narrow filling defect in the terminal ileum (which may result in a differential diagnosis of CD). CT will also demonstrate the narrowed segment with proximal distension and the associated lymphadenopathy. When the diagnosis is clear and the patient has not yet developed obstructive symptoms, treatment with antituberculous medication is advised and may be curative. Where obstruction is present, or the possibility of CD or lymphoma requires clarification, ileocaecal resection is often required (see ***Chapters 6 and 65***).

Actinomycosis

Abdominal actinomycosis is rare. It is caused by infection with *Actinomyces israelii* and usually develops several weeks after an apparently straightforward perforated appendicitis. An abscess develops and spreads to the retroperitoneal tissues and the adjacent abdominal wall, eventually becoming the seat of multiple indurated discharging sinuses. At first, the discharge from the sinuses is thin, watery and inoffensive, but it may later become thicker and malodorous. Secondary fistulation may occur and the tissues may become extensively indurated and woody. In contrast to tuberculosis, however, mesenteric lymph nodes are not involved and the lumen of the intestine is not narrowed. Haematogenous spread via the portal vein may lead to multiple liver abscesses.

Pus should be sent for bacteriological examination, which will reveal the characteristic sulphur granules. Penicillin or co-trimoxazole treatment is required and should be prolonged and in high dosage.

Human immunodeficiency virus

Human immunodeficiency virus (HIV) infection is associated with a number of proctological problems (see ***Chapter 80***). Intestinal complications are common after the development of acquired immunodeficiency syndrome (AIDS), when opportunistic organisms can cause gastroenteritis (***Summary box 74.2***). HIV may also cause a specific enteropathy. Treatment is directed towards the relevant organism and surgery should be avoided if possible.

Summary box 74.2

Opportunistic intestinal infections in patients with AIDS

- Bacterial
  - *Salmonella*
  - *Shigella*
  - *Yersinia*
  - *Campylobacter*
  - *Mycobacterium avium–intracellulare* (MAI)
- Viral
  - *Cytomegalovirus*
- Protozoal
  - *Cryptosporidium*
  - *Giardia*
- Fungal
  - *Candida albicans*

TUMOURS OF THE SMALL INTESTINE

Small bowel tumours are rare and in total account for less than 10% of gastrointestinal neoplasia.

Benign

The majority of small bowel neoplasms are benign, comprising adenomas, lipomas, haemangiomas and neurogenic tumours. They are frequently asymptomatic and identified incidentally, but can present with intussusception, small bowel obstruction and bleeding that may cause anaemia or may even be overt. Where these lesions do cause anaemia, the cause can be difficult to diagnose, as CT or small bowel contrast studies do not show them easily. Capsule endoscopy or small bowel endoscopy have been used successfully where the facilities exist. Symptomatic lesions can be treated by small bowel resection.

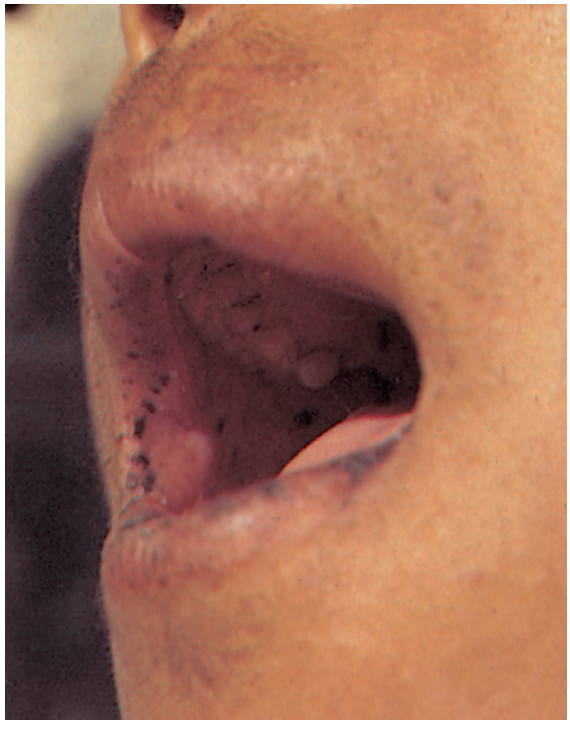

Figure 74.3 Melanin spots on the lips of a patient with Peutz–Jeghers syndrome (courtesy of Major PCM Manta, Indian Medical Service).

Peutz-Jeghers syndrome

This is an autosomal dominant condition characterised by melanosis of the mouth and lips, with multiple hamartomatous (benign tumour-like malformations resulting from faulty development in an organ) polyps in the small bowel and colon (***Figure 74.3***). Melanin spots can also occur on the digits and perianal skin. Mutation of the *STK11* gene on chromosome 19 has been found in a proportion of patients. Long-term follow-up of the original family described by Peutz has shown reduced survival as a consequence of complications of bowel obstruction and the development of a range of cancers. Regular colonic surveillance should be performed and female patients should attend breast and cervical screening. Despite the increased risk of malignancy in general, malignant change in the polyps themselves is uncommon. Resection may be indicated, however, for heavy and persistent or recurrent bleeding or intussusception. Polyps may be removed by enterotomy or, at laparotomy, snared via a colonoscope introduced via an enterotomy. Heavily involved segments of small intestine may occasionally be resected.

James Israel, 1848–1926, first found sulphur granules in pus from a discharging sinus in a man's neck. Later, he became a famous Berlin urologist.
John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, The New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

Malignant

Small bowel malignancy is rare, classically presents late and is most often diagnosed after surgery for small bowel obstruction. Four types will be considered, which account for over 99% of small bowel malignancies: adenocarcinoma, neuroendocrine tumours (NETs), lymphomas and gastrointestinal stromal tumours (GISTs).

Adenocarcinoma

Small bowel adenocarcinoma is more often found in the jejunum than in the ileum and, although the aetiology is unknown, it is more common in patients with CD, coeliac disease, familial adenomatous polyposis, hereditary non-polyposis colon cancer and Peutz–Jeghers syndrome. The tumours present with anaemia, overt gastrointestinal bleeding, intussusception or obstruction. Prognosis is poor, particularly in patients with CD, in whom these tumours often present late because the symptoms are commonly mistaken for those of CD and treated conservatively. When diagnosed, surgical treatment is a resection of 5 cm of non-involved bowel either side of the lesion and the affected mesentery (***Figure 74.4***). A right hemicolectomy is likely to be required for tumours of the distal ileum.

Neuroendocrine tumours

NETs (previously known as carcinoid tumours) occur throughout the gastrointestinal tract, most commonly in the appendix, ileum and rectum in decreasing order of frequency. They arise from Kulchitsky cells at the base of intestinal crypts (of Lieberkuhn). The primary is usually small, although significant lymph node metastases can occur. In up to one-third of cases of small bowel NETs, the tumours are multiple. They may produce dense fibrosis in the surrounding tissues, resulting in distortion and scarring of the bowel and associated mesentery, giving them a characteristic radiological appearance. NETs can produce a number of vasoactive peptides, most commonly 5-hydroxytryptamine (serotonin), but also histamine, prostaglandins and kallikrein. When they metastasise to the liver, the 'carcinoid syndrome' can become evident because the vasoactive substances escape the filtering actions of the liver. The clinical syndrome itself consists of reddish-blue cyanosis, flushing attacks, diarrhoea, borborygmi, asthmatic attacks and, eventually, pulmonary and tricuspid stenosis (***Summary box 74.3***). Classically, the flushing attacks are induced by alcohol.

Surgical resection is usually sufficient for patients with primary disease, but the incidence of recurrence is significant.

Summary box 74.3

Carcinoid syndrome

- Diarrhoea
- Bronchospasm
- Facial/upper chest flushing
- Palpitations
- Tricuspid regurgitation

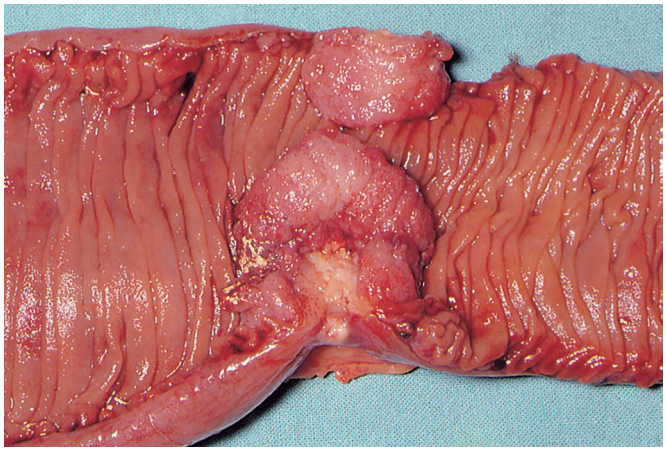

Figure 74.4 Small bowel adenocarcinoma.

The extent of disease can be assessed preoperatively using octreotide scanning (somatostatin receptor scintigraphy), which may detect otherwise clinically unapparent primary and secondary tumours. Plasma markers of tumour bulk, such as chromogranin A concentrations, may be useful markers of disease recurrence, as well as of prognostic value.

Hepatic resection can be carried out in patients with metastatic disease. The treatment has been transformed by the use of octreotide (a somatostatin analogue), which reduces both flushing and diarrhoea, and octreotide cover is usually used in patients with a carcinoid syndrome who have surgery to prevent a carcinoid crisis resulting from liberation of vasoactive substances following handling of the tumour. NETs generally grow more slowly than most metastatic malignancies and patients may live with metastatic disease for many years. The tumour is not usually sensitive to chemo- or radiotherapy (see ***Chapter 69***).

Lymphoma

Small bowel lymphoma may be primary or, more commonly, secondary to systemic lymphoma. The incidence of small bowel lymphoma is increased in patients with CD and immunodeficiency syndromes. The classification of lymphoma is beyond the scope of this chapter but a number of points are worth noting briefly. It is rare for Hodgkin's lymphoma to affect the small bowel and most Western-type lymphomas are non-Hodgkin's B-cell lymphomas. They usually present with anaemia, bleeding, perforation, anorexia and weight loss.

Small bowel T-cell lymphoma can develop in patients with coeliac disease. It usually presents with worsening of the patient's diarrhoea, pyrexia of unknown origin and local obstructive symptoms. Mediterranean lymphoma is found mostly in North Africa and the Middle East and is often widespread at diagnosis. Burkitt's lymphoma can aggressively affect the ileocaecal region, particularly in children. The mainstay of treatment for these conditions is chemotherapy; however, surgery may be required for obstruction, perforation or bleeding.

Nikolai Kulchitsky, 1856–1925, Professor of Histology, Kharkov, Ukraine, who left Russia after the Revolution of 1917 and later worked at University College, London, UK. He described these cells in 1897.
Johann Nathaniel Lieberkühn, 1711–1756, physician and anatomist, Berlin, Germany, described these glands in 1745.
Thomas Hodgkin, 1798–1866, lecturer in morbid anatomy and curator of the museum, Guy's Hospital, London, UK, described lymphadenoma in 1832.
Denis Parsons Burkitt, 1911–1993, Irish-born surgeon who worked in Kampala, Uganda.

Gastrointestinal stromal tumours

GISTs are mesenchymal tumours and the distinction between benign and malignant types is difficult even on histological examination. Increased size and high levels of *c-kit* (CD117) staining are associated with malignant potential. GISTs are found most commonly in the stomach but can be found in other parts of the gut. They occur most commonly in the 50- to 70-year age group. Although the cause is unknown, patients with neurofibromatosis have an increased risk of developing these types of tumour. Patients may be asymptomatic and the tumour may present as an incidental mass on a CT scan. Symptoms include lethargy, pain, nausea, haematemesis or melaena. Surgery is the most effective way of treating GISTs as the tumour is radioresistant and is not sensitive to conventional chemotherapy. Imatinib is a tyrosine kinase inhibitor that has been shown to be effective in advanced cases and may also have a role in adjuvant treatment. It may be used preoperatively to reduce tumour size; however, the involuting tumour may perforate, precipitating a surgical crisis (see ***Chapters 11 and 67***).

Figure 74.5 Meckel's diverticulum.

CONNECTIVE TISSUE DISORDERS

Intestinal diverticula

Diverticula (hollow outpouchings) are a common structural abnormality that can occur from the oesophagus to the rectosigmoid junction. Small bowel diverticula may be congenital or acquired. In congenital diverticula all three coats of the bowel are present in the wall of the diverticulum (e.g. Meckel's diverticulum).

Acquired diverticula

These often develop in the jejunum and arise from the mesenteric side of the bowel as a result of mucosal herniation at the point of entry of the blood vessels, where there is a potential defect in the muscularis layer. Jejunal diverticula can vary in size and are frequently multiple. They are commonly asymptomatic and present as an incidental finding at surgery or on radiological imaging. However, they can result in malabsorption, due to bacterial overgrowth, or present as an acute abdominal emergency if they become inflamed or perforate. Bleeding from a jejunal diverticulum is a rare complication (compared with sigmoid diverticular disease). Elective resection of an affected small bowel segment causing malabsorption can be effective, provided there is only a limited amount of jejunum involved. If perforated jejunal diverticulitis is found at emergency laparotomy, a small bowel resection should be performed and a decision made between primary anastomosis and stoma formation. This will depend on the degree of contamination, physiological stability and local resources for managing a patient with a high-output jejunostomy.

Complications resulting from extensive jejunal diverticulosis can be extremely difficult to treat. In severe cases, much of the proximal small intestine may be involved, effectively precluding resection. Prolonged antibiotic therapy for bacterial overgrowth may be preferable, and antibiotics (metronidazole, ciprofloxacin, rifaximin) may be rotated in an attempt to avoid antibiotic resistance. Limited resection, leaving remaining segments of affected jejunum, may be feasible, but may also fail to deal adequately with bacterial overgrowth, recurrent attacks of inflammation or bleeding.

Meckel's diverticulum

A Meckel's diverticulum is a persistent remnant of the vitellointestinal duct and is present in about 2% of the population. It is found on the antimesenteric side of the ileum approximately 60 cm from the ileocaecal valve and is classically 5 cm long (2% prevalence; 2 feet [60 cm] from ileocaecal valve; 2 inches [5 cm] long). A Meckel's diverticulum is a congenital diverticulum (***Figure 74.5***). It contains all three coats of the bowel wall and has its own blood supply. It may be vulnerable to obstruction and inflammation in the same way as the appendix; indeed, when a normal appendix is found at surgery for suspected appendicitis, a Meckel's diverticulum should be looked for by examining the small bowel, particularly if free fluid or pus is found (see ***Chapter 76***). In approximately 20% of cases, the mucosa of a Meckel's diverticulum contains heterotopic epithelium of gastric, colonic or pancreatic type. The presence of heterotopic mucosa may predispose to the development of complications (***Summary box 74.4***).

The vast majority of Meckel's diverticula are asymptomatic and a Meckel's diverticulum is notoriously difficult to visualise with contrast radiology. Meckel's diverticulum may however present clinically in the following ways.

Haemorrhage. If gastric mucosa is present, peptic ulceration can occur and present as painless dark rectal bleeding or melaena. If the stomach, duodenum and colon are excluded as a source of bleeding by endoscopy, radioisotope scanning with technetium-99m may demonstrate a Meckel's diverticulum.

Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.

Diverticulitis. Meckel's diverticulitis presents like appendicitis, although if perforation occurs the presentation may resemble a perforated duodenal ulcer.

Intussusception. A Meckel's diverticulum can be the lead point for ileoileal or ileocolic intussusception.

Chronic ulceration. Pain is felt around the umbilicus, as the site of the diverticulum is midgut in origin.

Intestinal obstruction. A band between the apex of the diverticulum and the umbilicus (also part of the vitello-intestinal duct) may cause obstruction directly, or by predisposing to the development of a volvulus around it.

Perforation. (*Figure 74.6*).

When found in the course of abdominal surgery, a Meckel's diverticulum can safely be left alone, provided it has a wide mouth and is not thickened. When there is doubt, it can be resected. The finding of a Meckel's diverticulum in an inguinal or femoral hernia has been described as 'Littre's hernia'.

Summary box 74.4

Features of Meckel's diverticulum

- Remnant of vitellointestinal duct
- Occurs in 2% of patients, 5 cm (2 inches) long, 60 cm (2 feet) from the ileocaecal valve, 20% heterotopic epithelium
- Should be looked for when a normal appendix is found at surgery for suspected appendicitis
- If a Meckel's diverticulum is found incidentally at surgery, it can be left provided it has a wide mouth and is not thickened
- Can be a source of gastrointestinal bleeding if it contains ectopic gastric mucosa

Meckel's diverticulectomy

A broad-based Meckel's diverticulum should not be amputated at its base and invaginated (as for an appendix), as there is the risk of stricture and of leaving heterotopic epithelium behind. It is safer simply to excise the diverticulum, either by resecting the diverticulum and suturing the defect at its base or by performing a limited small bowel resection with anastomosis. This can also be achieved with a linear stapler–cutter. If the base of the diverticulum is indurated, it is on balance safer to perform a limited small bowel resection of the entire involved segment, followed by an anastomosis.

VASCULAR ANOMALIES OF THE INTESTINE

Mesenteric ischaemia

Mesenteric vascular disease may be classified as acute intestinal ischaemia – with or without occlusion – venous, chronic arterial, central or peripheral. The superior mesenteric vessels are the visceral vessels most likely to be affected by embolisation or thrombosis. Occlusion at the origin of the SMA is almost invariably the result of thrombosis, whereas emboli tend to lodge at the origin of the middle colic artery. Inferior mesenteric artery involvement is usually clinically silent because of a rich collateral circulation.

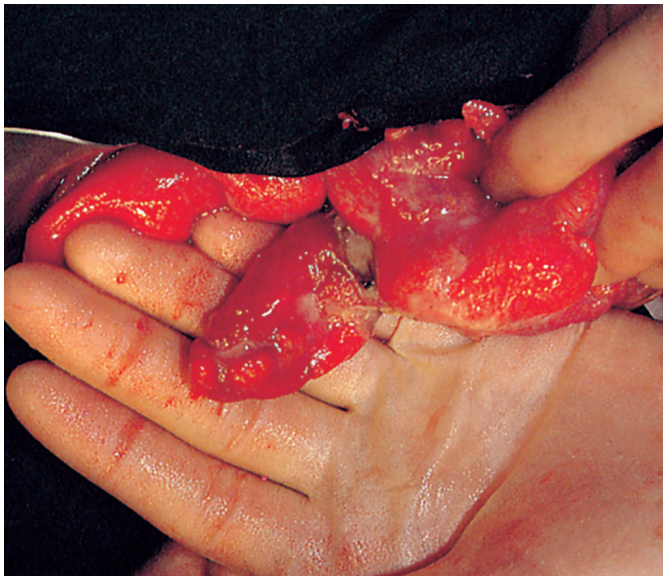

Figure 74.6 Gangrenous Meckel's diverticulitis.

SMA emboli may be carried from the left atrium in atrial fibrillation, the left ventricle after mural myocardial infarction, vegetations on mitral and aortic valves associated with endocarditis or an atheromatous plaque from an aortic aneurysm. Primary thrombosis is associated with atherosclerosis and vasculitides, including conditions such as thromboangitis obliterans and polyarteritis nodosa. Primary thrombosis of the superior mesenteric veins may occur in association with factor V Leiden disorder, portal hypertension, portal pyaemia, sickle cell disease and in women taking the oral contraceptive pill. A specific form of 'non-occlusive mesenteric ischaemia' (in which the vessels are normal but flow is critically reduced) may complicate critical illness, possibly because of alterations in splanchnic blood flow.

Irrespective of whether the occlusion is arterial or venous, haemorrhagic infarction occurs. The mucosa is especially sensitive to ischaemic injury because of its high metabolic activity. The intestine and its mesentery become swollen and oedematous, especially with venous occlusion. Bloodstained fluid exudes into the peritoneal cavity and bowel lumen. The changes develop rapidly and irreversible injury, ranging in severity from mucosal necrosis and sloughing to full-thickness infarction, usually occurs within 6 hours at most. If the main trunk of the SMA is involved, the infarction usually covers an area from just distal to the DJ flexure to the splenic flexure. Usually, a branch of the main trunk is implicated and the area of infarction is smaller.

Clinical features

The most important clue to an early diagnosis of acute mesenteric ischaemia is sudden onset of severe abdominal pain in a

Alexis Littre, 1658–1746, surgeon and Lecturer in Anatomy, Paris, France, described Meckel's diverticulum in a hernial sac in 1700, 81 years before Meckel was born.

patient with atrial fibrillation or atherosclerosis. The pain is typically in the central abdomen and is out of all proportion to the physical findings. Persistent vomiting and defecation occur early, with the subsequent passage of altered blood. Abdominal tenderness may be mild initially, with rigidity being a late feature. Shock, with features of both hypovolaemia and sepsis, rapidly ensues.

Investigation

Investigation will usually reveal a profound neutrophil leukocytosis, a severe metabolic acidosis and raised blood lactate. A contrast-enhanced CT scan will show bowel wall enhancement absent or reduced and there may be free fluid in the abdomen. Gas may be present within the intestinal wall and occasionally in the mesenteric and portal vein, a late and ominous sign.

Treatment

Mesenteric venous thrombosis may be treated by anticoagulation with close monitoring. An immediate laparotomy with embolectomy or revascularisation of the SMA by vascular bypass may be considered in early cases of arterial ischaemia, followed by postoperative anticoagulation. However, the condition is usually diagnosed late in the disease process and the mortality rate is extremely high. In the young, all affected bowel should be resected, whereas in the elderly or infirm the situation may be deemed incurable. Where the demarcation between viable and non-viable bowel is uncertain a planned relook laparotomy may be useful.

After extensive enterectomy, it is usual for patients to require intravenous nutrition. The young, however, may sometimes develop sufficient intestinal digestive and absorptive function to lead relatively normal lives. In selected cases, consideration may be given to small bowel transplantation (see ***Chapter 91***).

Chronic small intestinal ischaemia

Chronic small intestinal ischaemia almost invariably results from atherosclerosis and affects the proximal superior mesenteric and coeliac vessels. Patients classically present with symptoms of severe central abdominal pain that comes on within 30–60 minutes of eating (mesenteric angina). Weight loss and diarrhoea due to malabsorption may also occur. The condition may be difficult to diagnose and is often overlooked. The presence of significant vascular disease on CT is common in elderly patients and in those with severe vascular disease and should not necessarily be assumed to indicate that abdominal symptoms are attributable to chronic ischaemia. Treatment is usually by selective visceral angiography, with stenting/angioplasty and, where this is not possible, bypass surgery. Smoking cessation is imperative and patients are usually anticoagulated.

STOMAS

A stoma is an artificial opening made in the bowel to divert faeces and flatus outside the abdomen, where they can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary, a stoma may be temporary or permanent (***Summary box 74.5***).

Summary box 74.5

Stomas

- May be colostomy or ileostomy
- May be temporary or permanent
- Temporary or defunctioning stomas are usually fashioned as loop stomas
- An ileostomy is spouted; a colostomy is flush
- Ileostomy effluent is usually liquid, whereas colostomy effluent is usually solid
- Ileostomy patients are more likely to develop fluid and electrolyte problems
- An ileostomy is usually sited in the right iliac fossa
- End-colostomy is usually sited in the left iliac fossa
- Whenever possible, patients should be counselled and sited by a stoma care nurse before operation

Loop ileostomy

A loop ileostomy is often used for defunctioning a low rectal anastomosis or an ileal pouch. A knuckle of ileum is exteriorised through a skin trephine in the right iliac fossa. An incision is made in the distal part of the knuckle, and this is then pulled over the top of the more proximal part to create a spout on the proximal side of the loop with a flush distal side still in continuity. This allows near perfect defunctioning, but also the possibility of restoration of continuity, by taking down the spout and reanastomosing the partially divided ileum.

The advantage of a loop ileostomy over a loop colostomy is the ease with which the bowel can be brought to the surface. Care is needed when the ileostomy is closed such that suture line obstruction does not occur. Closure of a loop ileostomy can be a technically challenging procedure, particularly if there are dense adhesions resulting from previous surgery.

End-ileostomy

An end-ileostomy is formed after a colectomy without anastomosis, when it may later be reversed, or after panproctocolectomy, when it is permanent. The ileum is normally brought through the rectus abdominis muscle. Careful attention should be paid to the terminal ileal mesentery to ensure that it is not too bulky. The use of a spout was originally described by Brooke; this should project some 2–4 cm from the skin surface (***Figure 74.7***). A disposable appliance is placed over the ileostomy so that it is a snug fit at skin level.

There may be an 'ileostomy flux' while the ileum adapts to the loss of the colon. While ileostomy output can amount to 4–5 litres per day, losses of 1–2 litres are more common. A consistent ileostomy output in excess of 1.5 litres is usually associated with dehydration and sodium depletion in the absence of intravenous therapy. Up to 20% of patients may require readmission for the treatment of dehydration after creation of

Bryan Nicholas Brooke, 1915–1998, Professor of Surgery, St George's Hospital, London, UK.

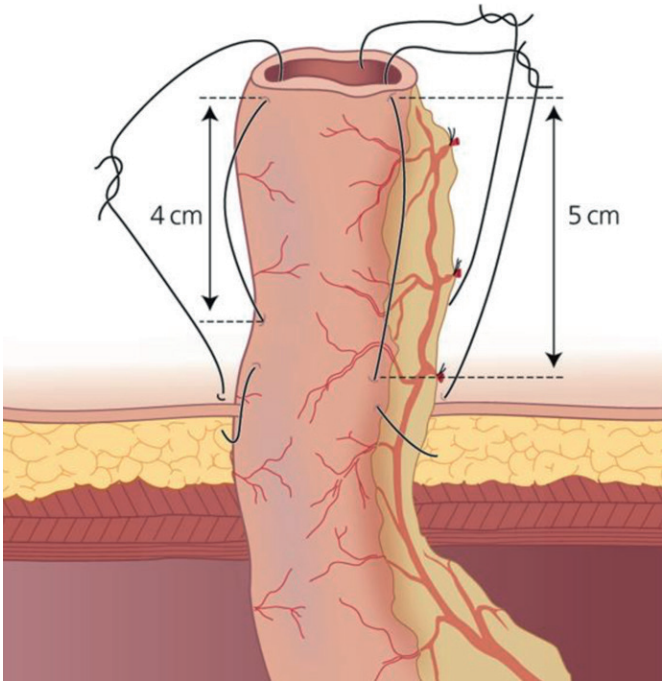

Figure 74.7 Construction of an end-ileostomy. The diagram is orientated such that the upper aspect of the stoma is to the right, thus when the sutures are tied the everted stoma is angled slightly inferiorly. (Reproduced with permission from O'Connell PR, Madoff RD, Solomon MJ (eds). *Operative surgery of the colon rectum and anus*, 6th edn. Boca Raton, FL: CRC Press, 2015.)

an ileostomy but the stools thicken in a few weeks and are usually semisolid in a few months. The help, skill and advice of the stoma care nurse specialist are essential. Modern appliances have transformed stoma care and skin problems are unusual (***Figure 74.8***). Complications of an ileostomy include prolapse, retraction, stenosis, bleeding, fistula and parastomal hernia.

Stoma bags and appliances

Stoma output is collected in a disposable adhesive bag. Ileostomy appliances tend to be drainable bags that are left in place for 48 hours, while colostomy appliances are simply changed two or three times each day. A wide range of such bags is currently available. Many now incorporate an adhesive backing, which can be left in place for several days. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

Complications of stomas

Stoma complications are underestimated and common (***Summary box 74.6***). On occasion, these complications require surgical revision. Sometimes, this can be achieved with an incision immediately around the stoma, but on occasion reopening the abdomen and freeing up the stoma may be necessary. Repair of parastomal hernias is particularly technically challenging and the recurrence rate is high. Simple suture of the parastomal hernia is associated with an almost 100% risk of recurrence and transfer to the opposite side of the abdomen, or insertion of a piece of prosthetic material within the abdominal wall around the stoma may be necessary (see ***Chapter 64***).

CONDITIONS CAUSING MALABSORPTION

Coeliac disease

Coeliac disease is the most common cause of malabsorption in the UK with a reported prevalence of 1:1800, although this may be an underestimate. It is characterised by a hypertrophic small bowel mucosa with atrophic villi and deep crypts. Loss of surface area and brush border enzymes results in malabsorption.

Coeliac disease is caused by an abnormal immune response to gluten, a cereal protein, although the exact mechanism remains unclear. There is a genetic component, as the disease is more common in first-degree relatives and has an association with HLA-B8. In children, coeliac disease presents with steatorrhoea and growth retardation. In adults, it may result in diarrhoea and weight loss but many patients simply present with iron deficiency anaemia. Some patients develop a characteristic skin rash (dermatitis herpetiformis).

The diagnosis is usually made after an endoscopic duodenal biopsy allows pathological examination of the mucosa. A blood test for immunoglobulin A anti-tissue transglutaminase (IgA tTGA) is relatively sensitive and specific for diagnosing coeliac disease, making it the preferred test for detection. Measurement of IgA antiendomysial antibodies (anti-EMA) should be used as a confirmatory test. A duodenal biopsy is usually indicated to confirm the diagnosis. The biopsy usually shows

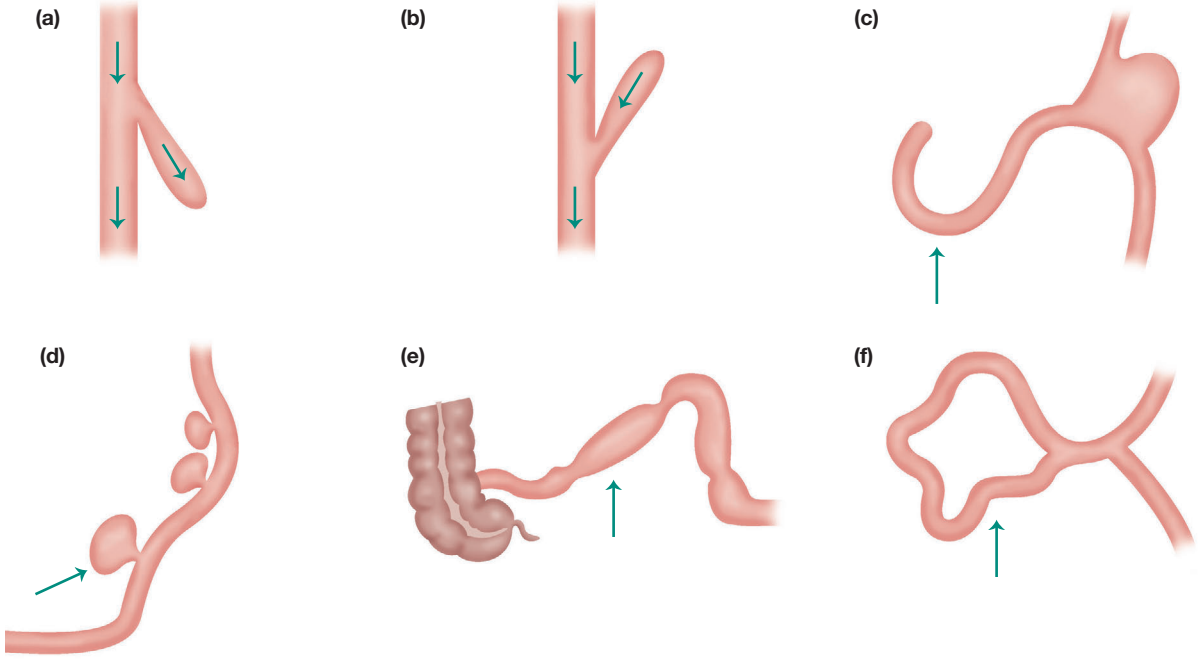

Figure 74.9 Common types of blind loop: **(a)** self-filling: deficiency occurs; **(b)** self-emptying: no deficiency occurs; **(c)** long afferent loop stasis in Pólya gastrectomy; **(d)** jejunal diverticula; **(e)** intestinal stricture causing stasis; **(f)** 'stenosis–anastomosis loop' syndrome.

flattening of the mucosa, marked inflammatory changes and characteristic findings of intraepithelial lymphocytes. All tests should be performed while the patient is on a gluten-containing diet as false-negative tests may occur if on a gluten-free diet.

Patients with coeliac disease may develop an acute inflammatory condition of the small intestine (ulcerative jejunoileitis) and have an increased risk of small bowel lymphoma and adenocarcinoma.

The main treatment for coeliac disease is the withdrawal of gluten from the diet by avoiding wheat, rye and barley. Surgery does not usually play a role in the management of coeliac disease and is primarily reserved for resection of malignancy.

Bacterial overgrowth

The small intestine can become colonised with bacteria normally confined to the colon if there is stasis resulting in delayed bacterial clearance (blind loop syndrome; ***Figure 74.9***). Similar complications may result from chronic small bowel obstruction, jejunal diverticulosis and ileocolic fistulation. Overgrowth in the upper small intestine results in fat malabsorption due to the deconjugation of bile salts, while vitamin B12 deficiency results from overgrowth more distally. There is usually relatively little effect on carbohydrate or protein metabolism. If steatorrhoea occurs, other serious malabsorption features may follow, including glossitis, osteomalacia, paraesthesia and peripheral neuropathy.

Improvement normally follows after intermittent therapy with oral antibiotics; metronidazole, ciprofloxacin, tetracycline and rifaximin are commonly used. Definitive treatment is surgical if the anatomical abnormality can be corrected, but this is not always possible.

ENTEROCUTANEOUS FISTULA

An abnormal connection between the small intestine and the skin can occur as a result of CD, radiotherapy or abdominal trauma, but the condition most commonly follows a surgical complication – either a leak from an anastomosis or an inadvertent enterotomy. At least 50% of small bowel enterocutaneous fistulae develop after surgery in which no small bowel has been resected as a result of injury to the intestine during division of adhesions. The frequency of this complication has been shown to increase with the number of previous laparotomies. Management of patients with an enterocutaneous fistula can be very challenging, especially when the fistula output is high (defined as >500 mL of effluent/day). The majority of low-output fistulae can be expected to heal spontaneously, provided there is no distal obstruction or disease at the fistula site. Reasons for failure of spontaneous healing also include epithelial continuity between the gut and the skin and an associated complex abscess.

The management of fistulae is based on well-established principles ('SNAP'; see ***Summary box 74.7***). An early return to theatre to try to treat the problem definitively (i.e. by

Eugen (Jeno) Alexander Pólya, 1876–1944, surgeon, St Stephen's Hospital, Budapest, Hungary.

attempting to restore bowel continuity) in a septic, malnourished patient is doomed to failure.

Summary box 74.7

Principles of management of enterocutaneous fistulae (SNAP)

- S, elimination of Sepsis and skin protection
- N, Nutrition – a period of parenteral nutrition may well be required
- A, Anatomical assessment
- P, definitive Planned surgery

Infected collections are best identified at CT (***Figure 74.10***) and can be drained percutaneously. Skin protection is important as small bowel effluent is caustic. Nutritional support must include fluid and electrolytes, which can be lost in high quantities from a proximal fistula, as well as carbohydrates, protein, fat and vitamins. Judgements have to be made between enteral and parenteral feeding: enteral feeding has advantages, but if the fistula is proximal or high output total parenteral nutrition will be required. Defining fistula anatomy is best done after careful discussion with the radiologist; a sequence of contrast studies (follow-through, fistulogram and enema) may well be required to define bowel length and plan a surgical strategy. Surgery can be extremely technically demanding and an anastomosis should be avoided in the presence of continuing intra-abdominal sepsis or when the patient is hypoalbuminaemic (<32 g/dL).

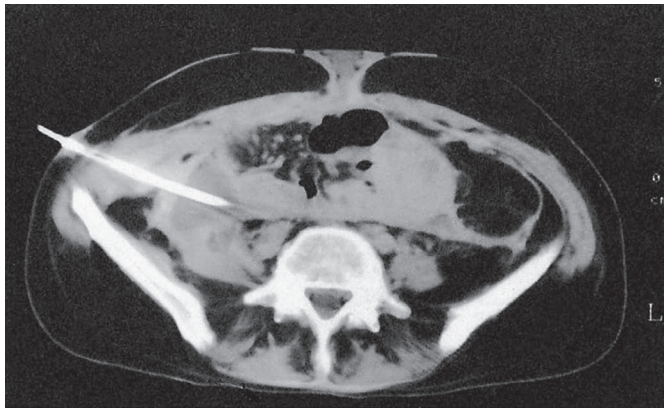

Figure 74.10 Computed tomography (CT) scan in a patient with a complex enterocutaneous fistula and an intra-abdominal abscess being drained with a CT-guided catheter.

SHORT BOWEL SYNDROME/ INTESTINAL FAILURE

Intractable diarrhoea with impaired absorption of nutrients following resection or bypass of the small intestine, ultimately leading to progressive malnutrition, is referred to as short bowel syndrome. When a patient is unable to maintain satisfactory fluid, electrolyte or nutritional homeostasis without intravenous administration of fluid, electrolytes or nutrients they are said to have intestinal failure. The mainstay of treatment for intestinal failure is parenteral nutrition.

The most common causes of short bowel syndrome are resection resulting from the management of CD and its complications (which accounts for almost half of cases), mesenteric vascular thrombosis, radiation enteritis and tumours. Although features of short bowel syndrome usually appear when there is less than 200 cm of small bowel, the length and nature of the remaining intestine are also important. In general, diseases that result in short bowel syndrome tend to preferentially affect the distal small intestine, and there is some evidence that the ileum, with its tighter intercellular junctions and consequently better fluid absorptive capacity, can assume the functions of a missing jejunum, but not *vice versa*. While the ileocaecal valve used to be considered important with regard to preservation of absorptive function, it is more likely that this is a reflection of the associated preservation of the distal ileum and right colon than the valve itself.

Patients with an intact colon are relatively protected from the effects of massive small bowel resection because of the ability of the colon to absorb not only fluid and electrolytes but also a modest amount of nutrient energy. Patients with as little as 100–200 cm of jejunum anastomosed to an intact colon may therefore be able to maintain satisfactory macronutrient, fluid and electrolyte status, although they will, of course, be at risk of fat-soluble and B12 vitamin deficiencies and will also generally need oral nutritional supplements of trace elements, vitamins and minerals. Some (but not all) patients with 50–100 cm of small intestine and an intact colon will have intestinal failure, as will almost all patients with 50 cm or less of jejunum anastomosed to an intact colon. In contrast, most patients with less than 200 cm and virtually all with less than 100 cm of small intestine ending in a stoma will have intestinal failure and will require long-term parenteral nutrition.

Medical management of patients with short bowel syndrome relies on the use of antidiarrhoeal agents (loperamide and codeine phosphate), drugs to reduce diarrhoea related to bile-salt malabsorption (cholestyramine), drugs to reduce the increased gastric acid secretion resulting from the loss of the small bowel 'brake' on gastric acid production (proton pump inhibitors) and enteral and parenteral vitamin and trace element supplements. Although there has also been interest in the use of drugs to promote intestinal adaptation, such as growth hormone, glutamine and, most recently, glucagon-like peptide 2 agonists, the mainstay of treatment for short bowel syndrome remains home parenteral nutrition (HPN). The development of this treatment in the late 1960s enabled the majority of patients with short bowel syndrome to enjoy a reasonably good quality of life, with long-term survival related principally to the underlying disease. HPN is, however, expensive and demanding and patients are at risk from catheter-related complications (notably catheter-related sepsis and occlusion), as well as metabolic complications (fibrotic liver disease, gallstones, metabolic bone disease and kidney stones).

Surgical procedures designed to improve the surface area or reduce the speed of transit of the remaining small intestine (and thus improve absorptive capacity) have shown some promise in children, but their place in managing adults with

established short bowel syndrome currently remains unclear. In some patients, the loss of venous access resulting from the complications of long-term intravenous feeding or the development of progressive liver dysfunction may represent indications for small bowel transplantation. The results of small bowel transplantation have progressively improved and 5-year patient survival now exceeds 80% in some centres (see ***Chapter 91***).

PART 11 | Abdominal

CHAPTER 75

Inflammatory bowel disease

Learning objectives

To understand:

- The aetiology and pathology underlying inflammatory bowel disease
- The distinguishing features of ulcerative colitis and Crohn's disease
- The principles of medical management
- The role of surgery in acute and elective settings
- The management of postoperative complications and long-term outcomes

INTRODUCTION

The term inflammatory bowel disease (IBD) is reserved for conditions characterised by the presence of idiopathic intestinal inflammation. Conditions such as infective or ischaemic enteritis are covered in ***Chapters 6, 74 and 77***.

Crohn's disease (CD) may affect any portion of the gastrointestinal tract from mouth to anus, most typically the distal ileum, the anal canal and the large bowel, whereas ulcerative colitis (UC) is confined to the large intestine. UC is characterised primarily by mucosal inflammation, whereas CD most typically involves transmural inflammation. On occasion there may be difficulty distinguishing UC from CD in the colon. This occurs in approximately 10% of patients with colitis; in such instances the term indeterminate colitis (IC) may be used.

The incidence and prevalence of IBD is highest in Europe and North America, where it affects around 3 in 1000 people. The overall incidence is steadily rising worldwide, linked to improved public hygiene, dietary changes and industrialisation. Both UC and CD occur in individuals who may have a genetic predisposition and who are exposed to environmental factors that trigger abnormal immune responses that lead to intestinal inflammation. Microscopic colitis includes two main subtypes: lymphocytic colitis and collagenous colitis (CC). The aetiology is uncertain but may reflect inappropriate immune responses to alterations in the gut microenvironment consequent to oral drug ingestion, particularly non-steroidal anti-inflammatory drugs.

UC is characterised by mucosal inflammation of the large bowel, always involving the rectum (proctitis) and extending to involve varying degrees of more proximal colon (colitis). When the entire colon and rectum are involved (pancolitis), some patients may also have a degree of 'backwash ileitis', in which there is secondary inflammation in the terminal ileum.

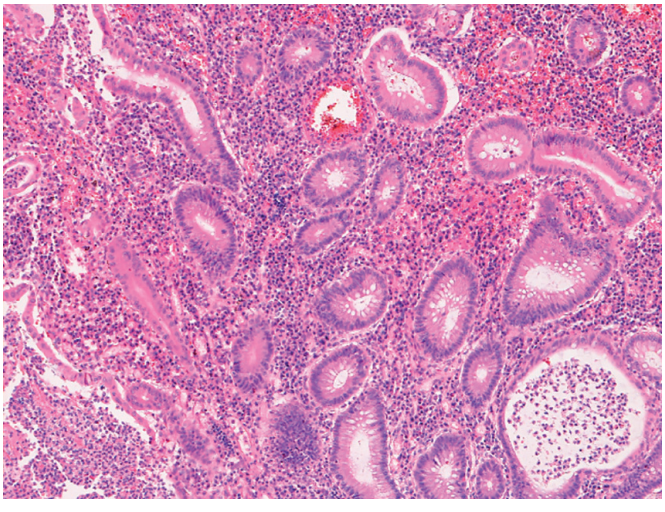

Figure 75.1 Mucosal biopsy in ulcerative colitis illustrating inflammatory infiltrate and crypt abscess formation.

UC is a chronic condition that tends to be relapsing and remitting. Early relapse and persistent disease within the first 2 years of diagnosis are both predictors of a severe disease course. The extent of disease may also change after initial diagnosis; half of patients with UC affecting the rectum or rectosigmoid progress to develop more proximal disease.

Histological hallmarks of UC typically include atrophy and distortion of the crypts, irregularity of the mucosal villi, marked infiltration of plasma cells within the deep lamina propria (basal plasmacytosis) and mucus depletion, but none of these is pathognomonic; the diagnosis ultimately depends on clinical correlation, disease course and elimination of other potential causes, especially infection (***Figure 75.1***). Pseudopolyposis occurs in almost one-quarter of cases. Stricturing in

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA.

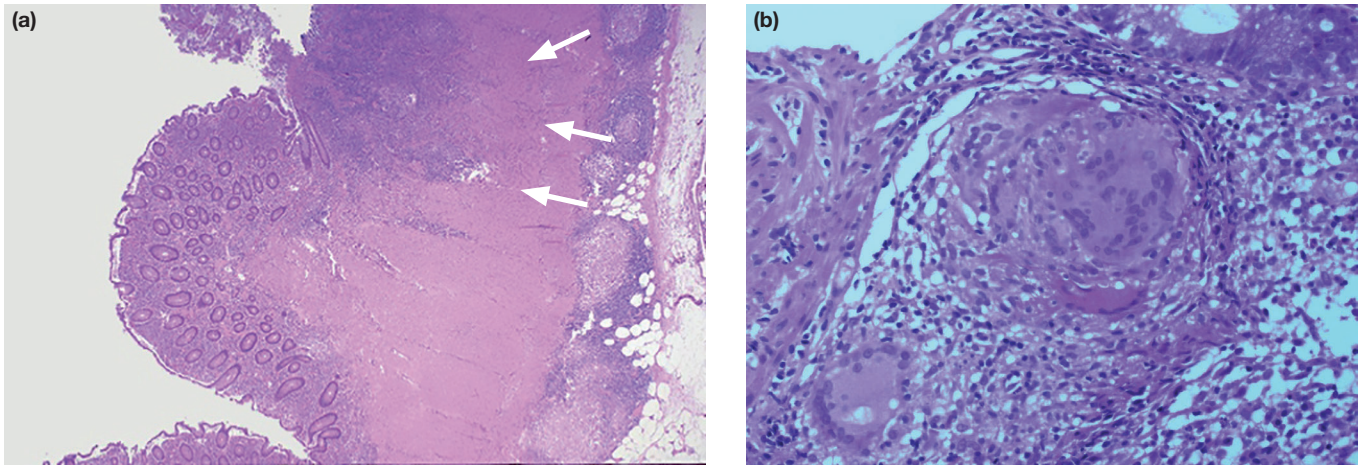

Figure 75.2 Photomicrographs of Crohn's disease illustrating mucosal ulceration and transmural inflammation (arrows) **(a)**; high-power view of non-caseating granulomas **(b)** (courtesy of Professor Kieran Sheahan, St Vincent's University Hospital, Dublin, Ireland).

UC is very unusual (unlike in CD) and should prompt urgent assessment because of the possibility of coexisting carcinoma. A small proportion of patients develop irregular mucosal swellings (dysplasia-associated lesions or mass [DALMs]), which are highly predictive of coexisting carcinoma.

CD (see ***Crohn's disease (regional enteritis)***) is characterised by discontinuous transmural inflammation of the bowel caused by transmural inflammation of any part of the gastrointestinal tract from mouth to anus, but most commonly the ileocaecal region, colon and anus. There is often a degree of rectal sparing when the colon is involved. The transmural inflammation may be patchy (rather than diffuse) and crypt distortion is commonly seen. Histology typically demonstrates discontinuous segments of disease or 'skip lesions', involvement of the terminal ileum and the presence of granulomas with a tendency for more marked inflammation in the proximal colon (***Figure 75.2***). Clinical correlation of histopathology with endoscopic and radiological findings is key to clinching the diagnosis of CD. Stricturing in the colon, while usually benign in CD, may mask an underlying neoplasm.

When endoscopic and histological appearances do not categorically confirm either UC or CD, and the term IC is used, the clinical phenotype may help define the diagnosis, especially if there are features of small bowel or perianal disease suggestive of CD. Patients with IC may later come to a definitive diagnosis of UC or CD, depending on the disease course.

CLINICAL MANIFESTATIONS

The clinical manifestations of IBD primarily depend on the diagnosis (either CD or UC), the location (small or large intestine, or both) and the extent of the disease. In the large bowel, the clinical presentation depends in large part on the extent of disease. If inflammation is confined to the rectum (proctitis), there is usually no systemic upset and extra-alimentary manifestations are rare. The main symptoms are rectal bleeding, tenesmus and mucous discharge. The disease often remains confined to the rectum, usually with a benign course. Colitis is almost always associated with bloody diarrhoea and urgency. Severe and/or extensive colitis may result in anaemia, hypoproteinaemia and electrolyte disturbances. Pain is unusual. Children with poorly controlled colitis may have impaired growth. The more extensive the disease, the more likely extraintestinal manifestations are to occur. Extensive colitis is also associated with systemic illness, characterised by malaise, loss of appetite and fever.

CLASSIFICATION OF SEVERITY

The assessment of the severity of colitis is determined by the frequency of bowel action and the presence of systemic signs of illness, as originally proposed by Truelove and Witts:

- **Mild disease** is characterised by fewer than four stools daily, with or without bleeding. There are no systemic signs of toxicity.
- **Moderate disease** corresponds to more than four stools daily, but with few signs of systemic illness. There may be mild anaemia. Abdominal pain may occur. Inflammatory markers, including erythrocyte sedimentation rate and C-reactive protein, are often raised.
- **Severe disease** corresponds to more than six bloody stools a day and evidence of systemic illness, with fever, tachycardia, anaemia and raised inflammatory markers. Hypoalbuminaemia is common and an ominous finding.
- **Fulminant disease** is associated with more than 10 bowel movements daily, fever, tachycardia, continuous bleeding, anaemia, hypoalbuminaemia, abdominal tenderness and distension, the need for blood transfusion and, in the most severe cases, progressive colonic dilation (toxic megacolon). This is a very significant finding, suggestive of disintegrative colitis, and an indication for emergency surgery if colonic perforation is to be avoided.

Sidney Charles Truelove, 1913–2002, gastroenterologist, Oxford, UK.
Leslie John Witts, 1898–1982, Nuffield Professor of Medicine, Oxford, UK.

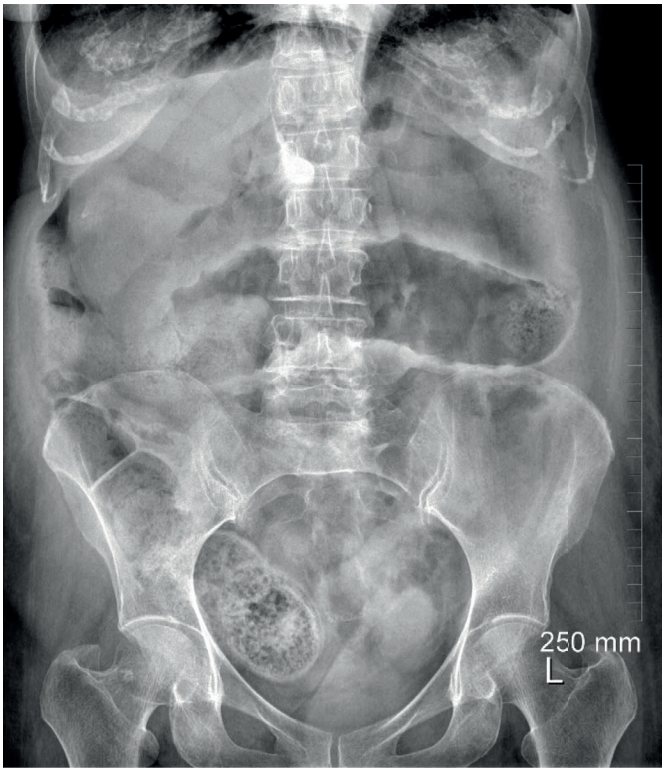

Figure 75.3 Supine abdominal radiograph of a patient with acute colitis showing toxic dilatation of the transverse colon with classical mucosal 'thumbprinting' of the colonic mucosa (courtesy of Mr Sean Martin FRCSI, St Vincent's University Hospital, Dublin, Ireland).

EXTRAINTESTINAL MANIFESTATIONS

Arthritis occurs in around 15% of patients and is typically an asymmetrical large joint polyarthropathy, affecting knees, ankles, elbows and wrists. Sacroiliitis and ankylosing spondylitis are 20 times more common in patients with UC than in the general population and are associated with the HLA-B27 genotype. Sclerosing cholangitis is associated with UC and can progress to cirrhosis and hepatocellular failure. Cholangiocarcinoma is a rare association, but its frequency is not influenced by colectomy (see ***Chapter 71***). The skin lesions erythema nodosum and pyoderma gangrenosum are associated with UC and both normally resolve with good colitis control. The eyes can be affected by uveitis and episcleritis.

ACUTE COLITIS

Approximately 5% of patients present with acute severe (fulminant) colitis. Intensive medical treatment leads to remission in 70% but the remainder require urgent surgery. Toxic dilatation should be suspected in patients who develop severe abdominal pain and confirmed by the presence on a plain abdominal radiograph of a colon with a diameter of more than 6 cm (***Figure 75.3***). A reduction in stool frequency is not always a sign of improvement in patients with acute severe colitis, and a falling stool frequency, abdominal distension and abdominal pain (resulting from progression of the inflammatory process through the colonic wall) are strongly suggestive of fulminant colitis and impending perforation. Plain abdominal radiographs or abdominal computed tomography (CT) may help monitor disease progression in patients with acute severe colitis, and a progressive increase in colon diameter despite medical therapy is an indication for urgent surgery. Colonic perforation is a grave complication with a mortality rate of 40%. Steroids may mask the physical signs. Severe haemorrhage is uncommon (1–2%) but may occasionally require urgent surgical intervention.

CANCER RISK IN COLITIS

The risk of cancer in ulcerative colitis increases with duration of disease. At 10 years from diagnosis, it is approximately 1%, increasing to 10–15% at 20 years and 20% at 30 years. Patients with pancolitis (defined as the presence of inflammation proximal to the splenic flexure) of more than 10 years' duration should be entered into endoscopic screening programmes in order to detect clinically silent dysplasia, which is predictive of increased cancer risk. The value of screening programmes remains somewhat controversial, as most patients with UC who develop cancer (approximately 3.5% of all patients) present between attendances for screening colonoscopy. Malignant change, often atypical and high grade, may be multifocal or submucosal (***Figure 75.4***). Colonoscopic surveillance with dye spray (chromoendoscopy) or multiple biopsies every 10 cm should look for subtle mucosal abnormalities, which can occur in flat mucosa or a DALM. Patients with UC and sclerosing cholangitis are also at a significantly greater risk of development of large bowel cancer.

INVESTIGATIONS

Endoscopy and biopsy

Rigid/flexible sigmoidoscopy can detect proctitis in the clinic; the mucosa is hyperaemic, bleeds on touch and there may be a

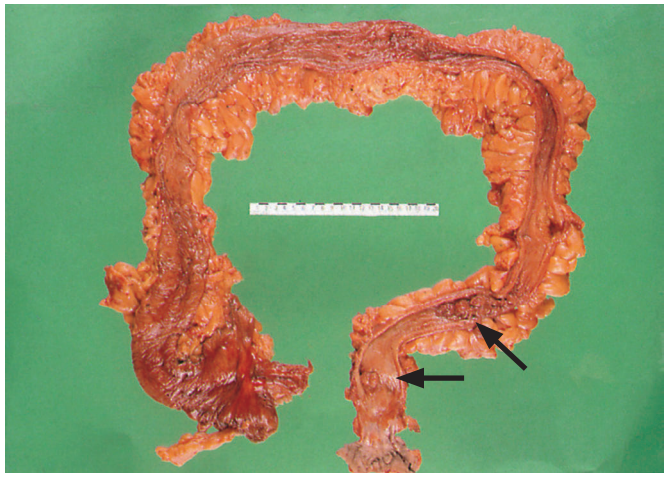

Figure 75.4 Resection specimen from a patient with longstanding ulcerative colitis showing a narrow tubular colon with areas of cancerous change in the rectum and sigmoid (arrows) (courtesy of the late Professor Brian Warren, John Radcliffe Hospital, Oxford, UK).

TABLE 75.1 Distinguishing ulcerative colitis (UC) and Crohn's disease (CD).

	UC	CD
Macroscopic		
Distribution	Colon/rectum	Anywhere in the gastrointestinal tract
Rectum	Always involved	Often spared
Perianal disease	Rare	Common
Fistula formation	Rare	Common
Stricture	Rare	Common
Microscopic		
Layers involved	Mucosa/submucosa	Full thickness
Granulomas	No	Common
Fissuring	No	Common
Crypt abscesses	Common	Rare

purulent exudate. Where there has been remission and relapse, there may be regenerative mucosal nodules or pseudopolyps. Later, tiny ulcers may be seen that appear to coalesce. Colonoscopy with biopsy has a key role in diagnosis and management:

- to establish the extent of inflammation, although colonoscopy is contraindicated in severe acute colitis because of the risk of colonic perforation;
- to distinguish between UC and Crohn's colitis (***Table 75.1***);
- to monitor the response to treatment;
- to assess longstanding cases for malignant change.

Endoscopic findings can be combined with clinical features and the physician's assessment to produce a disease activity score. The most widely used is the Mayo score, which provides a useful tool for measuring disease progression or response to treatment (***Table 75.2***).

Radiology

A plain abdominal film may indicate the severity of disease in the acute setting and is particularly valuable in demonstrating the development of toxic megacolon. Barium enema has been replaced by CT, although a contrast study will show a featureless colon. CT findings in pancolitis may show significant thickening of the colonic wall, as well as inflammatory stranding in the colonic mesentery (***Figure 75.5***).

Bacteriology

A stool specimen should be sent for microbiological analysis when UC is suspected in order to exclude infective colitides, notably *Campylobacter*, which may be very difficult to distinguish from acute severe UC. *Clostridium difficile* colitis may need to be considered in populations at risk of this disease (see ***Chapter 77***). Cytomegalovirus infection is a major pathogen in immunocompromised patients and can be difficult to distinguish from UC. Superimposed infection may precipitate fulminant colitis.

TREATMENT

Effective treatment of UC requires a multidisciplinary approach to management. Members of the IBD multidisciplinary team typically include specialists in IBD gastroenterology, colorectal surgery, IBD nursing, stoma therapy, gastrointestinal and interventional radiology, pathology, dieticians and nutritional support services, clinical psychologist and other specialties according to the individual patient's need.

Summary box 75.1

Principles of management of ulcerative colitis

- Most patients are maintained on optimised medical therapy
- Acute severe colitis (ASC) requires multidisciplinary management
- Toxic dilatation or impending complication should be suspected if the patient develops abdominal tenderness or distension, or deteriorates clinically
- Patients with colitis are at increased risk of developing cancer; those with pancolitis of long duration are most at risk

TABLE 75.2 Scoring system for assessment of ulcerative colitis activity.

Finding

Medical treatment

Improved understanding of the complex cell signalling pathways that underlie aberrant immune responses in both UC and CD has radically changed treatment algorithms. The focus is now on both clinical and endoscopic remission end points with the aim of controlling symptoms and preventing disease progression. The particular choice of anti-inflammatory agent or immunosuppressive drug, the sequence and combination of use must take into account individual disease phenotypes, coexisting conditions, patient preferences, response to treatment, side effects and treatment availability. There has been a paradigm shift in treatment algorithms from escalation therapy in response to treatment failure to a top-down approach predicated on achieving clinical and endoscopic remission with subsequent de-escalation of treatment to maintain remission.

Conventional first-line treatment has been 5-aminosalicylic acid (5-ASA) derivatives given topically (per rectum) or systemically. These act as inhibitors of the cyclo-oxygenase enzyme system and are formulated to protect the aspirin-related drug from degradation before reaching the colon. Used as a single agent, 5-ASA is useful in treating ulcerative proctitis and as maintenance therapy following induction of remission.

Corticosteroids have been the mainstay of treatment used either topically or systemically. They have a widespread anti-inflammatory action and are frequently used in combination with 5-ASA derivatives to deliver prompt relief of symptoms.

The immunosuppressive drugs azathioprine and ciclosporin can be used to maintain remission and as steroid-sparing agents should maintenance therapy be required. Azathioprine is a purine analogue that is metabolised to 6-mercaptopurine (6-MP) and works by inhibiting cell-mediated immune responses. 6-MP may be given directly for the same effects. Approximately 10% of people have deficient thiopurine methyltransferase (TPMT) and 1 in 300 people have no enzyme activity, causing inefficient metabolism of 6-MP. The resulting high pharmacological concentrations may cause adverse effects such as myelosuppression. Testing of TPMT activity should be undertaken before commencing treatment.

Ciclosporin acts by inhibiting cell-mediated immunity. Short-course intravenous ciclosporin treatment is associated with remission in 80% of patients; however, many patients relapse after completion of treatment.

The monoclonal antibodies infliximab and adalimumab both act as antagonists to tumour necrosis factor alpha (TNFα), which has a central role in inflammatory cascades. Infliximab, a murine chimeric monoclonal antibody, was the first available monoclonal antibody for the treatment of CD. It is administered as an intravenous infusion most frequently to induce remission in moderate to severe disease and may be used as maintenance treatment once remission has been achieved. Adalimumab, an entirely human monoclonal antibody, is an alternative to infliximab that also targets TNFα. It can be self-administered by patients, which is advantageous in long-term maintenance. Trough levels and antibodies to anti-TNFα monoclonal antibodies should be monitored to ensure optimal dosing and efficacy of treatment.

Recently, ustekinumab, a monoclonal antibody against interleukin-12/23; vedolizumab and etrolizumab, anti-integrin monoclonal antibodies; tofacitinib, a JAK (Janus kinase) inhibitor; and ozanimod, an S1P (sphingosine-1-phosphate) receptor modulator have received regulatory approval for treatment of IBD. The complexity and best sequencing of treatment options requires multidisciplinary specialist input and is beyond the remit of this chapter (see ***Further reading***).

Nutritional support

It is essential that nutritional status is evaluated in all patients with IBD. Nutritional support is frequently required. Patients with moderate nutritional impairment will require nutritional supplementation and severely malnourished patients may require enteral tube or even intravenous feeding. Anaemia, hypoproteinaemia and electrolyte, vitamin and metabolic bone problems must all be addressed. Nutritional optimisation has been shown to improve surgical outcomes but it is important to recognise that a significant improvement in nutritional status is very unlikely in the setting of active infection; in patients with abscesses, effective drainage remains the overwhelming priority.

Acute severe colitis

Patients with a mild attack usually respond to a course of oral prednisolone. A moderate attack often responds to oral prednisolone, twice-daily steroid enemas and 5-ASA. Failure to achieve remission as an outpatient is an indication for admission. Acute severe colitis occurs in up to 10% of patients, who require hospital admission. Regular assessment of vital signs, weight and the abdomen are required. A stool chart should be kept, regular clinical review is required and supine abdominal radiographs should be done when there is clinical concern for toxic megacolon. The presence of mucosal islands or intramural gas on plain radiographs, increasing colonic diameter or a sudden increase in pulse and temperature may indicate impending colonic perforation. Limited endoscopic assessment and reassessment is useful in monitoring response to treatment. Fluid and electrolyte balance must be maintained,

anaemia corrected and adequate nutrition provided, often parenterally.

Initial treatment is with intravenous steroids. Regular and joint review by a gastroenterologist and a colorectal surgeon is essential to identify patients who are failing to make anticipated progress and to ensure that surgery is neither inappropriately delayed nor inappropriately undertaken. Patients should be supported by IBD specialist nurses and early introduction to a stoma therapist is considered best practice.

Instigation of immunosuppressive therapy with either intravenous ciclosporin A or an anti-TNFα agent may be appropriate; however, surgery should be considered if rescue therapy does not result in rapid clinical improvement for the patient. Clinical deterioration requires urgent colectomy.

Indications for surgery

Surgery has a significant role in managing complications of IBD and in improving quality of life for patients with IBD. Current best practice ensures that surgeons and stoma therapists are an integral part of the multidisciplinary team throughout a patient's journey and that surgery is not presented as a last resort. Patients are then more likely to accept timely surgical intervention when indicated and be better prepared for life with a temporary or permanent stoma.

The overall lifetime risk of colectomy for a patient with UC is about 20%. Common indications for surgery in the emergency setting include refractory acute severe colitis or its complications, including perforation, toxic megacolon or, rarely, colonic haemorrhage not controlled by endoscopic or interventional radiological means.

The indications for surgery in UC are:

- severe or fulminating disease failing to respond to medical therapy;
- chronic disease with anaemia, frequent stools, urgency and tenesmus;
- steroid-dependent disease where remission cannot be maintained without substantial doses of steroids with harmful side effects;
- intolerance or side effects of medical therapy required to control the disease, e.g. steroid psychosis, azathioprine-induced pancreatitis;
- growth retardation in children or adolescents;
- neoplastic change: patients who have severe dysplasia or carcinoma;
- associated sclerosing cholangitis;
- extraintestinal manifestations;
- rarely, severe haemorrhage or stenosis causing obstruction.

Operative treatment

Emergency

In the emergency situation (or for a patient who is malnourished or on high-dose steroids), the safest procedure is subtotal colectomy and end-ileostomy. The rectosigmoid remnant may be left long and can either be brought out as a formal mucous fistula or closed just beneath the skin as a subcutaneous mucous fistula (***Figure 75.6***); alternatively, it can be closed off with staples across the upper rectum at the pelvic brim and rectal decompression achieved via a transanal catheter. This operation has the advantage that the patient avoids the risks of pelvic dissection while unwell and that colonic histology can be assessed to distinguish between UC and CD. Restorative surgery can be contemplated at a later date when the patient is no longer on steroids and has fully recovered. The mesentery should be divided where convenient and there is no evidence for or against preservation of the omentum in the laparoscopic era, when resection or preservation is a matter of surgical convenience. Most surgeons would recommend close dissection for UC and a greater degree of mesocolic resection for CD given the potential role for the mesentery

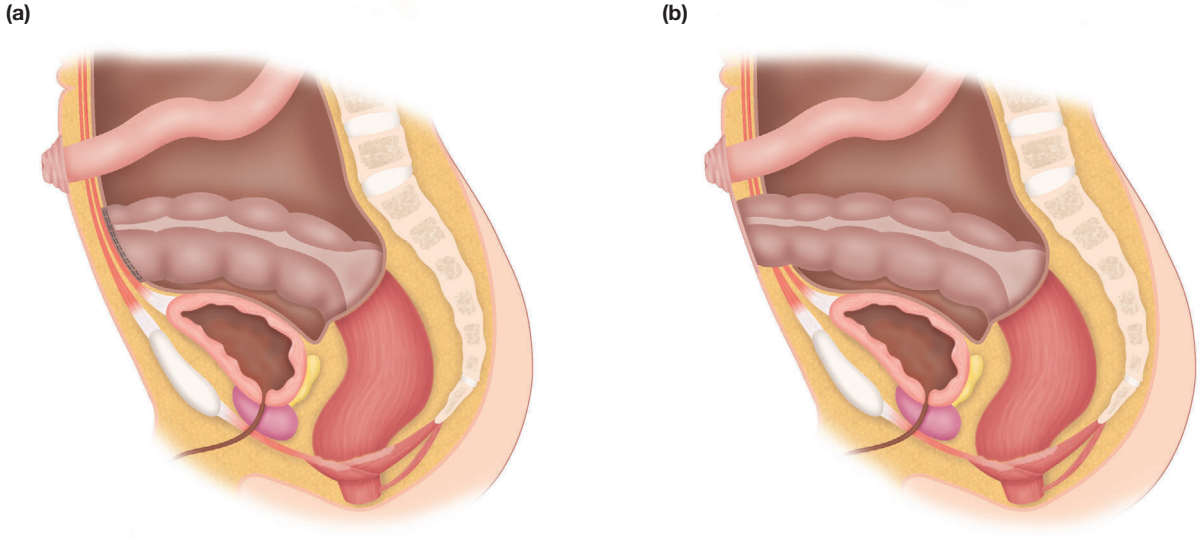

Figure 75.6 Subfascial closure of the rectal remnant following subtotal colectomy and end-ileostomy for acute ulcerative colitis **(a)**. The rectal remnant can alternatively be brought to the skin as a mucus fistula **(b)**.

postulated in CD. Dissection of the left colon is continued to divide the sigmoid at a level that will comfortably reach the skin as a mucous fistula unless this part of the bowel is severely diseased, in which case resection at the sacral promontory is the preferred approach.

Urgent subtotal colectomy for acute severe colitis can be performed laparoscopically, provided the surgeon and theatre team have adequate experience, with care to avoid perforation when handling friable bowel with laparoscopic instruments. Emergency colectomy for septic complications of acute severe colitis should be carried out in a timely fashion and should not be delayed pending availability of laparoscopic colorectal expertise.

Proctectomy is rarely needed in the urgent or emergency situation and should be avoided as pelvic dissection of the diseased rectum is difficult, carries risks to bladder and sexual function, prolongs the surgery in a critically ill patient, increases the risk of mortality and reduces the potential for later restorative surgery.

Fulminant colitis or toxic megacolon can also occur in CD, but less frequently than in UC. Without a pre-established diagnosis, distinction is usually not possible unless there is clear radiological evidence of small bowel CD or clinically apparent perianal CD. In the urgent setting subtotal colectomy for pancolitis should be performed as for UC, preferably with omental resection and a more radical approach to the mesentery. In situations where a diagnosis of colonic CD is established a more tailored segmental resection may be considered in highly selected patients. Primary anastomosis should be avoided in the acute setting and in immunosuppressed patients.

Elective

In the elective setting the following operations are available – all of these can be successfully performed laparoscopically in experienced hands:

- subtotal colectomy and ileostomy (as in an urgent colectomy);
- proctocolectomy and permanent end-ileostomy;
- restorative proctocolectomy with ileal pouch–anal anastomosis (IPAA);
- subtotal colectomy and ileorectal anastomosis;
- segmental colectomy (Crohn's colitis only).

Segmental resections are not recommended for UC as, even when the right colon is not obviously involved, there is a high recurrence rate in the remaining colon. Segmental colonic resection may be considered in selected patients with isolated CD. Subtotal colectomy with ileostomy is performed electively in frail patients, patients who cannot be weaned from steroids and when there is doubt as to the underlying diagnosis. In such situations, restorative surgery or completion proctectomy can be considered at a future date.

Complications of CD including fibrotic strictures not amenable to endoscopic dilatation and enteric fistulae are common indications for elective surgery in patients with CD. Patients who have previously undergone emergency resection and stoma formation will also require follow-up for counselling about restoration of bowel continuity.

Preoperative optimisation and timing of surgery

For many patients who require surgical intervention for colitis, the timing of surgery will be a critical part of shared decision making between clinicians and patient. In the elective setting, patients will want to plan surgery around social, educational, family and work commitments to minimise the impact of surgery and postoperative recovery on their lives. As proctectomy carries small but recognised risks to sexual function and fertility, patients may choose to defer surgery until after completing their families or consider sperm, oocyte or embryo storage to allow assisted fertility at a later date.

Steroid therapy in both UC and Crohn's colitis increases the risk of postoperative complications, although it is difficult to quantify this effect. Patients treated with steroids have an increased risk of infectious complications and poor healing. It is likely that there is a dose-related aspect to this phenomenon. In view of this, steroid use should be reduced as much as possible prior to surgery, preferably below 10 mg prednisolone per day, particularly if an anastomosis is planned. Both anti-TNFα and anti-integrin biological therapies also increase the risk of postoperative complications and should be discontinued wherever possible between 14 and 30 days prior to surgery.

Venous thromboembolism prophylaxis

Patients with IBD have a threefold increased risk of venous thromboembolism compared with the general population and this risk increases in patients who require surgery. The rate of thromboembolic events after surgery for IBD is around 3%, with the strongest predictors of thromboembolic complications being stoma formation, preoperative steroid therapy, ileoanal pouch formation and increased length of stay. The risk of venous thromboembolism is higher in patients with UC than in those with CD. Because of the increased risk of venous thromboembolism, extended chemoprophylaxis has been recommended with low-molecular-weight heparin used for up to 28 days after any abdominal procedure for IBD.

Panproctocolectomy and ileostomy

This operation removes the entire colon and rectum and, by doing so, removes any risk of colorectal neoplasia or colitic symptoms; it results in a permanent ileostomy. It has a lower complication rate than an ileal pouch procedure, although the perineal wound can be problematic (10% fail to heal) and stoma problems are common. It is indicated for patients who are not candidates for restorative surgery owing to impaired anal sphincter function, comorbidities or patient preference. The colectomy is performed as above. In UC, provided there is no concern regarding rectal cancer, a close rectal dissection may be performed to minimise damage to the pelvic nerves, avoiding erectile and bladder dysfunction. Recent evidence suggests that the mesorectum should be excised when proctectomy is performed in CD as the mesentery itself may be involved in the inflammatory process and delay perineal healing.

In UC without dysplasia or cancer present, an intersphincteric dissection of the anal canal should be performed. This results in a smaller perineal wound and fewer healing problems. In CD, wider excision of the anal canal and diseased

perineum may be required if perianal disease is present. A permanent end-ileostomy is formed. The position of the ileostomy should be carefully sited preoperatively with the expert guidance of a stoma nurse specialist.

Restorative proctocolectomy with ileal pouch–anal anastomosis

Although restoration of bowel continuity by ileoanal anastomosis was first performed by Nissen in 1933 and later by Ravitch and Sabiston, the functional outcomes were poor and the operation was rarely performed. The combination of improved surgical techniques, better understanding of the physiology of faecal continence and the relative success of the continent ileostomy operation (Kock pouch) led Parks and Nicholls in the 1970s to reintroduce the concept of IPAA first promulgated by Bacon in the 1950s. Parks and Nicholls devised an 'S' pouch and later a 'W' pouch configuration; however, these have been generally superseded by the 'J' pouch described by Utsunomiya, which is technically easier to construct and avoids a potentially obstructing efferent limb from the pouch reservoir (***Figure 75.7***).

Early pouch surgery included dissection of the rectal muscularis propria (mucosal proctectomy) but it is now clear that continence is better if the mucosa immediately above the dentate line (anal transitional zone) is preserved. A distal mucosectomy to the upper anal canal with anastomosis at the dentate line is now reserved for patients with rectal mucosal dysplasia and selectively for patients in whom the operation is performed for familial adenomatous polyposis (FAP) (see ***Chapter 77***). Usually the anastomosis is double-stapled to the top of the anal canal, preserving the upper anal mucosa (***Figure 75.8***), although a hand-sewn pull-through anastomosis is also possible. Care must be taken to ensure that the anastomosis is to the anal canal and not the distal rectum as residual inflamed mucosa behind may cause persistent symptoms, so-called cuffitis.

IPAA is usually performed as a two-stage procedure with a covering loop ileostomy that may be closed at an interval once pouch healing has been confirmed, usually by means of a Gastrografin (water soluble) contrast enema radiograph. In patients who have previously undergone an urgent colectomy or those with IC in whom a colectomy had provided a definitive diagnosis of UC, the operation is considered to have been a three-stage procedure. In highly selected individuals whose operation is elective and immunosuppressive medication has been discontinued a one-stage operation without ileostomy may be considered. The modified two-stage approach of initial subtotal colectomy and end-ileostomy followed by proctectomy with pouch formation and without diversion is the standard of practice in many specialist centres.

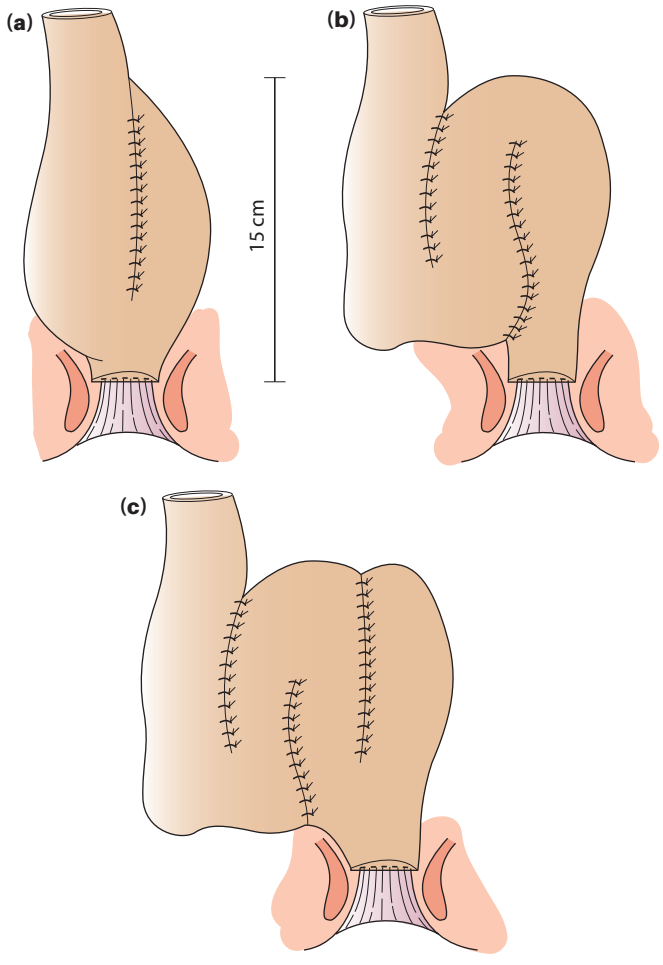

Figure 75.7 Ileoanal anastomosis with a pouch. A substitute rectum is made from joined folds of ileum to form an expanded pouch of small intestine. The pouch is then joined directly to the anus at the level of the dentate line, all other rectal mucosa having been removed. Three ways of forming a pouch are illustrated: **(a)** a simple reversed 'J'; **(b)** an 'S' pouch; **(c)** a 'W' pouch.

Postoperative complications include pelvic infection (usually resulting from a leak at the ileoanal anastomosis or, in a 'J' pouch, from the top of the 'J'), postoperative small bowel obstruction (which may occur in as many as 10–15% of patients) and pouch–vaginal fistula.

The frequency of evacuation is determined by pouch volume, completeness of emptying, reservoir inflammation and intrinsic small bowel motility, but is typically between three and eight evacuations in each 24-hour period, of which at least one evacuation is nocturnal. Stool frequency, urgency and minor faecal incontinence are common, but usually reduce with time

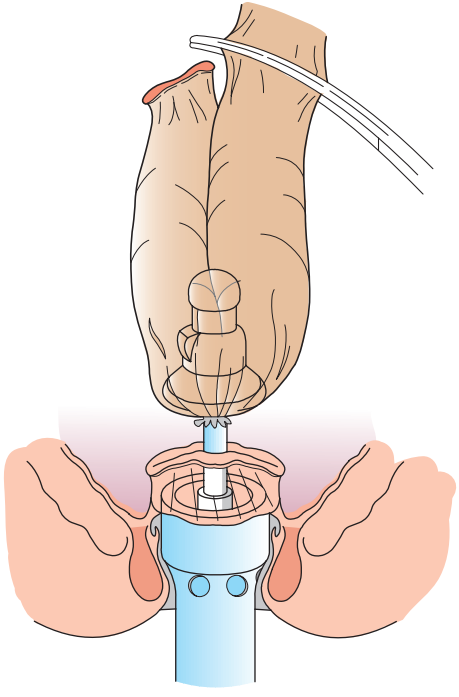

Figure 75.8 Stapled 'J' pouch with the stapler creating an ileal pouch–anal anastomosis

as ileal pouch capacity increases. The majority of patients with IPAA have a very good quality of life. The main reasons for pouch failure are pelvic infection, poor functional outcome and pouchitis (see below). Follow-up of patients with IPAA shows that, although the functional outcome may deteriorate with ageing, between 85% and 90% of patients retain their IPAA in the long term.

Women of reproductive age should be advised of potentially reduced fertility, as well as vaginal dryness, owing to denervation of the secretory glands of the vaginal mucosa. Laparoscopic or robotic techniques may reduce this effect; however, women who have not completed their family may elect for a colectomy with ileostomy and IPAA at a later date.

Pouchitis is inflammation of the ileal pouch mucosa that occurs to varying degrees in up to 50% of patients who undergo IPAA for UC. Interestingly, pouchitis is exceedingly rare after IPAA for FAP, suggesting that there is an inherent enteric mucosal proinflammatory response to an altered gut-associated microbiome following IPAA for UC. Pouchitis usually responds to a short course of antibiotic therapy, notably with metronidazole or ciprofloxacin, and can be followed by maintenance with probiotics. In a small percentage of patients (3–5%), pouchitis is recurrent or persistent such that pouch excision may be necessary. In such cases, previously undiagnosed CD and pouch ischaemia should be considered as alternative diagnoses.

Kock ileal pouch reservoir

The Kock pouch was originally designed as a continent urostomy but later adapted as a continent ileostomy for patients following proctocolectomy for IBD. The technique confirmed the safety of a small bowel reservoir, but difficulties with prolapse of the nipple valve mechanism required for continence and the success of IPAA as a mechanism to retain continence and anatomical continuity has meant that the operation is now rarely performed.

Colectomy and ileorectal anastomosis

This procedure is occasionally performed in UC if there is minimal rectal inflammation. A very considerable percentage (at least 50%) of patients with a quiescent rectum after total colectomy will develop significant mucosal inflammation in the rectum once the faecal stream has been re-established. Although rectal inflammation can be controlled with medical treatment, functional results may be disappointing. If the rectum is preserved, then annual rectal inspection is advocated. This procedure has the advantage of avoiding a stoma and the risk to sexual function associated with rectal dissection, and so may provide a useful transition in highly selected patients.

INDETERMINATE COLITIS

Approximately one in 10 patients with colitis presents with histological features that make their disease difficult to characterise. While the clinical history may suggest the diagnosis in some cases (for example, a history of recurrent perianal sepsis and fistulation would make a diagnosis of CD more likely), in others it may remain unclear whether a patient has UC or CD. In such cases, it may still be appropriate to offer IPAA after detailed informed consent, but the risks of pouch failure appear to be significantly higher (up to 25–30%) and patients should be advised accordingly.

CROHN'S DISEASE (REGIONAL ENTERITIS)

Chronic inflammatory disease of the ileum, possibly first recognised by Morgagni in 1761 and described separately by Leśniowski and Dalziel in the early twentieth century, is known as Crohn's disease after a key publication by Crohn, Ginzburg and Oppenheimer in 1932. It is characterised by a chronic full-thickness inflammatory process that can affect any part of the gastrointestinal tract from the lips to the anal margin. It is most common in North America and northern Europe, with an annual incidence of 8 per 100 000. CD is slightly more common in women and is most frequently diagnosed between the ages of 25 and 40 years. There is a second peak of incidence around the age of 70 years. The prevalence is highest among white people, notably in North America and north-western Europe. CD is less common in central Europe

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy.
Antoni Leśniowski, 1867–1940, Professor of Surgery, Warsaw University, Warsaw, Poland.
Thomas Kennedy Dalziel, 1861–1924, surgeon, Western Infirmary, Glasgow, UK.
Leon Ginzburg, 1989–1988, surgeon, Mount Sinai Hospital, New York, NY, USA.
Gordon D Oppenheimer, 1900–1974, surgeon, Mount Sinai Hospital, New York, NY, USA.

and less prevalent still in South America and Africa. The incidence is rising in Asia, which is attributed to increased urbanisation. There are differences in clinical manifestations in Asian populations, with a higher male predominance, more perianal involvement, fewer extraintestinal manifestations and worse clinical outcomes. The prevalence of CD seems to be three to five times higher in the Ashkenazi Jewish population, although it is lower in the Jewish population in Israel, suggesting the importance of environmental factors.

Aetiology

The aetiology of CD remains incompletely understood but is thought to involve a complex interplay of genetic and environmental factors. Although CD shares some features with chronic infections, particularly tuberculosis, no causative organism has ever been demonstrated. There is an intriguing similarity to Johne's disease of cattle, a chronic inflammatory enteropathy resulting from infection with *Mycobacterium paratuberculosis*, suggesting that CD may have a related aetiology. Some studies have identified mycobacterial DNA more frequently in tissue from patients with CD than in tissue from controls, but trials have not demonstrated any therapeutic benefit of treating CD with antituberculous drugs.

A wide variety of foods and a highly refined diet have been implicated in CD; however, no conclusive link has been proven. There is considerable recent interest in food additives, particularly preservatives that may support a proinflammatory dysbiosis in the gut microbiome. An association with high levels of sanitation in childhood has also been implicated. Smoking increases the relative risk of CD threefold and is an exacerbating factor after diagnosis, contrary to the protective effect seen in UC. Smoking cessation has a beneficial effect on disease activity comparable to that of medical therapies and is therefore an essential component in the effective management of CD.

Genetic factors are important in CD. Approximately 10% of patients have a first-degree relative with the disease, and concordance approaches 50% in monozygotic twins. Inheritance is thought to involve multiple genes with low penetrance. Variants of NOD2/CARD15, a gene involved in intracellular recognition of bacteria, have been shown to have a strong association with CD. Recent genome-wide association studies have identified activation of over 200 genes in IBD, some of which are associated with CD and others with UC. Most patients have no identifiable germline mutational signature, and epigenetic mutations are more likely to be involved.

Both UC and CD are associated with alterations in the gut microbiome, with generally decreased microbial diversity. New techniques including next-generation 16S ribosomal RNA sequencing allow detailed analysis of individual microbial communities within the gut with sequential studies informing changes that might be associated with disease activity. Despite over a decade of intense study, no definitive signature of either CD or UC has been established, other than reduced microbial diversity, particularly in CD.

Pathogenesis

In both CD and UC increased gut mucosal permeability appears to develop at a relatively early stage and may lead to increased passage of luminal antigens that induce a cell-mediated inflammatory response. Proinflammatory cytokines, such as interleukin-2 and tumour necrosis factor, are then released. It has been suggested that CD is associated with a defect in suppressor T cells. It is unclear whether the proposed increase in intestinal permeability is a cause or consequence of the disease process. Animal studies have suggested that the increase in gut permeability develops because of changes in bacterial recognition proteins and an increase in inflammatory gene activation before macroscopic evidence of inflammation develops. Studies of healthy and apparently unaffected first-degree relatives of patients with CD suggest that gut permeability is increased, which in turn suggests that a genetically determined increase in gut permeability, perhaps combined with an abnormal immune-mediated response to colonisation of the gut with enteric microflora, may initiate the disease.

Pathology

The terminal ileum is the most commonly affected segment of bowel in patients with CD, often occurring in combination with other areas of disease. More proximal small bowel is less frequently involved. Colitis alone occurs in up to one-third of cases, the stomach and duodenum are affected in around 5% of cases, but perianal lesions are common, affecting up to 50% of patients. Perianal disease occurs in 25% of patients with small bowel disease and in 75% of patients with Crohn's colitis.

Macroscopically CD is characterised by fibrotic thickening of the intestinal wall with narrowing (stricturing) of the lumen and fat wrapping (encroachment of mesenteric fat around the bowel) (***Figure 75.9***). There is usually dilated bowel just proximal to the stricture and deep mucosal ulcerations with linear or serpiginous (snake-like) patterns in the strictured area itself. Oedema between ulcers gives rise to a characteristic cobblestone appearance of the mucosa (***Figure 75.10***). The transmural inflammation (a pathognomonic feature of CD) may lead to segments of bowel becoming adherent to each other and to surrounding structures, forming inflammatory masses with mesenteric abscesses and fistulation into adjacent organs (***Figure 75.11***). The serosa is usually opaque, with thickening of the mesentery and enlarged mesenteric lymph nodes. CD is characteristically discontinuous, with inflamed areas separated by apparently normal intestine, so-called skip lesions.

Microscopically focal areas of chronic inflammation involving all layers of the intestinal wall with lymphoid aggregates are characteristic of CD. Non-caseating giant cell granulomas found in 60% of patients are pathognomonic of CD (***Figure 75.2***). They are most commonly seen in anorectal disease. Multifocal arterial occlusions are found in thickened muscularis propria. There may be nerve cell hyperplasia and deep, fissuring ulceration within affected areas. Characteristically, and unlike in UC, there may be completely normal areas immediately next to areas of severe inflammation.

Heinrich Albert Johne, 1839–1910, pathologist, Dresden, Germany.

Figure 75.9 Crohn's disease of the ileocaecal region showing typical thickening of the wall of the terminal ileum with encroachment of mesenteric fat.

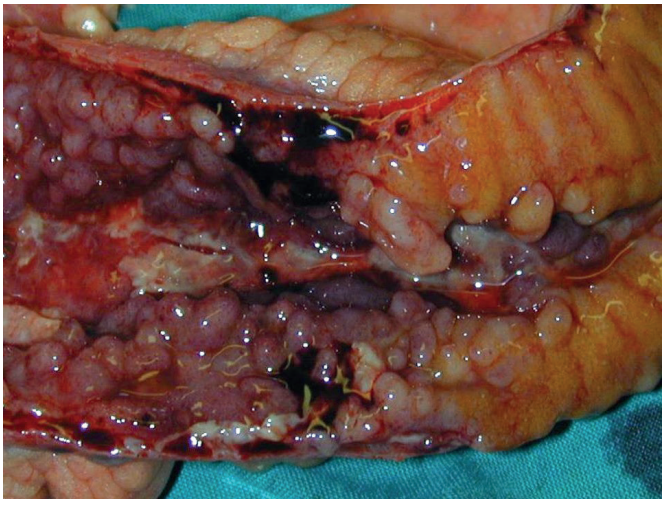

Figure 75.10 Crohn's disease of the terminal ileum illustrating longitudinal ulceration and cobblestone mucosa.

Clinical features

The clinical presentation depends on the pattern of disease. Occasionally, CD presents acutely with ileal inflammation and symptoms and signs resembling those of acute appendicitis or, much less commonly, free perforation of the small intestine resulting in a local or diffuse peritonitis. CD may present with acute severe colitis but this is considerably less common than in UC.

Small bowel CD often presents with bouts of abdominal pain and mild diarrhoea. A tender mass may be palpable in the right iliac fossa. Intermittent fever, anaemia and weight loss are common. After months of repeated attacks characterised by acute inflammation, the affected area of intestine stenoses with fibrosis, causing chronic obstructive symptoms. Children developing the illness before puberty may have retarded growth and sexual development. As CD progresses, transmural fissuring, intra-abdominal abscesses and fistulae may develop.

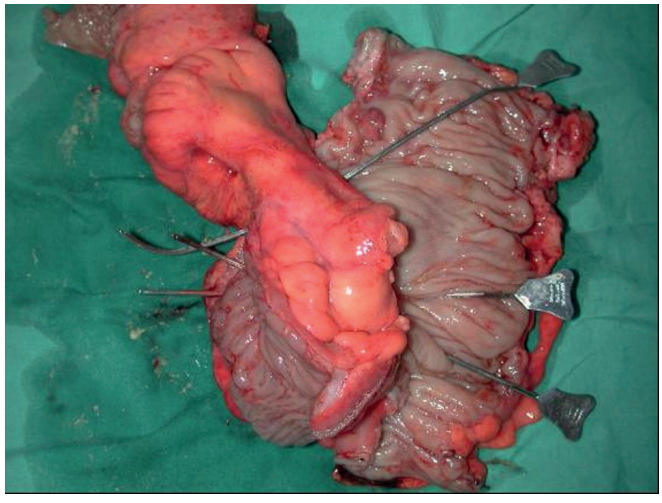

Figure 75.11 Resected specimen of terminal ileum and sigmoid colon illustrating Crohn's disease of the terminal ileum with multiple enterocolic fistulae.

Fistulation may occur into adjacent loops of bowel (enteroenteric or interloop fistulae). Occasionally, a mobile loop of sigmoid loop may become adherent to the affected terminal ileum, resulting in ileosigmoid fistulation (***Figure 75.11***). The fistula tracks in such cases are usually small and the profuse diarrhoea that results from ileosigmoid fistulation is due primarily to bacterial overgrowth (attributable to colonisation of the small bowel with colonic flora) rather than passage of small bowel content into the colon. Fistulation may also occur into the bladder (enterovesical), the female genital tract or, less commonly, the duodenum. Fistulation to the abdominal wall (enterocutaneous fistula) may also develop spontaneously or following appendicectomy in unrecognised CD, but more commonly presents as a complication of abdominal surgery.

Colonic Crohn's disease

Colonic involvement is found in 30% of patients with CD, frequently in association with perianal disease, and may coexist with small bowel pathology. Colonic CD presents with symptoms of colitis and proctitis as described for UC, although toxic megacolon is much less common. Colonic strictures may form just as are seen in small bowel CD. Endoscopic dilatation may be performed in expert hands as an alternative to surgical resection. Distinguishing between CD and UC is often difficult and requires clinical and pathological patterns to be combined. The presence of skip lesions, rectal sparing, non-caseating granulomas or perianal disease will point to CD (***Figure 75.12***).

Many patients with CD present with perianal problems. In the presence of active disease, the perianal skin can have a bluish tinge. Large, oedematous and inflamed skin tags are common. Fissures and superficial ulcers with undermined edges are relatively painless and can heal with bridging of epithelium. Deep cavitating ulcers are usually found in the upper anal canal; they can be painful and cause perianal abscesses and fistulae. Fistulation through the posterior wall of the vagina may lead to rectovaginal fistula and continuous leakage of gas and/or faeces per vagina (see ***Chapter 80***).

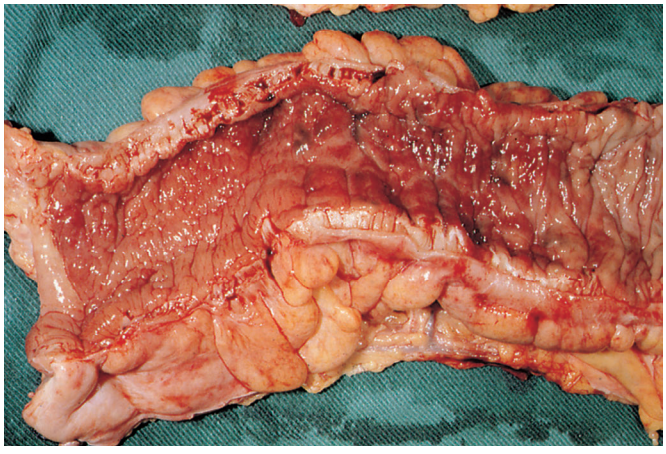

Figure 75.12 Colonic Crohn's disease. Note the normal mucosa on either side of the inflammatory stricture (courtesy of Professor Brian Warren, John Radcliffe Hospital, Oxford, UK).

TABLE 75.3 The Montreal classification of Crohn's disease.

A: age at diagnosis	A1	≤16 years old
	A2	17–40 years old
	A3	>40 years old
B (behaviour): progression	B1	Inflammatory
	B2	Stenosing
	B3	Penetrating
	p	Perianal (can exist with any of the above)
L: location	L1	Ileal
	L2	Colonic
	L3	Ileocolonic
	L4	Upper digestive tract; can be added to any of the three above

After Silverberg MS, Daly MJ, Moskovitz DN *et al*. Diagnostic misclassification reduces the ability to detect linkage in inflammatory bowel disease genetic studies. *Gut* 2001; **49**: 773–6.

The rectal mucosa is often spared in CD and will feel normal on rectal examination. If involved, it may feel thickened, nodular and irregular. Severe CD proctitis may occasionally be mistaken for cancer. Perianal disease is frequently associated with dense, fibrous stricturing (stenosis) at the anorectal junction. Incontinence may develop because of destruction of the anal sphincter musculature owing to inflammation, abscess formation, fibrosis and repeated surgical drainage. In severe cases, the perineum may become densely fibrotic, rigid and covered with multiple discharging openings (watering-can perineum).

Each patient with CD should have their disease phenotype (manifestations) classified according to the Montreal classification (***Table 75.3***). This is important as it allows an overview of disease progression in the individual patient over time, and enables group comparisons and evaluations. The Montreal classification specifies age at diagnosis, behaviour and disease location.

Extraintestinal manifestations

The extraintestinal manifestations of CD are similar to those that occur in UC. Primary sclerosing cholangitis is relatively rare in CD, compared with UC. Gallstones are common, as an inflamed or absent (because of resection) terminal ileum leads to reduced absorption of bile salts. Amyloidosis is common but is rarely symptomatic. Metastatic CD can occur in the vagina and/or skin with nodular ulcers, which demonstrate non-caseating granulomas when biopsied. Such cutaneous CD can be virtually indistinguishable macroscopically from hidradenitis suppurativa.

Investigations

Laboratory

A full blood count should be performed as anaemia is common, resulting from iron deficiency owing to blood loss, malabsorption or chronic disease. Vitamin B12 and folate deficiency may occur as a consequence of terminal ileal disease or resection. Active inflammatory disease is usually associated with low serum albumin, magnesium, zinc and selenium. Acute-phase protein measurements (C-reactive protein) and erythrocyte sedimentation rate may correlate with disease activity.

An elevated faecal concentration of calprotectin, a protein marker of mucosal inflammation, may support a diagnosis of CD in patients with new onset of persistent gastrointestinal symptoms. It can also be used to monitor disease activity in the long-term management of established CD.

Endoscopy

Colonoscopic examination may be normal or show patchy inflammation. Characteristically, there are areas of normal mucosa in between areas of inflammation that are irregular and ulcerated, with a mucopurulent exudate. The earliest findings are often aphthous ulcers surrounded by a rim of erythematous mucosa. These become larger and deeper with increasing severity of disease. There may be stricturing, and it is important to exclude malignancy at these sites by multiple and often repeated mucosal biopsies. An irregular Crohn's stricture with polypoid mucosa may be almost macroscopically indistinguishable from malignancy. The terminal ileum may be ulcerated and strictured. In patients who have had previous ileocaecal resection and anastomosis, recurrent disease usually presents first with aphthous ulceration just proximal to the anastomosis. Interval colonoscopy is therefore important in the follow-up after surgery for CD.

Upper gastrointestinal symptoms may require upper gastrointestinal endoscopy, which may reveal deep longitudinal ulcers and cobblestoning of the mucosa in the duodenum, stomach or, rarely, in the oesophagus or mouth. Enteroscopy may reveal jejunal ulceration and stricturing. Capsule endoscopy, which allows visualisation of the entire small intestinal mucosa by telemetry, has a useful role in those patients with evidence of chronic gastrointestinal symptoms or blood loss and where no evidence of ulceration can be found with more

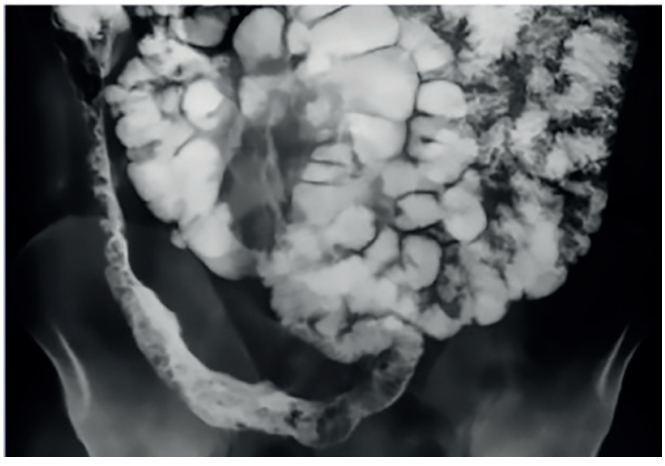

Figure 75.13 Radiograph showing a small bowel enema illustrating a long, strictured segment of terminal ileum due to Crohn's disease (string sign of Kantor).

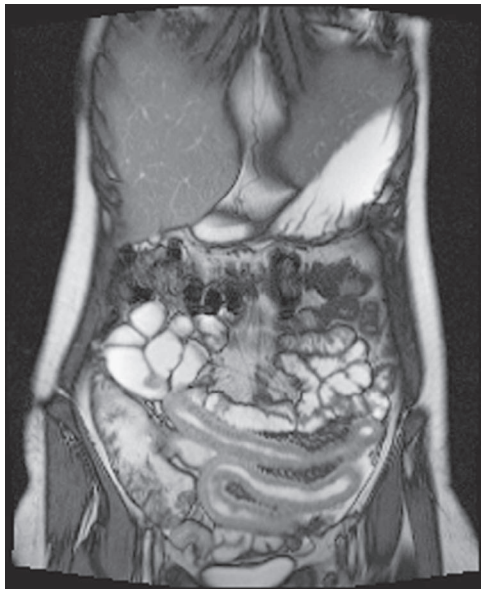

Figure 75.14 Magnetic resonance enteroclysis demonstrating small bowel inflammation (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

conventional endoscopic assessment. Investigation of the small intestine by capsule endoscopy should not be undertaken when there is a suspicion of stricture because of the possibility of the capsule becoming impacted in the narrow segment. A biodegradable test capsule can be used if this is a source of concern.

Imaging

High-resolution ultrasound in expert hands can demonstrate inflamed and thickened bowel loops as well as fluid collections and abscesses – the string sign of Kantor (***Figure 75.13***).

CT scans with oral contrast are widely used in the investigation of abdominal symptoms and can demonstrate fistulae, intra-abdominal abscesses and bowel thickening or dilatation. Magnetic resonance imaging (MRI) is useful in assessing complex perianal disease and has been shown to be an excellent method for investigating the small bowel. Magnetic resonance enterography (oral contrast) or enteroclysis (contrast administered via nasoduodenal tube) is particularly effective at demonstrating small bowel stricturing, including the string sign of Kantor, and avoids the need for repeated exposure to large doses of ionising radiation in young patients (***Figure 75.14***). A labelled white cell scan is occasionally of value to determine whether or not a segment of bowel is actively inflamed and to guide decisions on medical treatment.

In patients with an enterocutaneous fistula, fistulography may help to demonstrate the anatomy and complexity of the fistula and allow adequate planning for future surgery.

Medical treatment

Steroids

Corticosteroids are widely used to treat acute flares of CD. They induce remission in 70–80% of cases of moderate to severe disease. They should be used in short courses and tapered once a response has been achieved. They reduce inflammation and are therefore ineffective in established fibrostenotic disease. Steroid enemas may be used in the rectum, where the benefits include reduced systemic bioavailability, although long-term use may still cause adrenal suppression. Oral steroid formulations such as budesonide have been devised, where the steroid moiety is removed in the portal circulation, thus reducing systemic side effects. Steroids should not be used as maintenance therapy and are usually replaced with immunomodulatory agents to minimise the risk of side effects associated with long-term steroid use.

Aminosalicylates

Colonic symptoms can be treated by 5-ASA agents in a similar manner to those in UC. These agents have limited efficacy in small bowel CD.

Antibiotics

Metronidazole and ciprofloxacin may be used, particularly for periods of a few weeks at a time, especially in perianal disease. Long-term use of metronidazole should be avoided as there is a risk of peripheral neuropathy. Ciprofloxacin also has significant side effects when used in the long term, including tendinitis and tendon rupture. Antibiotics may be used to treat an inflammatory mass or an abscess. In general, however, a confirmed abscess should be treated by percutaneous drainage and/or surgery as antibiotics alone will not treat a Crohn's mass effectively.

Immunomodulatory agents

Azathioprine is used for its additive and steroid-sparing effects and currently represents standard maintenance therapy. It is a purine analogue, which is metabolised to 6-MP, and works by inhibiting cell-mediated immune responses (see ***Medical treatment of ulcerative colitis***).

John Leonard Kantor, 1890–1947, gastroenterologist, Presbyterian Hospital, New York, NY, USA, described his string sign in 1934.

Ciclosporin acts by inhibiting cell-mediated immunity. Short-course intravenous ciclosporin treatment is associated with remission in 80%; however, there is relapse after completion of treatment in many cases. Methotrexate is a drug that has a wide effect on DNA synthesis and immune signalling and can also be used in CD, although it is used less frequently in the biological era.

Monoclonal antibody (biologic) therapy

Infliximab, a murine chimeric anti-TNFα monoclonal antibody, and adalimumab, an entirely human anti-TNFα monoclonal antibody, are widely used to induce remission in moderately severe and severe CD. Third-generation monoclonal antibody therapies vedolizumab and etrolizumab prevent leukocyte migration preferentially in the gastrointestinal tract and may therefore have fewer side effects. More recently ustekinumab has entered widespread use as a CD therapy. It targets interleukin-12/23 to dampen the autoimmune system.

Monoclonal antibody therapy is currently widely used for induction and maintenance of remission. Early and aggressive use in patients at high risk for early recrudescent disease after surgery (for example, penetrating phenotype, early mucosal inflammation or aphthous ulceration at follow-up colonoscopy) may reduce (or at least postpone) the need for subsequent surgery. Perforation and abscess formation are usually regarded as contraindications to the use of biological therapy, although biologicals may be safely used after percutaneous drainage. While biologicals may reduce inflammation and may occasionally achieve healing of fistula openings in anal disease, the fistula tracks may remain patent and cessation of therapy is associated with a high risk of reactivation. Care must be taken before starting biological therapy to ensure that there is no active sepsis and that a diagnosis of intestinal tuberculosis has been excluded (see ***Chapter 65***).

Nutritional support

Nutritional support is frequently required in CD. Patients with moderate nutritional impairment will require nutritional supplementation and severely malnourished patients may require enteral tube or even parenteral nutrition. Anaemia, hypoproteinaemia and electrolyte, vitamin and metabolic bone problems must all be addressed. Elemental diet or parenteral nutrition can induce remission in up to 80% of patients, an effect comparable to steroids, but almost all patients relapse rapidly after cessation of therapy. Nutritional optimisation has been shown to improve surgical outcomes, but it is important to recognise that a significant improvement in nutritional status is unlikely in the setting of active infection and, in patients with abscesses, effective drainage remains the overwhelming priority.

Endoscopic dilatation in Crohn's disease

Although penetrating disease will often require surgical resection, stricturing may be amenable to endoscopic treatment. This may be accomplished by enteroscopy or colonoscopy, depending on the site of the stricture. Dilatation of an inflamed or ulcerated stricture is contraindicated because of the risks of perforation, but balloon dilatation of fibrostenotic disease may result in substantial symptomatic improvement and obviate the need for surgery in selected cases. It is most suited for short (<5 cm) fibrostenotic strictures, including those seen at a previous anastomosis.

Indications for surgery

Population-based studies show that approximately 70% of patients with CD will require a bowel resection in the first decade after diagnosis, and 40% will require a further resection in the decade after their index resection. Recent population-based data in the era of monoclonal antibodies suggest that the incidence of surgery may be falling, but surgery nevertheless remains a key component of treatment.

Surgical resection will not cure CD. Surgery therefore focuses on managing the complications of the disease (***Summary box 75.2***). As many of these indications for surgery may be relative, joint management by an aggressive physician and a conservative surgeon is ideal and decisions regarding surgical intervention are best made by a multidisciplinary team in consultation with the patient and recognising their preferences. The fundamental principle is to preserve healthy gut and to maintain adequate function. Intestinal resection should be kept to the minimum required to treat the local consequences of disease to mitigate against the potential for short bowel syndrome (see ***Chapter 91***).

In laparoscopic surgery it may be more difficult to assess the full length of the small intestine, so up-to-date preoperative small bowel imaging is important. While surgery carries perioperative risks, it also carries significant benefits, notably in patients with isolated terminal ileal disease, in whom a prolonged period of good health may be achieved. The relative benefits of surgical resection and long-term medical therapy in CD can be very finely balanced and require careful consideration and discussion with the patient within the setting of a combined gastroenterological and surgical IBD clinic.

Summary box 75.2

Principles of management of CD

- Close liaison between physician and surgeon is crucial
- Both medical and surgical treatment options should be considered; however, surgery should not be delayed when there is a clear indication
- Patients must be optimised prior to surgery; this may include radiological drainage of sepsis, antibiotic treatment and nutritional support
- CD is a chronic relapsing disease with a high likelihood of reoperation; the surgeon must take every reasonable effort to preserve bowel length and sphincter function
- Shared decision making with patients to accommodate their treatment preferences

Occasionally unsuspected ileal inflammation is found during emergency appendicectomy. Determining whether or not to resect the ileum in this situation is a complex clinical decision that should be made by a senior surgeon.

This decision involves an assessment of the likelihood that the ileitis is an expression of CD rather than another aetiology such as *Yersinia* infection; an assessment of the likelihood of remission with medical therapy rather than surgery; risk of enterocutaneous fistulation from appendiceal base leakage; and an assessment of the rest of the small bowel for the presence of additional sites of inflammation. In the current era of monoclonal therapy, it would be controversial to resect uncomplicated terminal ileitis found during an emergency procedure for suspected appendicitis, as this is likely to respond to medical therapy. If reasonably safe, appendicectomy is now encouraged for histological confirmation in limited previously undiagnosed disease, with appendicectomy carried out using a laparoscopic stapler to reduce the risk of enterocutaneous fistula (see ***Chapter 76***).

The course of CD after surgery is unpredictable, but recrudescence (a better term than recurrence) is common. Symptomatic recrudescence does not seem to be related to the presence of disease at the resection line. The cumulative probability of recrudescence requiring surgery for ileal disease is approximately 20%, 40%, 60% and 80% at 5, 10, 15 and 20 years, respectively, after a previous resection.

Surgery for CD is technically demanding as the involved mesentery is thickened and oedematous and healing may be impaired (see ***Chapter 65***). The patient may be malnourished, on immunosuppressants or have active infection/sepsis, or potentially all three. Decision making regarding the timing and nature of surgery to be undertaken is key to a satisfactory outcome of surgical treatment, and frequently requires experience and multidisciplinary discussion with other healthcare professionals and, most importantly, the patient. A key decision must be made whether to anastomose the apparently healthy bowel ends after macroscopically apparent disease has been resected, as anastomotic leaks and fistulation represent a considerable problem after surgery for CD. Intra-abdominal septic complications are more common if one or more of the following risk factors are present:

- current high-dose steroid therapy (>10 mg prednisolone for >4 weeks before surgery);
- current or very recent (<14 days) preoperative monoclonal antibody therapy;
- preoperative significant weight loss (>10% premorbid weight);
- coexisting abdominal sepsis (notably an abscess or fistula);
- low serum albumin <30 g/L.

If any risk factors are present (and particularly if more than one risk factor is present as the risks appear to be additive), one should consider exteriorising the bowel to create a stoma, with distal segment closure left close to the ileostomy site, and plan a delayed anastomosis when the risk factors have been corrected.

Ileocaecal or colonic resections can be undertaken laparoscopically, with the potential advantage of smaller incisions and potentially shorter recovery time. Reoperative surgery is technically demanding and ileosigmoid or ileoduodenal adhesions and fistulae can be difficult to safely dissect laparoscopically. Laparotomy should be considered in this setting. Although CD is usually regarded as a contraindication to ileal pouch surgery, the other options (panproctocolectomy or total colectomy with ileorectal anastomosis) are frequently appropriate and there may be considerable rectal sparing in CD, justifying the latter. Where the diagnosis of CD is firmly established, segmental rather than total colectomy may be appropriate.

The range of operations performed for CD depends on the pattern of disease; the most common are outlined below:

- **Ileocaecal resection** is the usual procedure for terminal ileal disease, with a primary anastomosis between the ileum and the ascending or transverse colon, depending on the extent of the disease. Ileostomy without primary anastomosis is indicated if the patient is unwell, has active infection or is nutritionally depleted.
- **Segmental resection** of short segments of small or large bowel strictures can be performed.
- **Colectomy and ileorectal anastomosis** may be undertaken for colonic CD with rectal sparing and a normal anus.
- **Subtotal colectomy and ileostomy** for Crohn's colitis accounts for 8% of such procedures for acute colonic disease. The indications are similar to those for UC.
- **Temporary loop ileostomy**. This can be used either in patients with acute distal CD, allowing remission and later restoration of continuity, or in patients with severe perianal or rectal disease.
- **Panproctocolectomy**. Many patients with severe anal disease failing to respond to medical treatment will eventually require a permanent colostomy. When this occurs in a setting of severe colonic disease, proctocolectomy and permanent ileostomy may be required.
- **Strictureplasty**. Strictured areas of CD (***Figure 75.15a***) can be treated by strictureplasty, a local widening procedure, to avoid small bowel resection and is thus an important bowel-sparing technique. Strictureplasty is particularly useful for the treatment of fibrostenotic disease when there is little or no active inflammation in the involved segment. Strictureplasty is contraindicated in the presence of a phlegmon, Crohn's associated cancer or haemorrhage due to mucosal ulceration. If there is any concern about malignancy at the site of a stricture, then frozen biopsy carried out intraoperatively may allow a strictureplasty to take place rather than resection, although resection and formal histological assessment remains the better option if there is any doubt. Multiple strictureplasties can be performed and strictureplasty can be combined with resection. The Heineke–Mikulicz technique of an antimesenteric longitudinal incision that is closed transversely is the most common technique. A Finney antimesenteric side-to-side anastomosis is used to treat long segments of stenosis when preservation of bowel length is important (***Figure 75.15b***).

Walter Hermann von Heineke, 1834–1901, Professor of Surgery, Erlangen, Germany.
Jan Mikulicz-Radecki, 1850–1905, surgeon, Kraków and later Königsberg and Wrocław, Poland.
John Miller Turpin Finney, 1863–1942, surgeon, Johns Hopkins Medical School, Baltimore, MD, USA.

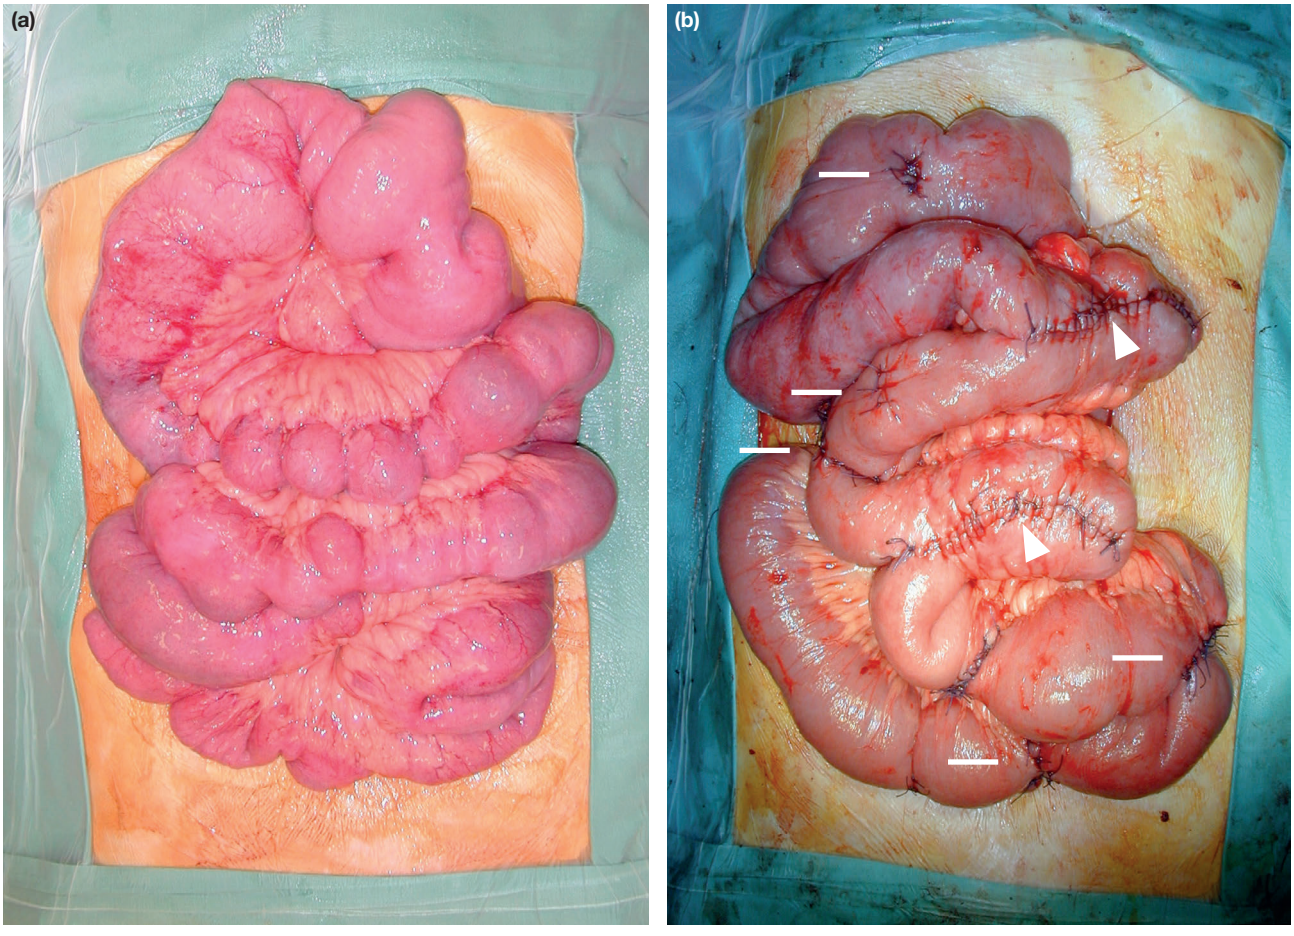

Figure 75.15 (a) Crohn's disease affecting the jejunum and ileum (jejunoileitis) with multiple strictures and bowel dilatation between skip lesions. **(b)** Same patient following multiple strictureplasties: Heineke–Mikulicz (arrows) and Finney (arrowheads).

Recent clinical research has pointed towards the importance of the mesentery in disease recurrence following resection (see ***Chapter 65***). Complete excision of macroscopically diseased mesentery may reduce the incidence of recurrence, as may anastomotic techniques that ensure that an anastomosis is fashioned on the antimesenteric aspect of the bowel (Kono-S procedure).

Irrespective of the site of resection or anastomotic technique used, it is important to follow patients closely in the postoperative months to ensure that recrudescence of CD is identified at a very early stage and medical treatment reinstituted. A strong case can be made for restarting prophylactic biological treatment subject to endoscopic review at 6 months following resection.

Perianal Crohn's disease

Perianal CD is distressing and often debilitating for patients. The most common presentation is with a perianal abscess: perianal swelling, redness and pain, followed by discharge of pus or faecal drainage to perianal skin or vagina, representing a fistulous connection. Management requires a combination of medical and surgical treatments. The role of surgery is to control infection in the first instance, and later to minimise recurrent infection, reduce drainage and to offer potential for fistula cure. If a fistula is seen at the time of abscess drainage, a seton may be placed. Otherwise, further examination under anaesthesia will be required for placement of draining seton(s) by an experienced colorectal surgeon.

MRI may aid identification of occult fistulae or sources of ongoing sepsis. Long-term drainage with setons prevents further tissue loss from undrained infection but also allows safe initiation of biological therapy. Infliximab or adalimumab therapy may be combined with seton insertion in the early phase of management of perianal fistulae. Once fistula discharge has reduced, typically after two or three doses, the seton can be removed. Laying open of fistulae (fistulotomy), commonly performed for fistulae resulting from the more common cryptoglandular perianal abscess, should generally be avoided in CD as the wound edges heal poorly.

Potentially curative surgical options include advancement flaps, fibrin glue, fistula plugs, ligation of the intersphincteric

Toru Kono, 1955–2021, Sapporo Higashi Tokushukai Hospital, Higahi-ku, Sapporo, Hokkaido, Japan.

fistula track (LIFT) and adipose-derived stem cell injection coupled with sutured closure of the internal fistula opening. The over-the-scope clip (OTSC®) and video-assisted anal fistula treatment (VAAFT) have only been used in small numbers of patients (see ***Chapter 80***).

Injection of adipose-derived mesenchymal stem cells into tissue surrounding complex anal fistula tracts is well tolerated and when used in combination with established treatments may increase fistula healing rates. The mechanisms of action are uncertain but are thought to relate to regenerative and anti-inflammatory cytokines produced by stem cells. The treatment is expensive and further trials are needed.

A diverting stoma may offer significant quality of life benefit in selected patients and should be offered to symptomatic patients in the presence of intractable symptomatic perianal disease or proctitis, or failure to control perianal sepsis. Proctectomy is a good option for some patients and a permanent stoma should not be viewed as a treatment failure as it may again offer significant improvement in quality of life in selected patients. Rectovaginal fistulae hardly ever close with medical management alone, and surgery to repair rectovaginal fistulae has relatively low success rates. Failure of surgical repair may result in further deterioration in symptoms if there is additional loss of functional anorectal, vaginal or perineal tissue, and ultimately stoma rates are high in this group of patients.

Ileal pouch–vaginal fistula

Ileal pouch–vaginal fistula is most commonly due to an anastomotic complication; however, a delayed presentation may reflect an underlying diagnosis of CD rather than UC. Management depends on cause: biological therapy for CD, diverting ileostomy if there is complex sepsis, and definitive repair with interposition of native tissue if the sepsis resolves and CD has been excluded.

Duodenal Crohn's disease

The duodenum is an uncommon site for CD and involvement is more commonly the result of inflammation in another part of the bowel as a bystander effect (secondary). This can often be managed by resection of the source of the fistula with direct duodenal repair if the defect is small or closure using an omental patch or duodenojejunostomy if the defect is sizeable. Duodenal strictures may be amenable to endoscopic balloon dilatation; however, strictureplasty, bypass gastrojejunostomy or gastroduodenostomy may be required.

SPECIALISATION IN INFLAMMATORY BOWEL DISEASE SURGERY

Many general surgeons have relatively little experience in managing patients with IBD. High-volume centres have lower morbidity and mortality rates after colectomy for emergency surgery for IBD and after primary ileocaecal resection for CD. Specialist units also have a lower failure rate following IPAA and are more likely to offer subsequent restorative surgery, rather than permanent stoma, for patients who have required emergency colectomy.

Less common aspects of IBD surgery, including the need for revision or excision pouch surgery, rectovaginal fistula management, Kock pouch formation or care of adolescent patients, require specialist expertise to achieve good outcomes.

PART 11 | Abdominal

CHAPTER 76

The vermiform appendix

Learning objectives

To understand:

- The aetiology and surgical anatomy of acute appendicitis
- The clinical signs and differential diagnoses of appendicitis
- The investigation of suspected appendicitis
- Evolving concepts in the management of acute appendicitis
- Basic surgical techniques, both open and laparoscopic
- The management of postoperative problems
- Tumours of the appendix and pseudomyxoma peritonei

INTRODUCTION

The importance of the vermiform appendix in surgery arises primarily from its propensity for inflammation, which results in the clinical syndrome known as acute appendicitis. Acute appendicitis is the most common cause of an 'acute abdomen' in young adults and, as such, the associated symptoms and signs have become a paradigm for clinical teaching. Appendicitis is sufficiently common that appendicectomy (termed appendectomy in North America) is the most frequently performed urgent abdominal operation and is often the first major procedure performed by a surgeon in training. Advances in modern radiographic imaging have improved diagnostic accuracy; however, the diagnosis of appendicitis remains essentially clinical, requiring a mixture of observation, clinical acumen and surgical science and as such it remains an enigmatic challenge and a reminder of the art of surgical diagnosis. Although much more uncommon, the appendix also has a propensity to the formation of tumours, which, despite humble and innocuous beginnings, may disseminate widely with dramatic clinical consequences.

Aside from its tendency to cause surgical pathology, the appendix, long thought to be a vestigial organ, may also have important roles in both immune function and maintaining the gut microbiota. The putative role of the appendix in the pathogenesis of ulcerative colitis (appendicectomy seems to be protective), for example, may be explained by its interaction with the intestinal flora and gut immune function.

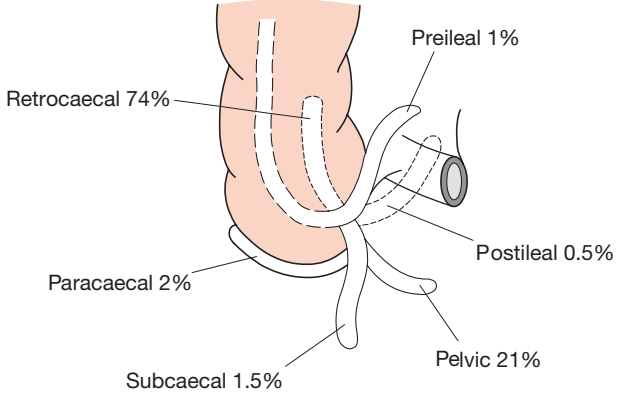

Figure 76.1 The various positions of the appendix (after Sir C Wakeley, London).

ANATOMY

The vermiform appendix is present only in humans, certain anthropoid apes and the wombat. It is a blind muscular tube with mucosal, submucosal, muscular and serosal layers. Morphologically, it is the undeveloped distal end of the large caecum found in many lower animals. At birth, the appendix is short and broad at its junction with the caecum, but differential growth of the caecum produces the typical tubular structure by about the age of 2 years (Condon). During childhood, continued growth of the caecum commonly rotates the appendix into a retrocaecal but intraperitoneal position (***Figure 76.1***). In approximately one-quarter of cases, rotation of the appendix does not occur, resulting in a pelvic, subcaecal or paracaecal position. Occasionally, the tip of the appendix becomes extraperitoneal, lying behind the caecum or ascending colon. Rarely, the caecum does not migrate during development to its normal position in the right lower quadrant of the abdomen. In these circumstances, the appendix can be found near the gallbladder or, in the case of intestinal malrotation, in the left iliac fossa, causing diagnostic difficulty if appendicitis develops (***Figure 76.2***).

A wombat is a nocturnal, burrowing Australian marsupial.

Robert E Condon, 1929–2015, Emeritus Professor of Surgery, Medical College of Wisconsin, WI, USA.

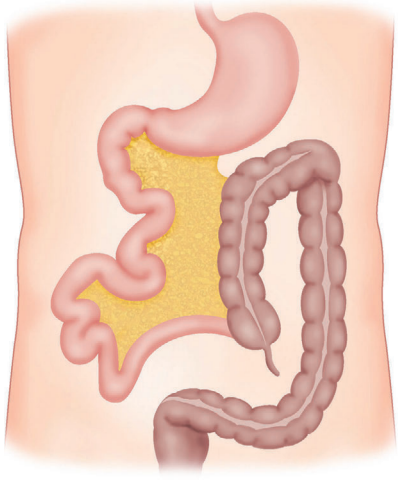

Figure 76.2 Left-sided caecum and appendix due to intestinal malrotation.

Gross anatomy

The position of the base of the appendix is constant, being found at the confluence of the three taeniae coli of the caecum, which fuse to form the outer longitudinal muscle coat of the appendix. At operation, use can be made of this to find an elusive appendix, as gentle traction on the taeniae coli, particularly the anterior taenia, will lead the operator to the base of the appendix. The mesentery of the appendix or mesoappendix arises from the lower surface of the mesentery of the terminal ileum and is itself subject to great variation. Sometimes, as much as the distal one-third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood vessels can be seen (***Figure 76.3***). In many adults, it becomes laden with fat, which obscures these vessels. The appendicular artery, a branch of the lower division of the ileocolic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes to lie in the free border of the mesoappendix. An accessory appendicular artery may be present but, in most people, the appendicular artery is an 'end-artery', thrombosis of which results in necrosis of the appendix (synonym: gangrenous appendicitis). Four, six or more lymphatic channels traverse the mesoappendix to empty into the ileocaecal lymph nodes.

Microscopic anatomy

The appendix varies considerably in length and circumference. The average length is between 7.5 and 10 cm. The lumen is irregular, being encroached on by multiple longitudinal folds of mucous membrane lined by columnar cell intestinal mucosa of colonic type (***Figure 76.4***). Crypts are present but are not numerous. In the base of the crypts lie argentaffin cells (Kulchitsky cells), which may give rise to neuroendocrine tumours (NETs) (see ***Neuroendocrine tumours of the appendix***). The submucosa contains numerous lymphatic aggregations or follicles. While no discernible change in immune function results from appendicectomy, the prominence of lymphatic tissue in the appendix of young adults seems to be important in the aetiology of appendicitis (see ***Acute appendicitis***).

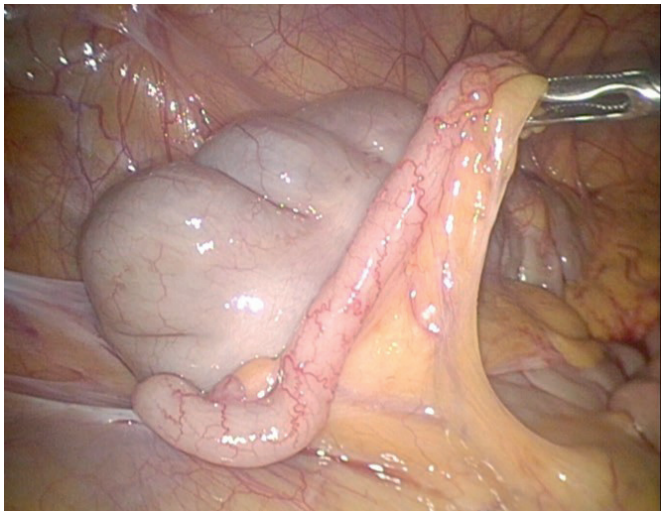

Figure 76.3 Laparoscopic view of a normal appendix with mesoappendix displaying the appendicular artery.

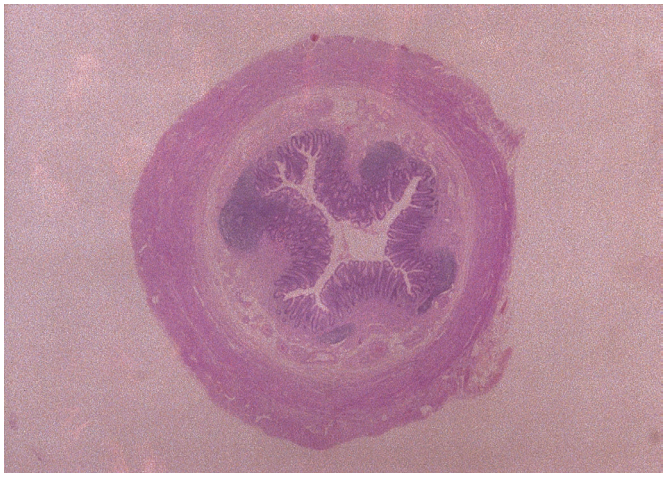

Figure 76.4 Normal vermiform appendix. The narrow lumen is bounded by mucosa, which may be arranged in folds. There is usually abundant lymphoid tissue in the mucosa, especially in younger individuals. This may encroach on and further narrow the lumen. The mucosa is bounded by a relatively thin muscularis mucosa (courtesy of Dr P Kelly, FRCPath, Dublin, Ireland).

Nikolai Kulchitsky, 1856–1925, Professor of Histology, Kharkov, Ukraine, who left Russia after the Revolution of 1917 and later worked at University College, London, UK. He described these cells in 1897.

ACUTE APPENDICITIS

While there are isolated reports of perityphlitis (fatal inflammation of the caecal region) from the late 1500s, recognition of acute appendicitis as a clinical entity is attributed to Reginald Fitz, who presented a paper to the first meeting of the Association of American Physicians in 1886 entitled 'Perforating inflammation of the vermiform appendix'. Soon afterwards, Charles McBurney described the clinical manifestations of acute appendicitis, including the point of maximum tenderness in the right iliac fossa that now bears his name.

The incidence of appendicitis seemed to rise greatly in the first half of the twentieth century, particularly in Europe, America and Australasia, with up to 16% of the population undergoing appendicectomy. In the past 30 years, the incidence has fallen dramatically in these countries, such that the individual lifetime risk of appendicectomy is 8.6% and 6.7% among males and females, respectively.

Acute appendicitis is relatively rare in infants and becomes increasingly common in childhood and early adult life, reaching a peak incidence in the teens and early twenties. After middle age, the risk of developing appendicitis is quite small. The incidence of appendicitis is equal among males and females before puberty. In teenagers and young adults, the male-to-female ratio increases to 3:2 at age 25; thereafter, the greater incidence in males declines.

Aetiology

There is no unifying hypothesis regarding the aetiology of acute appendicitis. Decreased dietary fibre and increased consumption of refined carbohydrates may be important. As with colonic diverticulitis, the incidence of appendicitis is lowest in societies with a high dietary fibre intake. In resource-poor countries that are adopting a more refined Western-type diet, the incidence continues to rise. This is in contrast to the dramatic decrease in the incidence of appendicitis in Western countries observed in the past 30 years. No reason has been established for these paradoxical changes; however, improved hygiene and a change in the pattern of childhood gastrointestinal infection related to the increased use of antibiotics may be responsible.

While appendicitis is clearly associated with bacterial proliferation within the appendix, no single organism is responsible. A mixed growth of aerobic and anaerobic organisms is usual. The initiating event causing bacterial proliferation is controversial. Obstruction of the appendix lumen has been widely held to be important, and some form of luminal obstruction, either by a faecolith (***Figure 76.5***) or by a stricture, is found in the majority of cases.

A faecolith (sometimes referred to as an appendicolith) is composed of inspissated faecal material, calcium phosphates, bacteria and epithelial debris. Rarely, a foreign body is incorporated into the mass. The incidental finding of a faecolith is a relative indication for prophylactic appendicectomy or an interval appendicectomy in a patient treated conservatively. A fibrotic stricture of the appendix usually indicates previous appendicitis that resolved without surgical intervention. Obstruction of the appendiceal orifice by tumour, particularly carcinoma of the caecum, is an occasional cause of acute appendicitis in middle-aged and elderly patients. Intestinal parasites, particularly *Enterobius vermicularis* (pinworm), can proliferate in the appendix and occlude the lumen.

Figure 76.5 Coronal reformat of a computed tomography scan of the abdomen obtained with oral and intravenous contrast, demonstrating an inflamed, enhancing and enlarged appendix that is curled in the midline extending towards the pelvis (arrow). It contains multiple radiopaque appendicoliths. There is extensive periappendiceal fat stranding (courtesy of Professor P MacMahon, FRCR, Dublin, Ireland).

Pathology

Obstruction of the appendiceal lumen seems to be essential for appendiceal perforation. However, in many cases of early appendicitis, the appendix lumen is patent despite the presence of mucosal inflammation and lymphoid hyperplasia. Occasional clustering of cases among children and young adults suggests an infective agent, possibly viral, which initiates an inflammatory response. Seasonal variation in the incidence is also observed, with more cases occurring between May and August in northern Europe than at other times of the year.

Lymphoid hyperplasia narrows the lumen of the appendix. Once obstruction occurs, continued mucus secretion and inflammatory exudation increase intraluminal pressure, obstructing lymphatic drainage. Oedema and mucosal

Reginald Heber Fitz, 1843–1913, Professor of Medicine, Harvard University, Boston, MA, USA.
Charles McBurney, 1854–1913, Professor of Surgery, Columbia College of Physicians and Surgeons, New York, NY, USA. In 1889 McBurney published a paper on appendicitis in which he stated, 'I believe that in every case the seat of greatest pain "determined by the pressure of one finger" has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus.'

ulceration develop with bacterial translocation to the submucosa. Resolution may occur at this point either spontaneously or in response to antibiotic therapy. If the condition progresses, further distension of the appendix may cause venous obstruction and ischaemia of the appendix wall. With ischaemia, bacterial invasion occurs through the muscularis propria and submucosa, producing acute appendicitis (***Figure 76.6***). Finally, ischaemic necrosis of the appendix wall produces gangrenous appendicitis, with free bacterial contamination of the peritoneal cavity. Alternatively, the greater omentum and loops of small bowel become adherent to the inflamed appendix, walling off the spread of peritoneal contamination and resulting in a phlegmonous mass or paracaecal abscess. Rarely, appendiceal inflammation resolves, leaving a distended mucus-filled organ termed a mucocele of the appendix.

Peritonitis occurs as a result of free migration of bacteria through an ischaemic appendicular wall, frank perforation of a gangrenous appendix or delayed perforation of an appendix abscess. Factors that promote this process include extremes of age, immunosuppression, diabetes mellitus, faecolith obstruction of the appendix lumen, a free-lying pelvic appendix and previous abdominal surgery that limits the ability of the greater omentum to wall off the spread of peritoneal contamination. In these situations, a rapidly deteriorating clinical course is accompanied by signs of diffuse peritonitis and systemic sepsis syndrome.

Clinical diagnosis

History

Appendicitis is relatively rare in infants under 36 months of age and, for obvious reasons, the patient is unable to give a history. Because of this, diagnosis is often delayed, and thus the incidence of perforation and postoperative morbidity is considerably higher than in older children.

In older age groups the classical features of acute appendicitis begin with poorly localised colicky abdominal pain. This is due to midgut visceral discomfort in response to appendiceal inflammation and obstruction. The pain is frequently first noticed in the periumbilical region and is similar to, but less intense than, the colic of small bowel obstruction. Central abdominal pain is associated with anorexia, nausea and usually one or two episodes of vomiting that follow the onset of pain (Murphy). Anorexia is a useful and constant clinical feature, particularly in children, who invariably also have vomiting. The patient often gives a history of similar discomfort that settled spontaneously. A family history is also useful as up to one-third of children with appendicitis have a first-degree relative with a similar history. In women of childbearing age pelvic disease can mimic acute appendicitis and a careful gynaecological history should be taken, concentrating on menstrual cycle, vaginal discharge and possible pregnancy.

Summary box 76.2

Symptoms of appendicitis

- Periumbilical colic
- Pain shifting to the right iliac fossa
- Anorexia
- Nausea

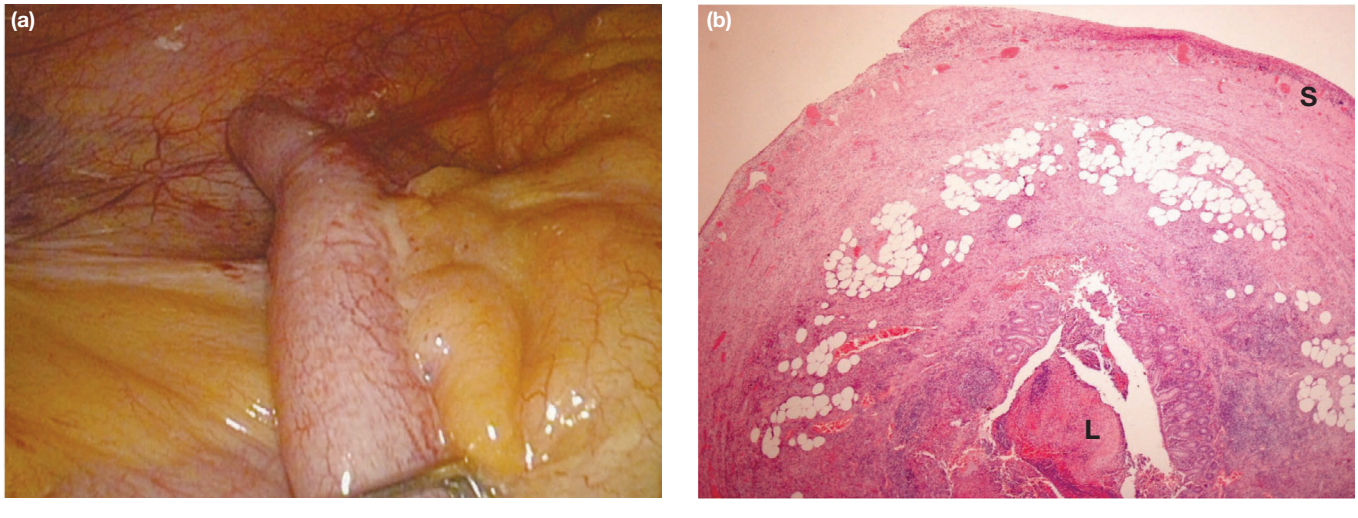

Figure 76.6 Acutely inflamed appendix with purulent exudate extending to the mesoappendix in a 28-year-old man as seen at laparoscopy **(a)** and a photomicrograph (original magnification ×20) **(b)** from the same patient showing the appendix with pus-filled lumen (L) and inflammation extending to inflamed serosa (S) (courtesy of Professor C O'Keane, FFPath, FRCPI, Dublin, Ireland).

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA.

With progressive inflammation of the appendix, the parietal peritoneum in the right iliac fossa becomes irritated, producing more intense, constant and localised somatic pain that begins to predominate. Patients often report this as an abdominal pain that has shifted and changed in character. Typically, coughing or sudden movement exacerbates the right iliac fossa pain.

The classic visceral–somatic sequence of pain is present in only about half of those patients subsequently proven to have acute appendicitis. A typical presentation includes pain that is predominantly somatic or visceral and poorly localised. Atypical pain is more common in the elderly, in whom localisation to the right iliac fossa is unusual. An inflamed appendix in the pelvis may not produce somatic pain involving the anterior abdominal wall, but instead cause suprapubic discomfort and tenesmus. In this circumstance, tenderness may be elicited only on rectal examination and is the basis for the recommendation that a rectal examination should be performed on every patient who presents with acute lower abdominal pain.

During the first 6 hours, there is rarely any alteration in temperature or pulse rate. After that time, slight pyrexia (37.2–37.7°C) with a corresponding increase in the pulse rate to 80–90 beats per minute is usual. However, in 20% of patients there is no pyrexia or tachycardia in the early stages. In children, a temperature greater than 38.5°C suggests other causes (e.g. mesenteric adenitis; see ***Differential diagnosis, Children***).

Typically, two clinical syndromes of acute appendicitis can be discerned: acute catarrhal (non-obstructive) appendicitis and acute obstructive appendicitis, the latter characterised by a more acute course. The onset of symptoms is abrupt and there may be generalised abdominal pain from the start. The temperature may be normal and vomiting is common, so the clinical picture may mimic acute intestinal obstruction.

Signs

The diagnosis of appendicitis rests more on thorough clinical examination of the abdomen than on any aspect of the history or laboratory investigation. The cardinal features are those of an unwell patient with low-grade pyrexia, localised abdominal tenderness, muscle guarding and rebound tenderness. Inspection of the abdomen may show limitation of respiratory movement in the lower abdomen. The patient is then asked to point to where the pain began and where it moved (pointing sign). Gentle superficial palpation of the abdomen, beginning in the left iliac fossa and moving anticlockwise to the right iliac fossa, will detect muscle guarding over the point of maximum tenderness, classically McBurney's point. Asking the patient to cough or gentle percussion over the site of maximum tenderness will elicit rebound tenderness (see ***Chapter 63***).

Deep palpation of the left iliac fossa may cause pain in the right iliac fossa, Rovsing's sign, which is helpful in supporting a clinical diagnosis of appendicitis. Occasionally, an inflamed appendix lies on the psoas muscle, and the patient, often a young adult, will lie with the right hip flexed for pain relief (the psoas sign). Spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manoeuvre will cause pain in the hypogastrium (the obturator test; Zachary Cope). Cutaneous hyperaesthesia may be demonstrable in the right iliac fossa, but is rarely of diagnostic value.

Summary box 76.3

Clinical signs in appendicitis

- Pyrexia
- Localised tenderness in the right iliac fossa
- Muscle guarding
- Rebound tenderness

Summary box 76.4

Signs to elicit in appendicitis

- Pointing sign
- Rovsing's sign
- Psoas sign
- Obturator sign

Special features, according to position of the appendix

Retrocaecal

Rigidity is often absent, and even application of deep pressure may fail to elicit tenderness (silent appendix), the reason being that the caecum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may be sufficient to cause flexion of the hip joint. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic

Occasionally, early diarrhoea results from an inflamed appendix being in contact with the rectum. When the appendix lies entirely within the pelvis, there is usually complete absence of abdominal rigidity, and often tenderness over McBurney's point is also lacking. In some instances, deep tenderness can be made out just above and to the right of the symphysis pubis. In either event, a rectal examination reveals tenderness in the rectovesical pouch or the pouch of Douglas, especially on the right side. Spasm of the psoas and obturator internus muscles may be present when the appendix is in this position. An inflamed appendix in contact with the bladder may cause frequency of micturition. This is more common in children.

Neils Thorkild Rovsing, 1862–1937, Professor of Surgery, Copenhagen, Denmark.
Sir Vincent Zachary Cope, 1881–1975, surgeon, St Mary's Hospital, London, UK
James Douglas, 1715–1742, anatomist and midwife who practised in London, UK, described this pouch in 1730.

TABLE 76.1 Differential diagnosis of acute appendicitis.

Children	Adult	Adult female	Elderly
Gastroenteritis	Regional enteritis	Mittelschmerz	Diverticulitis
Mesenteric adenitis	Ureteric colic	Pelvic inflammatory disease	Intestinal obstruction
Meckel's diverticulitis	Perforated peptic ulcer	Pyelonephritis	Colonic carcinoma
Intussusception	Torsion of testis	Ectopic pregnancy	Torsion appendix epiploicae
Henoch–Schönlein purpura	Pancreatitis	Torsion/rupture of ovarian cyst	Mesenteric infarction
Lobar pneumonia	Rectus sheath haematoma	Endometriosis	Leaking aortic aneurysm

Postileal

In this case, the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhoea is a feature and marked retching may occur. Tenderness, if any, is ill defined, although it may be present immediately to the right of the umbilicus.

Differential diagnosis

Although acute appendicitis is the most common abdominal surgical emergency, the diagnosis can be extremely difficult at times. There are a number of common conditions that it is wise to consider carefully and, if possible, exclude. The differential diagnosis differs in patients of different ages; in women, additional differential diagnoses are diseases of the female genital tract (***Table 76.1***).

Children

The diseases most commonly mistaken for acute appendicitis are **acute gastroenteritis** and **mesenteric lymphadenitis**. In mesenteric lymphadenitis, the pain is colicky in nature and cervical lymph nodes may be enlarged. It may be impossible to clinically distinguish **Meckel's diverticulitis** from acute appendicitis. The pain is similar; however, signs may be central or left sided. Occasionally, there is a history of antecedent abdominal pain or intermittent lower gastrointestinal bleeding.

It is important to distinguish between acute appendicitis and **intussusception**. Appendicitis is uncommon before the age of 2 years, whereas the median age for intussusception is 18 months. A mass may be palpable in the right lower quadrant, and the preferred treatment of intussusception is reduction by careful barium enema.

Henoch–Schönlein purpura is often preceded by a sore throat or respiratory infection. Abdominal pain can be severe and can be confused with intussusception or appendicitis. There is nearly always an ecchymotic rash, typically affecting the extensor surfaces of the limbs and on the buttocks. The face is usually spared. The platelet count and bleeding time are within normal limits. Microscopic haematuria is common.

Lobar pneumonia and pleurisy, especially at the right base, may give rise to right-sided abdominal pain and mimic appendicitis. Abdominal tenderness is minimal, pyrexia is marked and chest examination may reveal a pleural friction rub or altered breath sounds on auscultation. A chest radiograph is diagnostic.

Adults

Terminal ileitis in its acute form may be clinically indistinguishable from acute appendicitis unless a doughy mass of inflamed ileum can be felt. An antecedent history of abdominal cramping, weight loss and diarrhoea suggests regional ileitis rather than appendicitis. The ileitis may be non-specific, due to Crohn's disease (***Figure 76.7***) or *Yersinia* infection. *Yersinia enterocolitica* causes inflammation of the terminal ileum, appendix and caecum with mesenteric adenopathy. If suspected, serum antibody titres are diagnostic, and treatment with intravenous tetracycline is appropriate. If *Yersinia* infection is suspected at operation, a mesenteric lymph node should be excised and divided, with half submitted for microbiological culture (including tuberculosis) and half for histological examination.

Ureteric colic does not commonly cause diagnostic difficulty, as the character and radiation of pain differs from that of appendicitis. Urinalysis should always be performed, and the presence of red cells should prompt a supine abdominal radiograph. A renal ultrasound or urogram will provide the diagnosis.

Right-sided acute **pyelonephritis** is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are tenderness confined to the loin, fever (temperature 39°C) and possibly rigors and pyuria.

In **perforated peptic ulcer**, the duodenal contents pass along the paracolic gutter to the right iliac fossa. As a rule there is a history of dyspepsia and a very sudden onset of pain that starts in the epigastrium and passes down the right paracolic gutter. In appendicitis, the pain starts classically in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions but, in perforated duodenal ulcer, the rigidity is usually greater in the right hypochondrium.

Johann Friedrich Meckel (the younger), 1781–1883, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.
Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, described this form of purpura in 1837.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA.
Alexandre Emile Yersin, 1863–1943, bacteriologist, Paris, France.

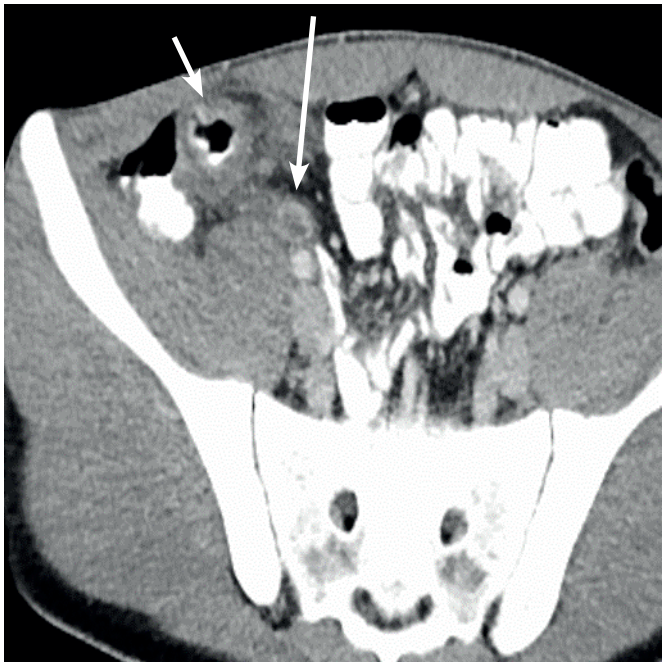

Figure 76.7 First presentation in a 19-year-old man with terminal ileitis, later confirmed to be Crohn's disease. Short arrow demonstrates abnormally thickened and inflamed terminal ileum. Long arrow indicates wall enhancement and enlargement of the appendix, indicating secondary acute appendicitis (courtesy of Professor P MacMahon, FRCR, Dublin, Ireland).

An erect chest radiograph will show gas under the diaphragm in 70% of patients. An abdominal computed tomography (CT) examination is valuable when there is diagnostic difficulty. **Testicular torsion** in a teenage or young adult male is easily missed. Pain can be referred to the right iliac fossa, and shyness on the part of the patient may lead the unwary to suspect appendicitis unless the scrotum is examined in all cases.

Acute pancreatitis should be considered in the differential diagnosis of all adults suspected of having acute appendicitis and, when appropriate, should be excluded by serum or urinary amylase measurement.

Rectus sheath haematoma is a relatively rare but easily missed differential diagnosis. It usually presents with acute pain and localised tenderness in the right iliac fossa, often after an episode of strenuous physical exercise. Localised pain without gastrointestinal upset is the rule. Occasionally, in an elderly patient, particularly one taking anticoagulant therapy, a rectus sheath haematoma may present as a mass and tenderness in the right iliac fossa after minor trauma.

Pelvic inflammatory disease comprises a spectrum of diseases that include salpingitis, endometritis and tuboovarian sepsis. The incidence of these conditions is increasing, and the diagnosis should be considered in every young adult female. Typically, the pain is lower than in appendicitis and is bilateral. A history of vaginal discharge, dysmenorrhoea and burning pain on micturition is a helpful differential diagnostic point. The physical findings include adnexal and cervical tenderness on vaginal examination. When suspected, a high vaginal swab should be taken for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* culture, and the opinion of a gynaecologist should be obtained (see ***Chapter 87***).

Midcycle rupture of a follicular cyst with bleeding produces lower abdominal and pelvic pain, typically midcycle, which is characteristic of **mittelschmerz**. Systemic upset is rare, a pregnancy test is negative and symptoms usually subside within hours. Occasionally, diagnostic laparoscopy is required. Retrograde menstruation may cause similar symptoms.

Torsion or haemorrhage of an ovarian cyst can prove a difficult differential diagnosis. When suspected, pelvic ultrasound and a gynaecological opinion should be sought.

It is unlikely that a ruptured **ectopic pregnancy**, with its well-defined signs of haemoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion or, still more, for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis except that the pain commences on the right side and stays there. The pain is severe and continues unabated until operation. Usually, there is a history of a missed menstrual period, and a urinary pregnancy test may be positive. Severe pain is felt when the cervix is moved on vaginal examination. Signs of intraperitoneal bleeding usually become apparent and the patient should be questioned specifically regarding referred pain in the shoulder. Pelvic ultrasonography should be carried out in all cases in which an ectopic pregnancy is a possible diagnosis.

In some patients with a long sigmoid loop, the colon lies to the right of the midline and it may be impossible to differentiate between **diverticulitis** and appendicitis. Abdominal CT scanning is particularly useful in this setting and should be considered in the management of all patients over the age of 60 years. Right-sided diverticulitis is more common in Asia and may be clinically indistinguishable from appendicitis. Abdominal CT scanning is particularly useful in making the distinction. As with left-sided diverticulitis, treatment should be conservative with intravenous antibiotics with recourse to laparoscopy or laparotomy in the face of clinical deterioration.

The diagnosis of **intestinal obstruction** is usually clear; the subtlety lies in recognising acute appendicitis as the occasional cause in the elderly. An abdominal CT scan will clarify the diagnosis.

When obstructed or locally perforated, **carcinoma of the caecum** may mimic or cause obstructive appendicitis in adults. A history of antecedent discomfort, altered bowel habit or unexplained anaemia should raise suspicion. A mass may be palpable and an abdominal CT scan diagnostic.

Rare differential diagnoses

Preherpetic pain of the right 10th and 11th dorsal nerves is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperaesthesia. There is no intestinal upset or rigidity. The herpetic eruption may be delayed for 3–8 hours.

Spinal conditions are sometimes associated with acute abdominal pain, especially in children and the elderly. These may include tuberculosis of the spine, metastatic carcinoma, osteoporotic vertebral collapse and multiple myeloma. The pain is due to compression of nerve roots and may be aggravated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent.

The abdominal crises of porphyria and diabetes mellitus need to be remembered. A urinalysis should be undertaken in every abdominal emergency. In cyclical vomiting of infants or young children, there is a history of previous similar attacks and abdominal rigidity is absent. Acetone is found in the urine but is not diagnostic as it may accompany starvation.

Typhlitis or leukaemic ileocaecal syndrome is a rare but potentially fatal enterocolitis occurring in immunosuppressed patients. Gram-negative or clostridial (especially *Clostridium septicum*) septicaemia can be rapidly progressive. Treatment is with appropriate antibiotics and haematopoietic factors. Surgical intervention is rarely indicated.

Investigation

The diagnosis of acute appendicitis is essentially clinical; however, a decision to operate based on clinical suspicion alone can lead to the removal of a normal appendix in 15–30% of cases. The premise that it is better to remove a normal appendix than to delay diagnosis does not stand up to close scrutiny, particularly in the elderly. A number of clinical and laboratory-based scoring systems have been devised to assist diagnosis. The most widely used is the Alvarado score (***Table 76.2***). A score of 7 or more is strongly predictive of acute appendicitis.

In patients with an equivocal score (5 or 6), abdominal ultrasonography or contrast-enhanced CT examination further reduces the rate of negative appendicectomy. Abdominal ultrasonography is more useful in children and thin adults, particularly if gynaecological pathology is suspected, with a diagnostic accuracy in excess of 90% (***Figure 76.8***). Modern CT is both sensitive and specific (approximately 95%) in the diagnosis of acute appendicitis (***Figure 76.9***) and worldwide there has been a steady increase in its use for this purpose. CT has been shown to reduce the rate of negative appendicectomy without an associated increased perforation rate (due to delay in diagnosis) and may be cost-effective as a result of shorter hospital stay. While the diagnostic accuracy of modern CT scanning for appendicitis is well established, radiation exposure and the theoretical carcinogenic effect are a concern. Low-dose protocols, which reduce the radiation dose to the patient by up to 80%, can be as reliable as standard dose scanning and may be more appropriately applied when considering a diagnosis of acute appendicitis, particularly in the younger adult.

Contrast-enhanced standard dose CT is especially useful in patients in whom there is diagnostic uncertainty, particularly older patients, where acute diverticulitis, intestinal obstruction and neoplasm are likely differential diagnoses.

Treatment

Non-operative management

There are two scenarios in which patients with acute appendicitis may be considered for non-operative treatment.

Uncomplicated appendicitis

While surgery remains the standard teaching, there is evidence to support a trial of conservative management in patients

Summary box 76.5

Preoperative investigations in appendicitis

- Routine
  - Full blood count
  - Urinalysis
- Selective
  - Pregnancy test
  - Urea and electrolytes
  - C-reactive protein
  - Supine abdominal radiograph
  - Ultrasound of the abdomen/pelvis
  - Contrast-enhanced abdomen and pelvic CT scan (consider low-dose protocol in young adults)

Arrow indicates a small pocket of free fluid more inferiorly in the RIF (courtesy of Dr D Byrne, Dublin, Ireland).

Alfredo Alvarado, contemporary, surgeon, Plantation, FL, USA.

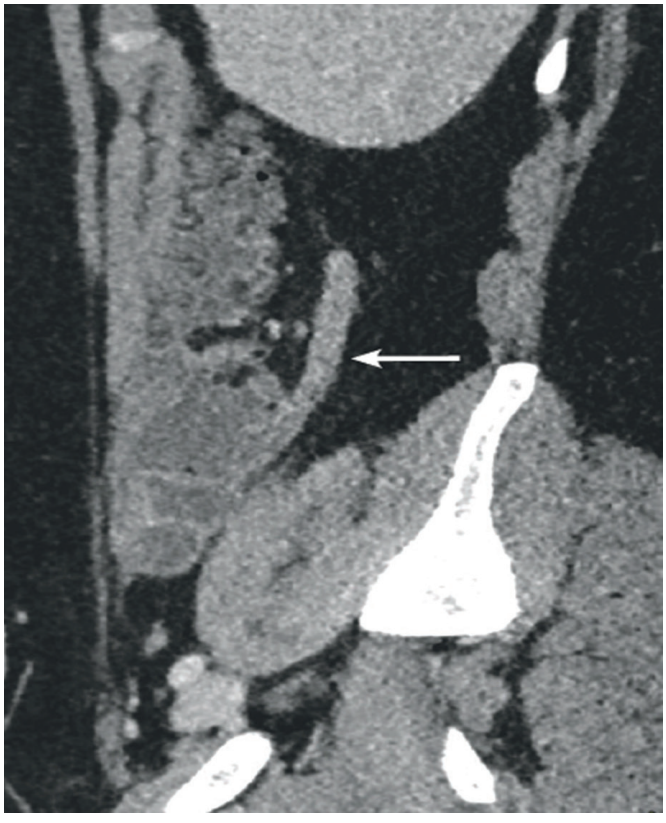

Figure 76.9 Sagittal reformat of a computed tomography scan of the abdomen obtained with oral and intravenous contrast, demonstrating an enlarged (10 mm), enhancing retrocaecal appendix with periappendiceal fat stranding. There is no evidence of necrosis, perforation or collection. No radiopaque appendicolith can be seen. **Figure 76.6** refers to the same patient (courtesy of Professor P MacMahon, FRCR, Dublin, Ireland).

with uncomplicated (absence of appendicolith, perforation or abscess) appendicitis. Treatment is bowel rest and intravenous antibiotics, often metronidazole and a third-generation cephalosporin. The available data indicate initial successful outcomes in approximately 85% of patients; however, between one-quarter and one-third of patients initially treated conservatively will require surgery within 1 year for recurrent symptoms. Subsequent surgery, if needed, tends to be uncomplicated and the overall postoperative complication rate is similar when patients treated conservatively and later needing surgery are compared with those undergoing surgery at the outset. Overall hospital length of stay is also similar when comparing patients in each group. Thus, antibiotic treatment of acute uncomplicated appendicitis appears to be safe and it allows a large number of patients to avoid invasive treatment; however, this information must be balanced by the high treatment failure rate and need for interval intervention.

Conservative treatment may be considered in the well patient with limited signs or those with high operative risk (multiple comorbidities); the patients must be aware of the high failure rate. As with conservative treatment of an appendix mass, patients over the age of 40 should be followed up to ensure that there is no underlying malignancy (see ***Neoplasms of the appendix and pseudomyxoma peritonei***).

In children, conservative treatment of uncomplicated appendicitis also appears to be safe in the short term with resolution of acute symptoms in approximately 90% of patients. Re-presentation with complicated appendicitis appears to be very rare; however, recurrent symptoms requiring surgery have been reported in up to 46% of patients. Notably, histological features of acute appendicitis may be present in only one-fifth of patients needing interval surgery.

Appendix mass

If an appendix mass is present and the condition of the patient is satisfactory, the standard treatment is the conservative Ochsner–Sherren regime. This strategy is based on the premise that the inflammatory process is already localised and that inadvertent surgery is difficult and may be dangerous. It may be impossible to find the appendix and, occasionally, a faecal fistula may form. For these reasons, it is wise to observe a non-operative programme but to be prepared to operate should clinical deterioration occur.

Summary box 76.6

Criteria for stopping conservative treatment of an appendix mass

- A rising pulse rate
- Increasing or spreading abdominal pain
- Increasing size of the mass

Careful recording of the patient's condition and the extent of the mass should be made and the abdomen regularly re-examined. It is helpful to mark the limits of the mass on the abdominal wall using a skin pencil. A contrast-enhanced CT examination of the abdomen should be performed and antibiotic therapy instigated. An abscess, if present, should be drained radiologically. Temperature and pulse rate should be recorded 4-hourly and a fluid balance record maintained. Clinical deterioration or evidence of peritonitis is an indication for early laparotomy. Clinical improvement is usually evident within 24–48 hours. Failure of the mass to resolve should raise suspicion of a carcinoma or Crohn's disease. Using this regime, approximately 90% of cases resolve without incident.

The need for interval appendicectomy in this cohort is much debated. The majority of patients will not develop recurrent appendicitis; however, recently published studies have identified higher than expected rates of underlying appendiceal neoplasm in those patients who do go on to interval appendicectomy, particularly those patients over the age of 40. A recent randomised clinical trial was terminated early owing to the unexpected finding of appendiceal tumour during follow-up in 29% (12/41) of patients aged more than 40 years who initially presented with periappendicular abscess. Low-grade appendiceal mucinous neoplasms (LAMNs)

Albert John Ochsner, 1858–1925, Professor of Clinical Surgery, The University of Illinois College of Medicine, Chicago, IL, USA.
James Sherren, 1876–1945, surgeon, The London Hospital, London, UK.

accounted for 42% of the unexpected tumours. This rate of incidental appendix tumour in patients presenting with abscess appears to be much higher than in the general population undergoing appendicectomy, suggesting a different pathogenesis in the former group. Careful consideration should be given to interval appendicectomy in this cohort of patients. At the very least, follow-up CT or magnetic resonance imaging (MRI) should be performed to ensure complete resolution of findings and patients should undergo colonoscopy.

Operative management

General principles

The traditional treatment for acute appendicitis is appendicectomy. While there should be no unnecessary delay, all patients, particularly those most at risk of serious morbidity, benefit by a short period of intensive preoperative preparation. Intravenous fluids, sufficient to establish adequate urine output (catheterisation is needed only in the very ill), and appropriate antibiotics should be given. Risk factors for venous thromboembolism should be considered and appropriate prophylaxis (mechanical and/or pharmacological) initiated. There is evidence that, in the absence of purulent peritonitis, a single perioperative dose of antibiotics reduces the incidence of postoperative wound infection. When peritonitis is suspected, therapeutic intravenous antibiotics to cover Gram-negative bacilli as well as anaerobic cocci should be given. Hyperpyrexia in children should be treated with salicylates in addition to antibiotics and intravenous fluids. With appropriate use of intravenous fluids and parenteral antibiotics, a policy of deferring appendicectomy after midnight to the first case on the following morning does not increase morbidity. However, when acute obstructive appendicitis is recognised, operation should not be deferred longer than it takes to optimise the patient's condition.

Appendicectomy should be performed under general anaesthetic with the patient supine on the operating table and may be undertaken using either an open or laparoscopic approach. When the appropriate equipment and expertise are available and cost allows, the laparoscopic approach is advantageous. The initial laparoscopy allows the diagnosis to be established and may reduce the negative appendicectomy rate. Furthermore, the patient may benefit from the quicker recovery afforded by a minimally invasive approach, the rate of wound infection is lower (when compared with open surgery) and, contrary to initial concerns, the incidence of postoperative pelvic collection does not appear to be increased.

When a laparoscopic technique is used, the bladder must be empty (ensure that the patient has voided before leaving the ward). Prior to preparing the entire abdomen with an appropriate antiseptic solution, the right iliac fossa should be palpated for a mass. If a mass is felt, it may, on occasion, be preferable to adopt a conservative approach. Draping of the abdomen is in accordance with the planned operative technique, taking account of any requirement to extend the incision or convert a laparoscopic technique to an open operation.

Surgical technique: conventional appendicectomy

When the preoperative diagnosis is considered reasonably certain, the incision that is widely used for appendicectomy is the so-called gridiron incision. The gridiron incision (described first by McArthur) is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its centre being along the line at McBurney's point (***Figure 76.10***). If better access is required, it is possible to convert the gridiron to a Rutherford Morison incision (see below) by cutting the internal oblique and transversus muscles in the line of the incision.

In recent years, a transverse skin crease (Lanz) incision has become more popular, as the exposure is better and extension,

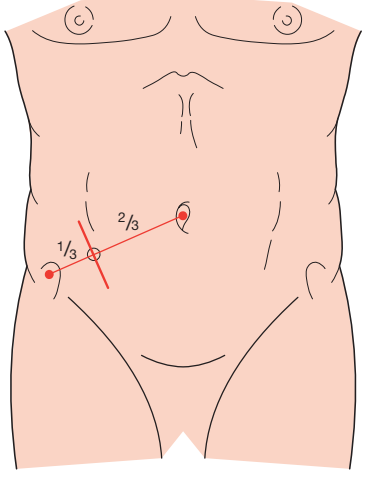

Figure 76.10 Gridiron incision for appendicitis, at right angles to a line joining the anterior superior iliac spine and umbilicus, centred on McBurney's point (courtesy of Professor M Earley, FRCSI, Dublin, Ireland).

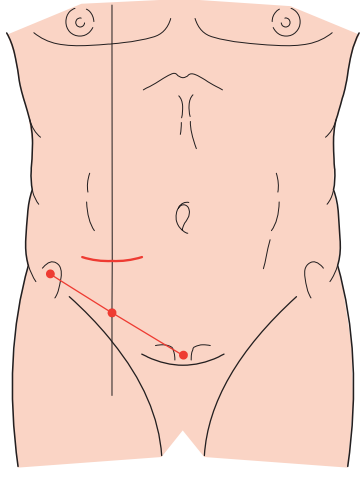

Figure 76.11 Transverse or skin crease (Lanz) incision for appendicitis, 2 cm below the umbilicus, centred on the midclavicular–midinguinal line (courtesy of Professor M Earley, FRSCI, Dublin, Ireland).

Gridiron, a frame of crossbeams to support a ship during repairs.
Lewis Linn McArthur, 1858–1934, surgeon, St. Luke's Hospital, Chicago, IL, USA.
James Rutherford Morison, 1853–1939, Professor of Surgery, Durham University, Durham, UK.
Otto Lanz, 1865–1935, surgeon, Amsterdam, The Netherlands.

when needed, is easier. The incision, appropriate in length to the size and obesity of the patient, is made approximately 2 cm below the umbilicus centred on the midclavicular–midinguinal line (***Figure 76.11***). When necessary, the incision may be extended medially, with retraction or suitable division of the rectus abdominis muscle.

When the diagnosis is in doubt, particularly in the presence of intestinal obstruction, a lower midline abdominal incision is to be preferred over a right lower paramedian incision. The latter, although widely practised in the past, is difficult to extend, more difficult to close and provides poorer access to the pelvis and peritoneal cavity.

Rutherford Morison's incision is useful if the appendix is para- or retrocaecal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney's point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

The caecum is identified by the presence of taeniae coli and, using a finger or a swab, the caecum is withdrawn. A turgid appendix may be felt at the base of the caecum. Inflammatory adhesions must be gently broken with a finger, which is then hooked around the appendix to deliver it into the wound. The appendix is conveniently controlled using a Babcock or Lane's forceps applied in such a way as to encircle the appendix and yet not damage it. The base of the mesoappendix is clamped in artery forceps, divided and ligated (***Figure 76.12a***). When the mesoappendix is broad, the procedure must be repeated with a second or, rarely, a third artery forceps. The appendix, now completely freed, is clamped with an artery forceps near its base and then ligated close to the junction with the caecum using an absorbable 2/0 ligature. The appendix is amputated between the artery forceps and the ligature (***Figure 76.12b***). When the appendix is retrocaecal and adherent, it may be an advantage to divide the base first. The appendiceal vessels are then ligated and gentle traction on the caecum will enable the surgeon to deliver the body of the appendix, which is then removed from base to tip. Occasionally, this manoeuvre requires division of the lateral peritoneal attachments of the caecum.

An absorbable 2/0 or 3/0 purse-string or 'Z' suture may then be inserted into the caecum about 1.25 cm from the base (***Figure 76.12c***). The stitch should pass through the muscle coat, picking up the taeniae coli. The stump of the appendix is invaginated (***Figure 76.12d***) while the purse-string or 'Z' suture is tied, thus burying the appendix stump.

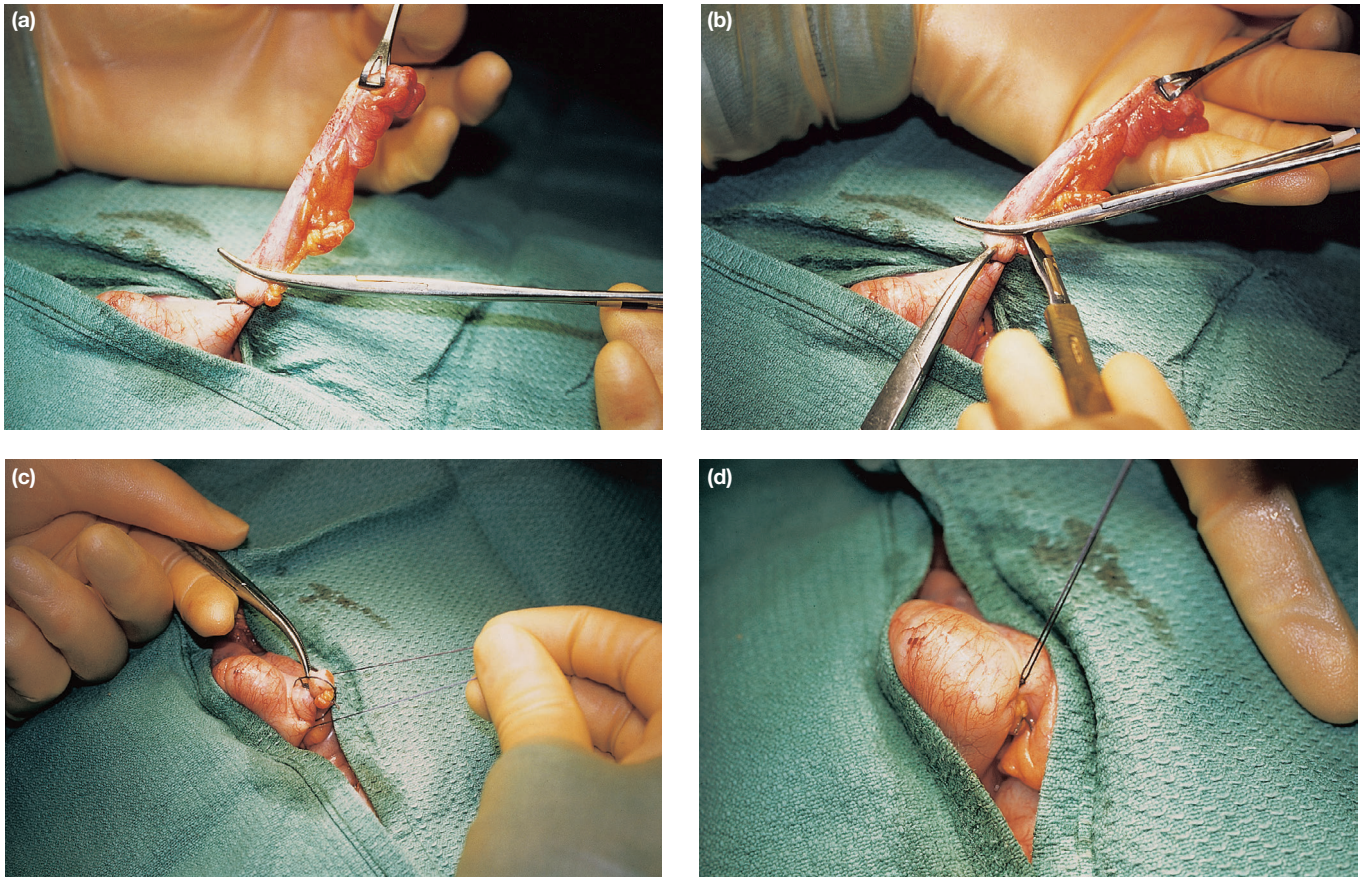

Figure 76.12 Appendicectomy. **(a)** The mesoappendix divided between artery forceps and ligated. **(b)** The appendix is ligated at its base and about to be divided. **(c)** 'Z' suture inserted prior to inversion of the appendiceal stump. **(d)** The appendiceal stump inverted, the 'Z' suture having been tied.

William Wayne Babcock, 1876–1963, surgeon, Philadelphia, PA, USA.
Sir William Arbuthnot Lane, 1856–1943, surgeon, Guy's Hospital, London, UK

When the caecal wall is oedematous, the purse-string suture is in danger of cutting out. If the oedema is of limited extent, this can be overcome by inserting the purse-string suture into more healthy caecal wall at a greater distance from the base of the appendix. Occasions may arise when, because of the extensive oedema of the caecal wall, it is better not to attempt invagination. Many surgeons believe invagination of the appendiceal stump is unnecessary.

Should the base of the appendix be gangrenous, ligation should not be attempted. Two stitches are placed through the caecal wall close to the base of the gangrenous appendix, which is amputated flush with the caecal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted seromuscular sutures. An alternative but more costly option when the appendix base is compromised is to resect the appendix with a cuff of healthy caecum using a single firing of a linear stapling device.

Surgical technique: laparoscopic appendicectomy

The most valuable aspect of laparoscopy in the management of suspected appendicitis is as a diagnostic tool, particularly in women of childbearing age. The placement of operating ports may vary according to operator preference and previous abdominal scars. Typically, a pneumoperitoneum is established using an open infraumbilical approach. This umbilical port serves as the camera port with two working ports inserted under direct vision, the first suprapubically and the second in the left lower quadrant. A moderate Trendelenburg tilt with elevation of the right side of the operating table improves exposure and assists delivery of loops of small bowel from the pelvis. The appendix is found in the conventional manner by identification of the caecal taeniae and is controlled using a laparoscopic tissue-holding forceps. Occasionally, it is necessary to divide the peritoneal attachments and mobilise the caecum in order to adequately expose the appendix. By elevating the appendix, the mesoappendix is then displayed. A dissecting forceps, hook or scissors diathermy is used to dissect the mesoappendix (***Figure 76.13a***) and expose the appendicular vessels, which may be coagulated or ligated using a clip applicator (***Figure 76.13b***). The appendix, free of its mesentery, can be ligated at its base with an absorbable loop ligature (***Figure 76.13c***) or a linear stapling device, divided (***Figure 76.13d***) and removed in a specimen bag through one of the operating ports. It is not usual to invert the stump of the appendix. Absorbable sutures are used to close the fascia at the umbilicus and at any port sites greater than 5 mm, and the small skin incisions may be closed with subcuticular sutures.

Problems encountered during appendicectomy

The finding of a normal appendix demands careful exclusion of other possible diagnoses, particularly terminal ileitis, Meckel's diverticulitis and tubal or ovarian causes in women. It is usual to remove the appendix to avoid future diagnostic difficulties, even though the appendix is macroscopically normal, particularly if a skin crease or gridiron incision has been made. A case can be made for preserving the macroscopically normal appendix seen at diagnostic laparoscopy, although approximately one-quarter of seemingly normal appendices show microscopic evidence of inflammation.

If the appendix cannot be found, the caecum should be mobilised and the taeniae coli should be traced to their confluence on the caecum before the diagnosis of 'absent appendix' is made.

If an appendix mass is found at operation, particularly at laparoscopy, it may be safer to abandon the procedure rather than risk bowel injury during attempted mobilisation. Any abscess should be drained, intravenous antibiotics administered and the patient carefully monitored during the postoperative period. Very rarely in the face of a frankly necrotic appendix, a caecectomy or partial right hemicolectomy is required.

Occasionally, a patient undergoing surgery for acute appendicitis is found to have concomitant Crohn's disease of the ileocaecal region. Providing that the caecal wall is healthy at the base of the appendix, appendicectomy can be performed without increasing the risk of an enterocutaneous fistula. Rarely, the appendix is involved with the Crohn's disease. In this situation, a conservative approach may be warranted; a trial of intravenous corticosteroids and systemic antibiotics can be used to resolve the acute inflammatory process.

Appendicitis in pregnancy

Appendicitis appears to be less common in pregnant than in non-pregnant females; however, it is the most common extrauterine acute abdominal condition in pregnancy, with an incidence of 0.5–1 per 1000 pregnancies. Appendicitis is slightly more common in the second trimester and, when compared with the non-pregnant population, presentation during pregnancy is more likely to be complicated. The diagnosis is often complicated by a delay in presentation as early non-specific symptoms are often attributed to the pregnancy. Obstetric teaching has been that the caecum and appendix are progressively pushed to the right upper quadrant of the abdomen as pregnancy develops during the second and third trimesters. However, pain in the right lower quadrant of the abdomen remains the cardinal feature of appendicitis in pregnancy.

Every attempt should be made to establish the diagnosis preoperatively as negative appendicectomy is associated with fetal loss in 4% and preterm labour in 10% of patients. Clinical diagnosis can be difficult and may be facilitated by ultrasound scanning, which carries no risk to the fetus and is highly specific; however, sensitivity in some series is low and its reliability varies according to the trimester. MRI scanning carries greater sensitivity but is more expensive and may not be widely available.

Delays in diagnosis or in the initiation of definitive treatment pose the greatest risk to the mother and pregnancy. Fetal loss occurs in 3–5% of cases of acute appendicitis in pregnancy but increases to 20% or more in the presence

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

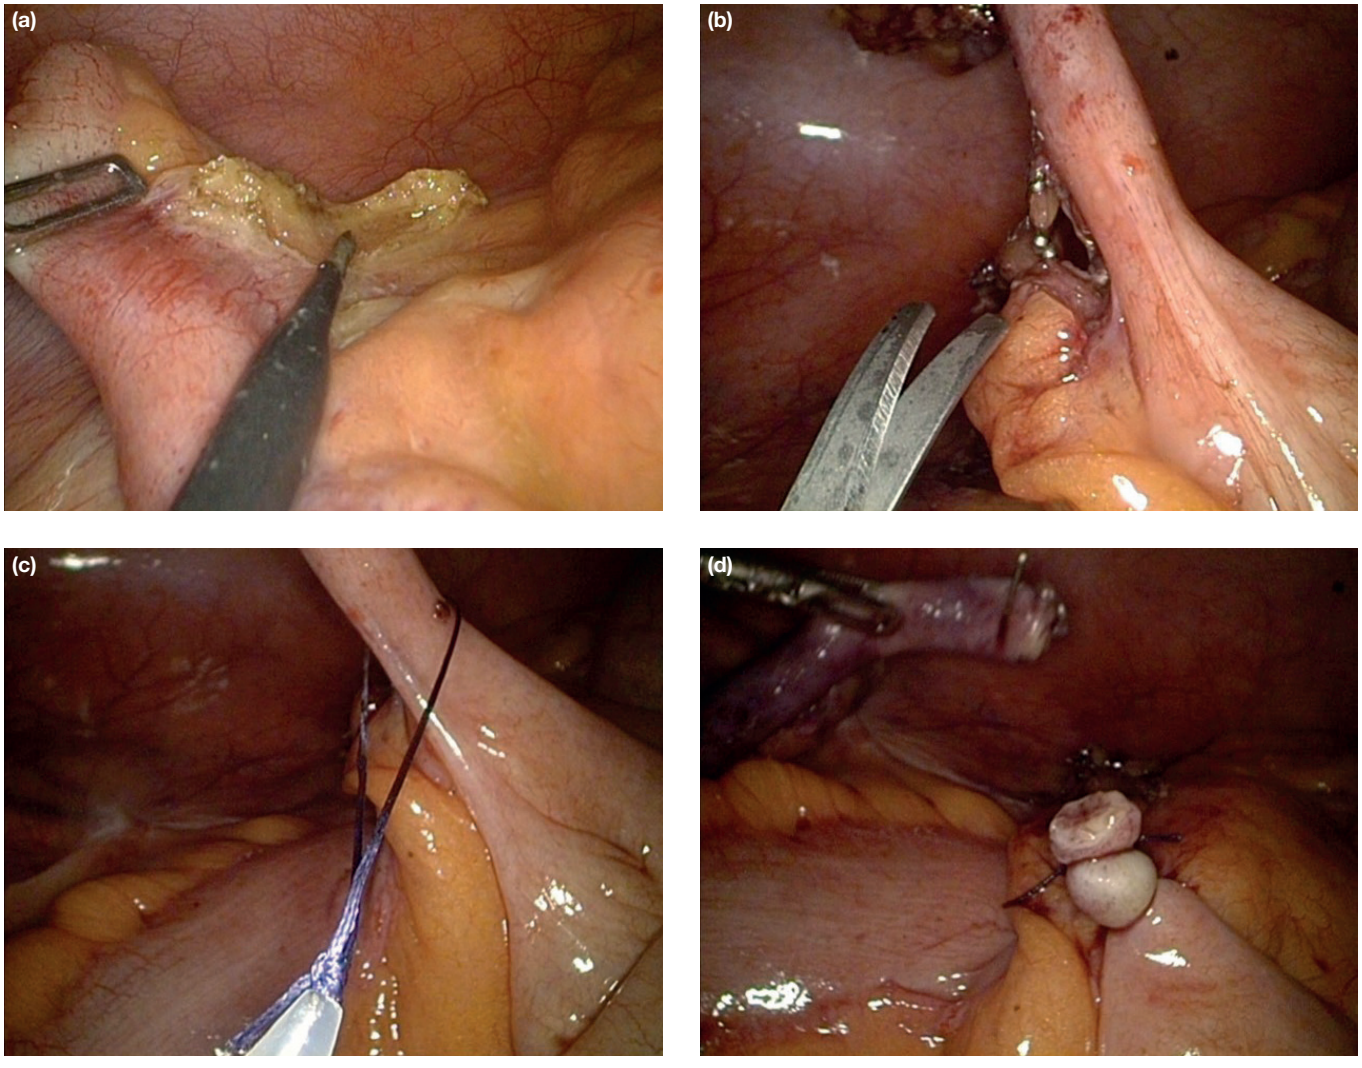

Figure 76.13 Laparoscopic appendicectomy. **(a)** Hook diathermy dissection of the mesoappendix. **(b)** The appendicular artery, ligated with clips, is divided. **(c)** The appendix base is ligated with absorbable ties. **(d)** Appendicectomy complete.

of perforation. There is insufficient evidence to support a non-operative approach and the pregnant patient with acute appendicitis should proceed to surgery. If the fetus is at a viable gestational age (23 weeks or more), appropriate obstetric and neonatal support should ideally be available. A laparoscopic approach is now considered to be safe in any trimester and, if used, should be initiated via the open Hasson technique. Data from a large series of pregnant women undergoing abdominal surgery (appendicectomy or cholecystectomy) reported a rate of obstetric complications of approximately 5%.

Postoperative complications

Postoperative complications following appendicectomy are relatively uncommon and reflect the degree of peritonitis that was present at the time of operation and intercurrent diseases that may predispose to complications.

Summary box 76.7

Checklist for unwell patients following appendicectomy

- Examine the wound and abdomen for an abscess
- Consider a pelvic abscess and perform a rectal examination
- Examine the lungs – consider pneumonitis or collapse
- Examine the legs – consider venous thrombosis
- Examine the conjunctivae for an icteric tinge and the liver for enlargement, and enquire whether the patient has had rigors (pylephlebitis)
- Examine the urine for organisms (pyelonephritis)
- Suspect subphrenic abscess

Wound infection

Wound infection is the most common postoperative complication, occurring in 5–10% of all patients. This usually presents with pain and erythema of the wound on the fourth or fifth

Harrith Hasson, 1931–2012, Professor of Gynecology, Chicago, IL, USA.

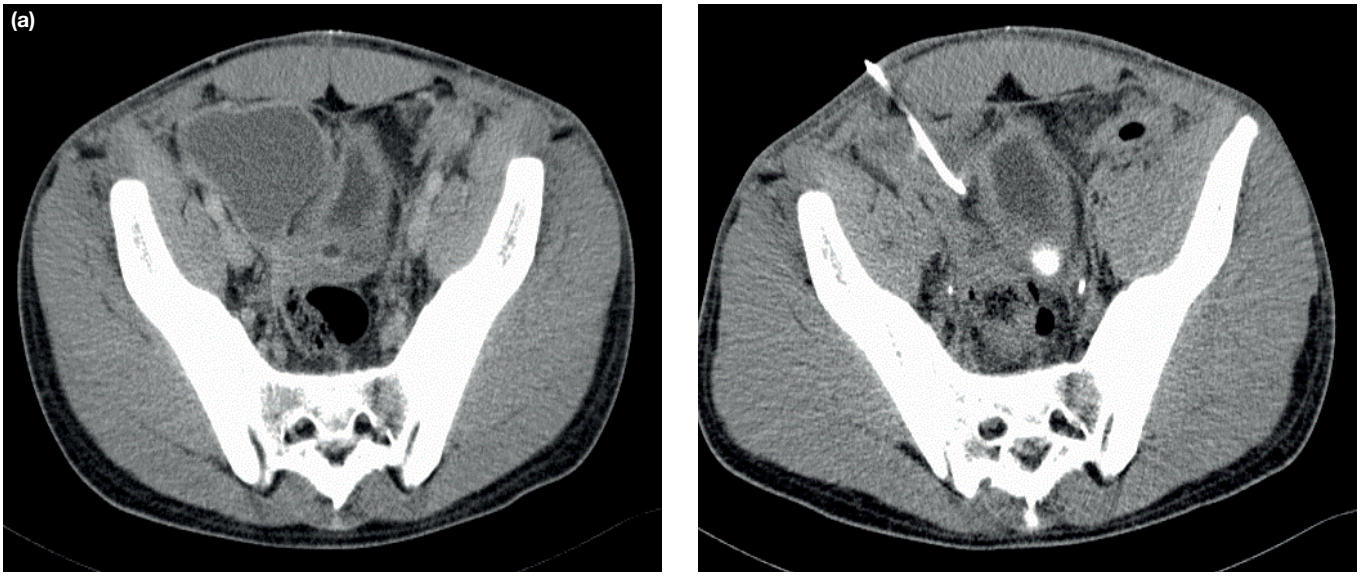

Figure 76.14 (a) Rim-enhancing collection in the right iliac fossa, 1 week after open appendicectomy for perforated appendicitis. **(b)** Successful radiological drainage with resolution of the abscess (courtesy of Professor P MacMahon, FRCR, Dublin, Ireland).

postoperative day, often soon after hospital discharge. Treatment is by wound drainage and antibiotics when required. The organisms responsible are usually a mixture of Gram-negative bacilli and anaerobic bacteria, predominantly *Bacteroides* species and anaerobic streptococci.

Intra-abdominal abscess

Approximately 8% of patients following appendicectomy will develop a postoperative intra-abdominal abscess. In an era of hospital discharge 24–48 hours following appendicectomy, patients should be advised prior to discharge that a spiking fever, malaise and anorexia developing 5–7 days after operation is suggestive of an intraperitoneal collection and that urgent medical advice should be obtained. Interloop, paracolic, pelvic and subphrenic sites should be considered. Abdominal ultrasonography and CT scanning greatly facilitate diagnosis and allow percutaneous drainage (***Figure 76.14***). Surgical exploration should be considered in patients suspected of having intra-abdominal sepsis but in whom imaging fails to show a collection, particularly those with continuing ileus.

Ileus

A period of adynamic ileus is to be expected after appendicectomy, and this may last a number of days following removal of a gangrenous appendix. Ileus persisting for more than 4 or 5 days, particularly in the presence of a fever, is indicative of continuing intra-abdominal sepsis and should prompt further investigation. Rarely, early during postoperative recovery, a Richter's type of hernia may occur at the site of a laparoscopic port insertion and may be confused with a postoperative ileus. A CT scan is usually definitive.

Respiratory

In the absence of concurrent pulmonary disease, respiratory complications are rare following appendicectomy. Adequate postoperative analgesia and physiotherapy, when appropriate, reduce the incidence.

Venous thrombosis and embolism

These conditions are rare after appendicectomy. Patients should undergo preoperative assessment of risk factors for venous thromboembolism and appropriate prophylactic measures should be taken.

Portal pyaemia (pylephlebitis)

This is a rare but very serious complication of gangrenous appendicitis associated with high fever, rigors and jaundice. It is caused by septicaemia in the portal venous system and leads to the development of intrahepatic abscesses (often multiple). Treatment is with systemic antibiotics and percutaneous drainage of hepatic abscesses as appropriate.

Faecal fistula

Leakage from the appendicular stump occurs rarely, but may follow if the encircling stitch has been put in too deeply or if the caecal wall was involved by oedema or inflammation. Occasionally, a fistula may result following appendicectomy in Crohn's disease.

Adhesive intestinal obstruction

This is the most common late complication of appendicectomy. At operation, a single band adhesion is often found to be responsible. Occasionally, chronic pain in the right iliac fossa is attributed to adhesion formation after appendicectomy. In such cases, laparoscopy is of value in confirming the presence of adhesions and allowing division.

August Gottlieb Richter, 1742–1812, lecturer in surgery, Göttingen, Germany.

RECURRENT ACUTE APPENDICITIS

Rarely, inflammation of the appendix may present as a chronic condition characterised by recurrent episodes of lower abdominal pain. Recurrent appendicitis is thought to arise as a consequence of incomplete self-limiting obstruction of the appendix lumen. The attacks vary in intensity and may occur every few months, and the majority of cases ultimately culminate in severe acute appendicitis. If a careful history is taken from patients with acute appendicitis, many remember having had milder but similar attacks of pain. The appendix in these cases is thickened and shows fibrosis indicative of previous inflammation.

NEOPLASMS OF THE APPENDIX AND PSEUDOMYXOMA PERITONEI

Tumours of the appendix may occur in up to 0.97 per 100 000 of the population. NETs account for approximately 30% of appendix neoplasms while epithelial tumours account for most other cases. Epithelial tumours may show mucinous or non-mucinous features and range in the aggressiveness of their behaviour from low grade to high-grade invasive with signet ring features (***Table 76.3***). A small percentage of appendix neoplasms fall into a third category known as mesenchymal tumours and include lymphoma, neuroma, GIST, Kaposi's sarcoma and granular cell tumour of the appendix.

Most patients with appendix neoplasms are asymptomatic at diagnosis and the appendix tumour is commonly an incidental finding at appendicectomy. Perforation of a mucinous appendix tumour with dissemination of epithelial cells and mucin production leads to a condition known as pseudomyxoma peritonei (PMP) (***Figure 76.15***).

Neuroendocrine tumours of the appendix

NETs of the appendix are slightly more common in females and have an overall incidence of 0.15–0.6 per 100 000 per year. They arise in subepithelial neuroendocrine cells (***Figure 76.16***) and the majority (70%) are located in the appendix tip. The average age at presentation is 40–50 years and most patients are asymptomatic with early-stage disease typically found at appendicectomy for acute appendicitis. Uncommonly, patients may present with symptoms due to a mass or metastatic disease. Carcinoid syndrome is extremely rare. A diagnosis of NET is based on immunohistochemical staining for synaptophysin and chromogranin A and tumours are classified as grade 1–3 according to their proliferative capacity (determined by the Ki-67 index and mitotic rate).

Treatment

The treatment and prognosis of NETs of the appendix is governed by their grade, the tumour size and the extent of tumour invasion. Fully resected low-grade tumours less than 1 cm in size with minimal serosal or mesoappendix invasion are considered fully treated by appendicectomy alone and no further treatment or follow-up is required. The optimum treatment of patients with tumours 1–2 cm in size that have been fully resected is less clear as metastases may occur, albeit rarely. Current guidelines recommend a single CT or MRI of the abdomen to out rule regional or distant metastatic disease. Further surgery in the form of oncological resection of the right colon should be considered in patients with larger tumours (>2 cm), in the case of incomplete resection at appendicectomy or for higher tumour grade (2 or 3), T4 disease or vascular invasion. In these patients the risk of regional lymph node involvement is increased; however, the potential benefit of further surgery must be weighed against the increased operative risk. No further follow-up is required when the completion hemicolectomy shows no evidence of residual disease. The presence of nodal disease or high-grade tumour mandates subsequent follow-up, typically with CT or

MRI at 6 and 12 months and then annually. For patients with early-stage NET the prognosis is excellent with 5-year survival of close to 100%. For those with advanced disease or distant metastases 5-year survival is typically less than 25%.

Goblet cell carcinoma

Goblet cell carcinomas (GCCs) of the appendix are a rare variant, accounting for less than 5% of appendix tumours. They display both neuroendocrine and glandular differentiation and are not considered true NETs. They may be classified as typical GCC or adenocarcinoma ex-GCC (Tang classification), with the latter group carrying a worse prognosis. GCCs display higher grade features than typical NETs and have a greater propensity for nodal and peritoneal dissemination; they should be treated in a similar fashion to appendix adenocarcinoma.

Epithelial tumours of the appendix

Epithelial neoplasms are found in 0.6% of appendicectomy specimens. Numerous classification systems have been proposed, leading to much confusion and difficulty when comparing treatment modalities and outcomes. Following a modified Delphi consultation process, a group of international experts proposed an updated classification system for appendiceal epithelial neoplasms. Tumours may be classified as mucinous or non-mucinous (intestinal type) and according to the degree of cytological atypia and architectural features (infiltrative versus pushing invasion) (***Table 76.3***).

Low-grade neoplasms

Most epithelial tumours of the appendix are classified as LAMNs. These lesions demonstrate minimal cytological atypia and are characterised by pushing rather than infiltrative invasion without evidence of destruction. In the case of appendix perforation, mucin may be found outside the appendix, the significance of which is increased when accompanied by the presence of epithelial cells. Low-grade tumours do not typically metastasise to regional lymph nodes and as such right hemicolectomy is not required. The importance of these lesions lies in their propensity to disseminate throughout the peritoneal cavity, causing the syndrome known as PMP. Patients with low-grade epithelial neoplasms and no evidence of mucin or epithelial cells beyond the appendix are thought to be at low risk of future PMP development. A colonoscopy should be performed to exclude associated colonic epithelial lesions and patients entered into a surveillance protocol for at least 5 years. Surveillance may take the form of clinical review, annual low-dose abdominopelvic CT scan and monitoring of appendix-related tumour markers (carcinoembryonic antigen [CEA], CA-19-9, CA-125). In patients with perforated tumours, particularly when extraluminal mucin contains epithelial cells, the risk of PMP is higher. In some experienced centres these patients may be considered for cytoreductive surgery with hyperthermic intraperitoneal chemotherapy (HIPEC), although a common approach is regular monitoring for the appearance of clinical or radiological features of PMP, which would then warrant surgery.

High-grade and invasive neoplasms

Appendiceal mucinous tumours displaying high-grade dysplasia are classified as high-grade appendiceal mucinous neoplasm (HAMN). Mucinous tumours with infiltrative invasion are classified as mucinous adenocarcinoma and may be well, moderately or poorly differentiated with or without the

presence of signet ring cells. Non-mucinous adenocarcinoma is considered to be similar to typical colorectal cancer.

Patients with high-grade tumour or invasive adenocarcinoma are at risk of lymph node involvement. According to current paradigms, they should undergo right hemicolectomy. Because of the risk of peritoneal metastases, cytoreductive surgery (CRS), to include right hemicolectomy with regional (right parietal) peritonectomy, omentectomy and HIPEC, may also be appropriate when the necessary expertise and experience are available. Consideration may also be given to performing bilateral salpingo-oophorectomy because of the risk of tumour seeding to the ovaries, although in patients of childbearing age the decision making is complex.

Pseudomyxoma peritonei

PMP is a rare condition typified by progressive peritoneal tumour deposits, mucinous ascites, omental cake (***Figure 76.17***) and ovarian involvement in females. The vast majority of cases arise as a result of perforation of a mucinous appendiceal tumour. Patients typically present with progressive and massive abdominal distension, anorexia and symptoms of bowel dysfunction. The condition is invariably fatal without intervention. Traditionally, PMP was thought to have an incidence of 1 per 1 000 000 per year, but it is now thought to be at least double that with recent estimates of 3.2 cases per 1 000 000 per year. The overall risk of developing pseudomyxoma following removal of an appendix harbouring epithelial tumour is approximately 9%, with the risk varying according to the tumour subtype and the mode of presentation, while it may be as high as 30–50% in the case of a mucinous adenocarcinoma of the appendix (***Figure 76.18***).

PMP is classified according to the degree of cytological atypia within the peritoneal deposits (***Table 76.4***) and its grading may differ from that of the causative primary appendiceal tumour. Elevated tumour markers (CEA, CA-125, CA-19-9)

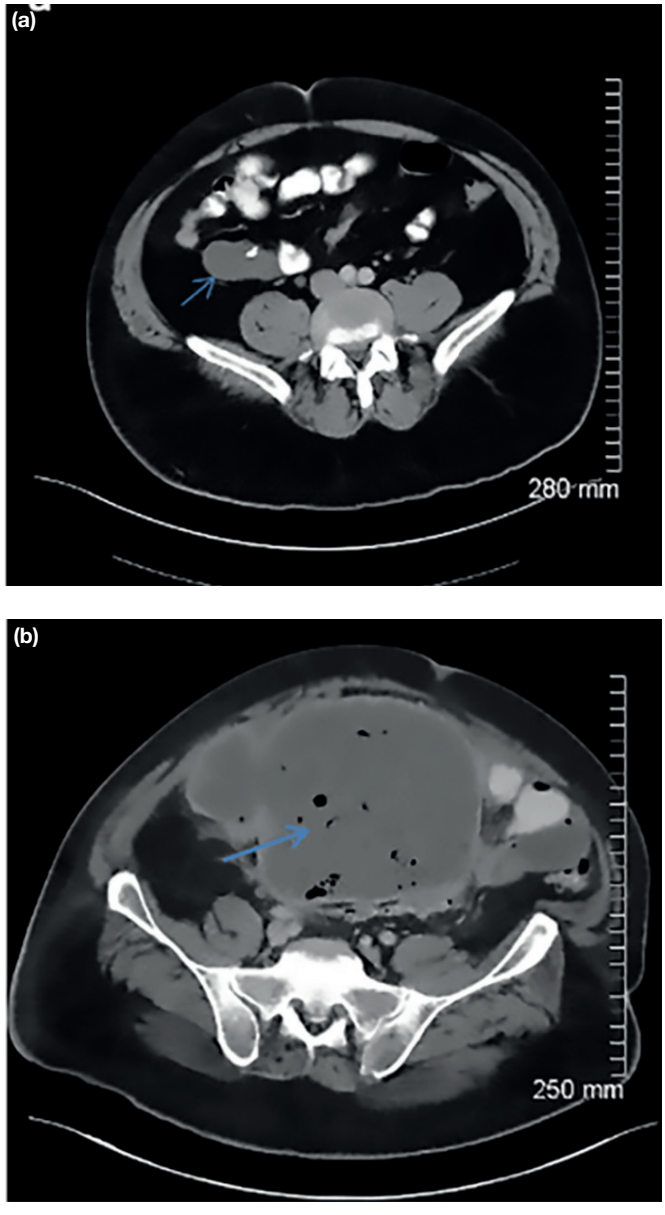

Figure 76.18 (a) Contrast-enhanced axial computed tomography (CT) image demonstrates a tubular cystic structure with calcification adjacent to the caecum compatible with an abnormally distended appendix (arrow). **(b)** Six-year follow-up postcontrast axial CT image demonstrated a 19 × 10 × 17 cm complex cystic mass in the right lower quadrant (arrow) highly suspicious for a mucinous tumour of the appendix with extensive peritoneal involvement and pseudomyxoma peritonei (courtesy of Professor Helen Fenlon, Dublin, Ireland).

predict a more aggressive phenotype and are associated with a worse prognosis.

Investigations

The investigation of a patient with PMP should include a high-resolution CT scan of the abdomen and pelvis with oral and intravenous contrast. A full colonoscopy should be performed to exclude a primary colorectal cancer. Laparoscopy may provide additional staging information by allowing direct visualisation of the small bowel where radiologically occult miliary disease may be found. Ideally laparoscopy should be performed at a centre where subsequent CRS would be undertaken. Laparoscopy also facilitates tissue diagnosis, although this is not always necessary. In experienced centres the clinical and radiological features are often sufficient to establish a diagnosis of PMP.

Treatment

Patients with PMP should be referred to a specialist centre with multidisciplinary expertise in the assessment and management of patients with peritoneal malignancy.

The accepted treatment is CRS combined with HIPEC (Sugarbaker). This approach combines multiple peritonectomy procedures with multivisceral resections as required to achieve a complete surgical clearance of the tumour (complete cytoreduction), which is augmented by HIPEC (typically mitomycin C or oxaliplatin) to eradicate presumed residual microscopic disease (***Figure 76.19***). The combined operation can take in excess of 10 hours and may require total abdominopelvic peritonectomy, greater and lesser omentectomy, bilateral salpingo-oophorectomy, hysterectomy, cholecystectomy, splenectomy, partial gastrectomy, colectomy and anterior resection of the rectum. The largest reported series of CRS/HIPEC for PMP comes from Basingstoke, UK (Moran). In their experience involving more than 1000 patients, a complete cytoreduction was achieved in approximately 75% of patients, with the remainder undergoing maximal tumour debulking. Although a potentially morbid procedure, in experienced centres the operative mortality rate following CRS/HIPEC is less than 2% with major postoperative morbidity in 15% of patients. Appropriate patient selection is critical and patients must have a sufficient performance status and be without major comorbidity in order to withstand the surgery. Preoperative evaluation, including nutritional assessment and optimisation, is paramount.

Following a complete cytoreduction 5- and 10-year survival rates of 87% and 70%, respectively, can be achieved. Poorer outcomes are seen in males, patients with elevated tumour markers and following resection of tumour showing high-grade or invasive features. Follow-up typically comprises at least annual clinical evaluation, monitoring of tumour markers and CT scan. Surveillance should be continued for at least 10 years as late recurrence is documented.

Systemic chemotherapy may be considered as first-line treatment in patients with high-grade or invasive unresectable disease or in the adjuvant setting following CRS/HIPEC, again in patients with high-grade tumour. Chemotherapy is not typically considered in patients with low-grade PMP.

Management of an incidental or unexpected tumour of the appendix

Incidental neoplasm in appendicectomy specimen

In a patient with an incidental finding of an appendix neoplasm and no current evidence of metastatic disease or PMP, subsequent treatment is dependent on the degree of cytological atypia within the primary tumour, the estimated risk of lymph node metastases and the future risk of developing PMP. In general, small low-grade tumours require surveillance only, whereas patients with larger tumour or adverse features may need further surgery.

Unexpected appendix tumour encountered at surgery

An inspection of the abdominal cavity should be performed to establish the presence of metastases or PMP. The appendix should be removed, with care taken to avoid spillage of its contents, to allow a pathological diagnosis, which will determine the need for subsequent intervention. In most cases the tumour can be removed by appendicectomy alone, with or without a cuff of caecum.

Paul H Sugarbaker, contemporary, surgeon, Washington DC, USA.
Brendan J Moran, contemporary, surgeon, Basingstoke, UK.

Incidental finding of pseudomyxoma peritonei encountered at surgery

The surgeon should perform a careful inspection of the abdominal cavity and record the extent and distribution of disease. A peritoneal or omental biopsy can be performed; however, care should be taken to minimise disruption of the anatomical planes. If the appendix is abnormal, an appendicectomy should be performed to allow a histological diagnosis. Ideally the planned procedure should then be aborted with a view to referring the patient to a centre experienced in the management of peritoneal malignancy.

PART 11 | Abdominal

CHAPTER 77

The large intestine

Learning objectives

To appreciate:
- The basic anatomy and physiology of the large intestine
- The range of conditions that may affect the large intestine

To understand:
- The aetiology and pathology of common large intestinal conditions
- The principles of investigation of large intestinal symptoms
- The importance of non-surgical management of large intestinal problems
- The principles of colonic surgery
- That complex intestinal problems are best managed by a multidisciplinary team
- The management of acute surgical problems of the large intestine

ANATOMY OF THE LARGE INTESTINE

The large intestine begins at the ileocaecal valve and extends to the anus. It is divided into the caecum, ascending colon, hepatic flexure, transverse colon with attached greater omentum, splenic flexure, descending colon, sigmoid colon and rectum. The large intestine is approximately 1.5 m long, but it can be concertinaed over an endoscope so the caecum can be reached with 70–90 cm of a colonoscope.

The external appearance of the colon is distinguished from the small bowel by the presence of taenia coli, three bands of longitudinal muscle that run from the appendix base to the rectosigmoid junction and fat-filled peritoneal tags known as appendices epiploicae found principally on the left side of the colon. The taenia coli act to pull the colon into its sacculated state, producing a series of haustrations that may be visible on abdominal radiograph and allowing distinction from distended small intestine, which has complete transverse markings caused by the valvulae conniventes (see ***Chapter 74***). The important posterior relations of the caecum and ascending colon are the right ureter, right gonadal vessels and duodenum and these must be protected at surgery. The left ureter, left gonadal vessels and tail of the pancreas must be protected when operating on the left colon.

The blood supply of the large intestine from the caecum to the distal transverse colon is derived from branches of the superior mesenteric artery and from the inferior mesenteric artery and its branches more distally. The middle colic artery is a prominent branch of the superior mesenteric artery arising soon after the origin, which divides almost immediately into two or three large arcades to supply the transverse colon. The precise vascular anatomy is variable and needs to be taken into account when performing colectomy, particularly total mesocolic excision for cancer (see ***Chapter 65***). Peripheral branches of the superior and inferior mesenteric vessels usually anastomose, resulting in a continuous vascular supply along the colon, referred to as the marginal artery of Drummond. This vessel is often the key blood supply to the vascular arcades, ensuring adequate perfusion of a colonic anastomosis; however, blood flow in the 'watershed' area of the splenic flexure representing the junction of the embryological mid- and hindgut may be tenuous. Sudden occlusion of the inferior mesenteric artery may leave the area of the splenic flexure poorly perfused, leading to an ischaemic colitis. Venous and lymphatic drainage of the colon follows the arterial supply and venous drainage is into the portal system. High ligation of the artery supplying a segment of colon will therefore also remove the lymphatic vessels and nodes, a key technical point in cancer surgery. The nerve supply to the large intestine is derived from the splanchnic nerves via sympathetic plexuses surrounding the superior (midgut) and inferior (hindgut) mesenteric arteries. Visceral pain from the part of the colon supplied by the superior mesenteric artery is thus felt, like that of the small intestine, in the periumbilical region, while pain from the colon distal to that point is felt suprapubically.

PHYSIOLOGY OF THE LARGE INTESTINE

The principal function of the colon is absorption of water; approximately 1000 mL of ileal content enters the caecum

Valvulae conniventes describes a fold of mucous membrane that passes across two-thirds of the bowel circumference.
Sir David Drummond, 1852–1932, born Dublin, Ireland, pathologist and physician at the Royal Victoria Infirmary, Newcastle (1878–1920), President of the British Medical Association (1921–1922) and vice chancellor of Durham University (1920–1922).

every 24 hours, of which only approximately 200 mL is excreted in faeces. Sodium absorption is efficiently accomplished by an active transport system, while chloride and water are absorbed passively. Fermentation of dietary fibre in the colon by the normal colonic microflora leads to the generation of short chain fatty acids, which are an important metabolic substrate for colonic mucosa. Diversion of the faecal stream, denying the mucosa of this nutrition, may lead to inflammatory changes in the colon downstream (diversion colitis). Absorption of nutrients, including glucose, fatty acids, amino acids and vitamins, can also take place in the colon.

Colonic motility is variable. In general, faecal residue reaches the caecum 4 hours after a meal and the rectum after 24 hours. Passage of stool is not orderly because of mixing within the colon (see ***Chapter 73***).

TUMOURS OF THE LARGE INTESTINE

Benign

The term 'polyp' is a clinical description of any protrusion of the mucosa. It encompasses a variety of histologically different tumours (***Table 77.1***). Polyps can occur singly, synchronously in small numbers or as part of a polyposis syndrome.

Metaplastic polyps

Metaplastic or hyperplastic polyps are common and are generally considered benign. Recently certain subtypes have been recognised to have malignant potential. Sessile serrated lesions and hyperplastic polyps ≥10 mm in diameter are associated with *KRAS*/*BRAF* mutation that may lead to methylation of tumour-suppressing genes, dysplasia and malignancy along what is termed the 'serrated pathway'. Such polyps should be removed and follow-up colonoscopy arranged (***Figure 77.1***).

TABLE 77.1 Classification of intestinal polyps.

Inflammatory	Inflammatory polyps (pseudopolyps in ulcerative colitis) (see ***Chapter 75***)

	Juvenile polyp
Serrated polyps (serrated lesions)	Hyperplastic polyp
	Sessile serrated lesion
	Sessile serrated lesion with dysplasia
	Traditional serrated adenomas
	Mixed polyp
Adenoma	Tubular
	Tubulovillous
	Villous
Malignant polyp	Adenocarcinoma

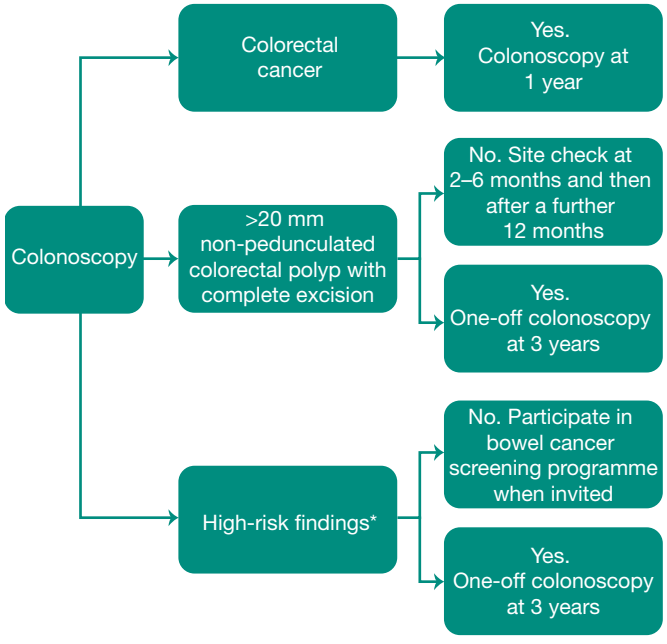

Figure 77.1 Recommendations for polyp follow-up. *Two or more premalignant polyps including at least one advanced polyp (serrated polyp >10 mm or with dysplasia, adenoma more than 10 mm in size or with high-grade dysplasia); or five or more premalignant polyps. (Adapted from Rutter MD, East J, Rees CJ *et al*. British Society of Gastroenterology/Association of Coloproctology of Great Britain and Ireland/Public Health England post-polypectomy and post-colorectal cancer resection surveillance guidelines. *Gut* 2020; **69**: 201–23.)

Adenomatous polyps

Adenomatous polyps are the most common polyps with malignant potential. The risk of malignancy is dependent on histology, morphology and size. Tubular adenomas have the lowest risk, with increasing risk as villous features predominate. Sessile and particularly depressed lesions have more malignant potential than pedunculated lesions (***Figure 77.2***). The risk of malignant change increases with size, almost one-third of large (>3 cm) colonic adenomas will have an area of invasive malignancy. Size is easily assessed endoscopically, which, alongside pit pattern and morphological classification, aids management. If felt appropriate and safe to resect endoscopically, various techniques are available, including hot or cold snare polypectomy for the most common smaller pedunculated lesions. Larger or flatter polyps may require infiltration of a solution to 'raise' the polyp before snare resection. The area of the polyp should be tattooed to facilitate later endoscopic or laparoscopic localisation of the site of the polyp. Failure of submucosal injection to elevate a polyp is suggestive of malignancy. In these circumstances, the site should be tattooed. A biopsy should not be taken if referral for endoscopic mucosal resection or endoscopic submucosal dissection is being considered. Such techniques carry a risk of colonic perforation and should only

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John's Hospital, The Hague, The Netherlands.

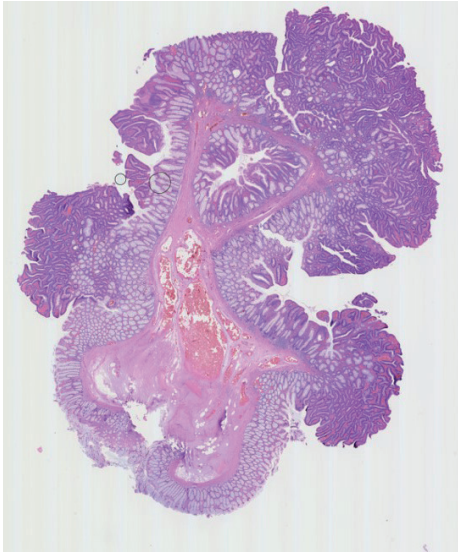

Figure 77.2 Pedunculated polyp of the large intestine showing tubulovillous changes at the apex and normal colonic mucosa at the base (courtesy of Dr Philip Kaye, Nottingham University Hospitals, Nottingham, UK).

be performed by an experienced endoscopist. Rectal adenomas may also be treated by endoscopic or transanal resection (see ***Chapter 79***).

Polyp surveillance

After successful endoscopic removal of polyps, there is a risk of further polyp development; however, the risk of subsequent development of colorectal cancer is low. The need for and frequency of follow-up surveillance endoscopy is dependent on polyp morphology, number and size, age and comorbidity of the patient, presence of a family history and accuracy and completeness of the index test. These factors allow polyps to be divided into low, intermediate and high risk. Recent guidelines (***Figure 77.1***) published by the British Society of Gastroenterology have identified patients at high risk needing follow-up colonoscopy as those with either:

- two or more premalignant polyps, including at least one advanced colorectal polyp (defined as a serrated polyp ≥10 mm in size or containing any grade of dysplasia or as an adenoma ≥10 mm in size or containing high-grade dysplasia); or
- five or more premalignant polyps.

Polyposis syndromes

Polyposis syndromes can be divided into familial adenomatous polyposis (FAP), attenuated familial adenomatous polyposis (AFAP), *MUTYH*-associated polyposis (MAP) and *NTHL1*-associated polyposis (NAP).

Familial adenomatous polyposis

FAP is defined clinically by the presence of more than 100 colorectal adenomas but is also characterised by duodenal adenomas and multiple extraintestinal manifestations (***Summary boxes 77.1 and 77.2***). Over 80% of cases come from those with a positive family history. The remainder arise as a result of new mutations in the adenomatous polyposis coli (*APC*) gene on the long arm of chromosome 5. FAP is inherited as an autosomal dominant condition and is consequently equally likely in men and women. The lifetime risk of colorectal cancer is up to 100% in those with an *APC* gene mutation. FAP can also be associated with benign mesodermal tumours such as desmoid tumours and osteomas. Epidermoid cysts can also occur (Gardner's syndrome); desmoid tumours in the abdomen spread locally to involve the intestinal mesentery and, although non-metastasising, they may become unresectable. Up to 50% of people with FAP have congenital hypertrophy of the retinal pigment epithelium (CHRPE), which can be used to screen affected families if genetic testing is unavailable.

Clinical features

Polyps are usually visible on sigmoidoscopy by the age of 15 years and will almost always be visible by the age of 30 years. Regular endoscopic surveillance in a suspected family member should therefore commence at the age of 12–14 years, even if a genetic mutation has not been identified. Patients with mutations located between codons 1286 and 1513 of the *APC* gene generally have a worse prognosis with earlier disease onset than those with mutations outside this region. Germline mutations at codon 1309 are associated with the most severe disease. AFAP, also associated with *APC* gene mutation, is associated with fewer than 100 polyps and may not present until the fourth decade.

If the diagnosis is made during adolescence, surgery is usually deferred to the age of 17 or 18 years unless symptoms develop. Malignant change is unusual before the age of 20 years. Examination of blood relatives, including cousins, nephews and nieces, is essential; a family tree should be constructed, and a register of affected families maintained. Referral to a medical geneticist is essential. If over 100 adenomas are present at colonoscopy, the diagnosis can be made confidently (***Figure 77.3***).

Summary box 77.1

Features of FAP

- Autosomal dominant inherited disease due to mutations of the *APC* gene
- More than 100 colonic adenomas are diagnostic
- Prophylactic surgery is indicated to prevent colorectal cancer
- Polyps and malignant tumours can develop particularly around the duodenal ampulla

Eldon John Gardner, 1909–1989, geneticist, The University of Utah, Salt Lake City, UT, USA, described this syndrome in 1950.

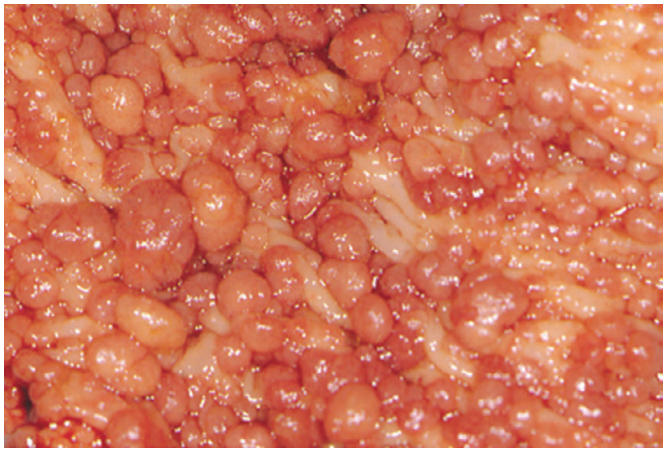

Figure 77.3 Familial adenomatous polyposis showing hundreds of adenomatous polyps.

Summary box 77.2

Extracolonic manifestations of FAP

- Endodermal derivatives
  - Adenomas and carcinomas, particularly around the duodenal ampulla but also stomach, small intestine, thyroid and biliary tree
  - Gastric fundic gland polyps
  - Hepatoblastoma
- Ectodermal derivatives
  - Epidermoid cysts
  - Pilomatrixoma
  - Congenital hypertrophy of the retinal pigment epithelium (CHRPE)
  - Brain tumours
- Mesodermal derivatives
  - Desmoid tumours
  - Osteomas
  - Dental problems

Treatment

The aim of surgery in FAP is to prevent the development of colorectal cancer. The surgical options are:

1. restorative proctocolectomy with an ileal pouch–anal anastomosis;
2. colectomy with ileorectal anastomosis (IRA);
3. total proctocolectomy and end-ileostomy.

As patients are often young, most prefer to avoid a stoma, restorative proctocolectomy with ileal pouch–anal anastomosis has the advantage of removing the whole colon and rectum without the need for a permanent stoma (see ***Chapter 75***). However, there is a pouch failure rate of approximately 10%. In addition, and particularly when a stapled anastomosis has been created, endoscopic surveillance is still required as malignant change can occur in the 'rectal cuff' (the small strip of rectal mucosa between the pouch and the dentate line). Some advocate complete mucosectomy of this residual cuff and a transanal anastomosis, although this may result in worse function. In experienced hands, a laparoscopic approach is associated with swifter recovery, improved cosmesis and perhaps increased fecundity in women.

For patients with relative rectal sparing (<20 polyps), total colectomy and IRA is an option to be considered, particularly as it is associated with less risk of sexual dysfunction in males and less infertility in females. However, the rectum requires regular endoscopic surveillance as up to 10% of patients will develop invasive malignancy in the rectum. In AFAP, patients may consider rectal preservation surgery on the understanding that their cancer risk is lower (around 2%) but still present.

Proctocolectomy and ileostomy is the recommended option for patients with poor anal sphincter function, those who have already developed a rectal cancer or those who wish to have a definitive single-stage procedure.

Postoperative surveillance

Because of the ongoing cancer risk, regular lifelong endoscopic surveillance of the rectum/pouch is important with biopsy of the rectal cuff unless mucosal proctectomy has been performed. Endoscopy is also carried out to detect upper gastrointestinal tumours, particularly around the duodenal ampulla (see ***Chapter 67***). A side-viewing duodenoscope is required. Despite surveillance, life expectancy is reduced because of extracolonic cancers and complications of desmoid tumours.

MUTYH-associated polyposis

The appearances of MAP can be similar to FAP but it is inherited as an autosomal recessive phenotype and predisposes individuals to multiple colonic polyps. If an *APC* pathogenic variant is not identified in an individual with colonic polyposis, molecular genetic testing of *MUTYH* should be considered. There is an increased risk of colorectal cancer of between three- and sixfold depending on the particular *MUTYH* mutation. Colonoscopy should be performed every 2 years. Colectomy is required when the number and/or characteristics of the polyps do not allow complete endoscopic resection or malignancy is diagnosed. Surveillance for duodenal adenomas is recommended.

NTHL1 tumour syndrome

NTHL1 tumour syndrome is a rare autosomal recessive cause of colorectal polyposis and increased lifetime risk for colorectal cancer. Colorectal polyps can be adenomatous, hyperplastic or sessile serrated. Management is similar to MAP.

Peutz–Jeghers and juvenile polyposis syndrome

Peutz–Jeghers syndrome (PJS) is an autosomal dominant genetic disorder characterised by the development of benign hamartomas in the gastrointestinal tract along with hyperpigmented lesions on the lips and oral mucosa. The main clinical risks are small bowel intussusception in children and increased incidence of gastrointestinal malignancy in adult life (see ***Chapter 74***).

Juvenile polyposis (JPS) is an autosomal dominant inherited condition that presents with hamartomatous polyps due to

mutations in the *BMPR1A*, *SMAD4* or *ENG* genes. Pigmentation characteristic of PJS is not present.

Lynch syndrome (hereditary non-polyposis colorectal cancer)

Lynch syndrome, previously known as hereditary non-polyposis colorectal cancer (HNPCC), is characterised by an increased risk of colorectal cancer and also cancers of the endometrium, ovary, stomach and small intestine, urinary tract, pancreas, prostate and kidney. It is an autosomal dominant condition caused by a mutation in one of four DNA mismatch repair genes (*MLH1*, *MSH2*, *MSH6* and *PMS2*). These genes, when functioning normally, code for mismatch repair (MMR) proteins, which repair sporadic mutations that occur in other genes. If faulty, mutations accumulate in other key genes, leading to characteristic repeat sequences of DNA, termed microsatellite instability (MSI), and acceleration of the adenoma–carcinoma sequence. Thus individuals with an MMR gene mutation tend to develop colorectal polyps at an early age (before the age of 50 years) that quickly become cancerous. Not everyone with a mutation develops cancer; the lifetime risk is 80%. Most cancers develop in the proximal colon. Females have a 30–50% lifetime risk of developing endometrial cancer.

Diagnosis

Lynch syndrome was historically diagnosed based on a family history of cancer and the clinical parameters set out in the Amsterdam (***Summary box 77.3***) and Bethesda criteria. Recent advances in immunohistochemistry allow for MMR proteins or MSI to be accurately identified in all colorectal tumours with subsequent genetic testing in patients and families of those proven positive.

Summary box 77.3

Amsterdam II criteria

- Three or more family members with a Lynch syndrome-related cancer (colorectal, endometrial, small bowel, ureter, renal pelvis), one of whom is a first-degree relative of the other two
- Two or more successive affected generations
- At least one tumour diagnosed before the age of 50 years
- FAP excluded
- Tumours verified by pathological examination

Because of the accelerated pathway from adenoma to cancer in Lynch syndrome those with a gene mutation should be offered 2-yearly endoscopic surveillance from age 25 years (*MLH1* and *MSH2* carriers) or 35 years (*MSH6* carriers). *PMS2* carriers should be offered 5-yearly screening beginning at age 35 years (see ***Further reading***). For patients with polyps that cannot be managed with endoscopic polypectomy or those who develop a cancer, an extended colectomy (*MLH1* and *MSH2* carriers) should be considered. The benefit of screening other areas of the gastrointestinal tract is unclear but gynaecological screening is recommended in accordance with the 2019 Manchester Consensus (see ***Further reading***).

Malignant: colorectal carcinoma

Epidemiology

In the UK, colorectal cancer is the second most common cause of cancer death. Approximately 42 000 patients are diagnosed with colorectal cancer every year in the UK. Approximately one-third of these tumours are in the rectum and two-thirds in the colon. The burden of disease is greater in men than in women (56% versus 44%). Colorectal cancer occurs less frequently in resource-poor than in resource-rich countries.

Aetiology

Most colorectal cancers are thought to develop from adenomatous polyps through a sequence of genetic mutations influenced by environmental factors. This adenoma–carcinoma sequence is based on strong observational evidence (***Summary box 77.4***). The adenoma–carcinoma sequence is not a simple stepwise progression of mutations but a complicated array of multiple genetic alterations, ultimately resulting in an invasive tumour. Mutations of the *APC* gene occur in two-thirds of colonic adenomas and are thought to develop early in the carcinogenesis pathway. *K-ras* mutations result in activation of cell signalling pathways and are more common in larger lesions, suggesting that that they are later events in mutagenesis. The *p53* gene is frequently mutated in carcinomas but not in adenomas and therefore thought to be a marker of invasion. A recent international consortium has identified four consensus molecular subtypes (CMSs) of colorectal cancer based on bioinformatic analysis of gene expression in more than 4000 patients. MSI, a feature of Lynch syndrome, may occur sporadically, particularly in right-sided tumours (CMS1), while others show *WNT* and *MYC* signalling activation (CMS2), metabolic dysregulation (CMS3) and transforming growth factor beta activation (CMS4). The value of this classification in interpreting tumour aetiology, biology and targeted treatment remains to be determined.

Summary box 77.4

Evidence for adenoma–carcinoma sequence

- The distribution of adenomas is similar to that of cancers (70% left sided)
- Larger adenomas are more likely to be dysplastic than small adenomas
- The majority of early cancers have adjacent adenomatous tissue
- Adenomas are found in one-third of specimens resected for colorectal cancer
- Incidence of colorectal cancer decreases within a screening programme that involves colonoscopy and polypectomy

Henry Thompson Lynch, 1928–2019, physician and geneticist, Omaha, NE, USA, first presented his findings of a family with a strong history of colorectal cancer without polyposis in 1964.

Worldwide, the prevalence of colorectal cancer is closely associated with intake of red meat and particularly processed meat products (haem and *N*-nitroso compounds). A protective effect of dietary fibre is also suggested by epidemiological studies. A long-held hypothesis is that increased roughage is associated with reduced colonic transit times that in turn reduce exposure of the mucosa to dietary carcinogens. However, there is increasing evidence associating the colonic microbiota with inflammation, gene methylation and dysplastic changes. Increased risks for colorectal cancer have also been associated with smoking and alcohol. Conversely, high magnesium and calcium intake may be protective. A protective potential for antioxidants such as vitamin E and selenium is as yet unproven.

The epidemiological evidence supporting prostaglandin inhibitors, particularly aspirin, in preventing colorectal cancer is substantial. Given the potential hazards of taking long-term aspirin, the challenge is to identify individuals for whom the protective benefits outweigh the harm. Other factors that increase the risk of developing colorectal cancer include inflammatory bowel disease (IBD) (see ***Chapter 75***). Cholecystectomy may marginally increase the risk of right-sided colon cancer.

Pathology

Macroscopically, the tumour may take one of several forms: annular cancers tend to give rise to obstructive symptoms whereas ulcerating cancers tend to present with bleeding. Most large bowel cancers (***Figure 77.4***) arise from the left colon, notably the rectum (38%), sigmoid (21%) and descending colon (4%). Cancer of the caecum (12%) and ascending colon (5%) is less common but may be gradually increasing in incidence. Cancer of the transverse colon (5.5%), flexures (2–3%) and appendix (0.5%) are relatively uncommon. Microscopically, the neoplasm is a columnar cell adenocarcinoma.

Spread

Colonic cancer can spread locally, via the lymphatics, bloodstream (haematogenous) or across the peritoneal cavity (transcoelomic spread). Direct spread may be longitudinal or radial. Radial spread may be retroperitoneal into the ureter, duodenum and posterior abdominal wall muscles or intraperitoneal into adjacent organs or the anterior abdominal wall.

In general, involvement of the lymph nodes by tumour progresses from those closest to the bowel along the course of lymphatics to central nodes. However, this orderly process does not always occur. Haematogenous spread is most commonly to the liver via the portal vein. One-third of patients will have liver metastases at the time of diagnosis and 50% will develop metastases at some point, accounting for the majority of deaths. The lung is the next most common site of metastatic disease whereas spread to the ovaries, brain, kidney and bone is less common. Colorectal cancer can spread from the serosa of the bowel or via subperitoneal lymphatics to other structures within the peritoneal cavity, including peritoneum, ovary and omentum.

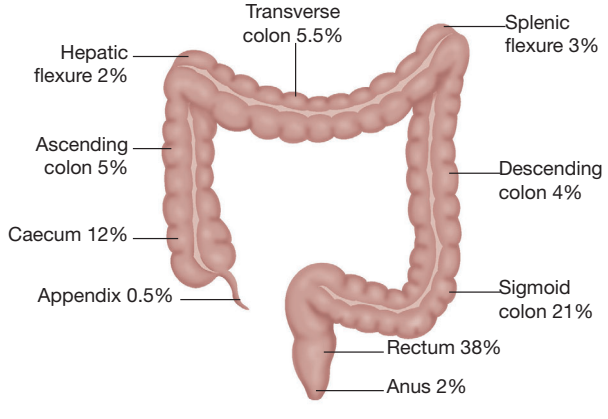

Figure 77.4 Distribution of colorectal cancer by site.

Staging colon cancer

Preoperative staging is important to decide whether patients can be managed with curative intent and whether they should have neoadjuvant therapy, undergo palliative interventions including colonic stenting or have symptomatic treatment. Additional interventions include ureteric stenting, en bloc resection for locally advanced disease, intraoperative chemotherapy (hyperthermic intraperitoneal chemotherapy [HIPEC]) for peritoneal disease or synchronous organ resection (e.g. liver, ovaries [Krukenberg tumour]). Information is collated, including patient characteristics (age, frailty, symptoms and comorbidities), endoscopic assessment, histological analysis of biopsies and imaging studies. These factors should be discussed in a dedicated preoperative multidisciplinary meeting. Postoperative pathological staging should also be discussed in the same forum, allowing for decisions about adjuvant therapy.

A variety of staging systems are described for colorectal cancer. Dukes' classification was originally described for rectal tumours but has been adopted for histopathological reporting of colon cancer. Although it is simple and widely recognised (***Summary box 77.5***) the more detailed TNM system is regarded as the international standard (***Summary box 77.6***).

Summary box 77.5

Dukes' staging for colorectal cancer

- A: Invasion of but not breaching the muscularis propria
- B: Breaching the muscularis propria but not involving lymph nodes
- C: Lymph nodes involved

Dukes himself never described a stage D, but this is often used to describe metastatic disease

Friedrich Ernst Krukenberg, 1871–1946, Professor of Gynaecology, Bonn, Germany
Cuthbert Esquire Dukes, 1890–1977, pathologist, St Mark's Hospital, London, UK. The original Dukes' classification in 1932 gave three stages, A–C.

Summary box 77.6

TNM classification for colonic cancer

(note the prefix y refers to neoadjuvant radio- or chemotherapy, p refers to pathological confirmation of stage; Union for International Cancer Control, 8th edn)

- T Tumour stage
  - T1 Tumour invades into submucosa
  - T2 Tumour invades into muscularis propria
  - T3 Tumour invades into non-peritonealised pericolic tissues or subserosa
  - T4a Tumour breaches visceral peritoneum
  - T4b Tumour directly invades another organ/structure
- N Nodal stage
  - N0 No nodes involved
  - N1 1–3 nodes involved (N1a, 1 regional lymph node involved; N1b, 2 or 3 regional lymph nodes involved; N1c, satellite extranodal tumour deposits)
  - N2 4 or more nodes involved (N2a, 4–6 regional lymph nodes involved; N2b, 7 or more regional lymph nodes involved)
- M Metastases
  - M0 No metastases
  - M1 Metastases (M1a, metastasis confined to 1 organ; M1b, metastasis to more than 1 organ; M1c, metastasis to the peritoneum)

Clinical features

Carcinoma of the colon typically occurs in patients over 50 years of age and is most common in the eighth decade of life. Emergency presentation occurs in 20% of cases and is associated with a considerably worse prognosis, even when matched for disease stage. A careful family history should be taken. A first-degree relative who has developed colorectal cancer before the age of 50 years may indicate one of the colorectal cancer familial syndromes. Tumours of the left side of the colon usually present with a change in bowel habit or rectal bleeding, while proximal lesions typically present with iron deficiency anaemia or a mass (***Figure 77.5***). Patients may present with metastatic disease.

Investigation of colon cancer

Screening

Colon cancer is suited to screening as the prognosis is better the earlier stage the disease is diagnosed and polypectomy allows the prevention of cancer development. In the UK screening is offered every 2 years to men and women aged 60–74 years, followed by colonoscopy in those who test positive. Originally a guaiac-based test was used, which detects peroxidase-like activity of faecal haematin. Studies suggested a 15–20% reduction in colorectal cancer-specific mortality in the screened population. More recently the faecal immunochemical test (FIT) has been introduced. This test is more accurate and easier to complete than the old faecal occult blood test. A one-off flexible sigmoidoscopy for people aged 55 was offered as a screening tool in the UK. It was shown to reduce colorectal cancer-specific mortality but is now being replaced with FIT screening.

Endoscopy

For symptomatic patients with rectal bleeding, direct referral from primary care for a flexible sigmoidoscopy is increasingly used. The patient is prepared with an enema and sedation is not usually necessary. The bowel can be assessed as far as the splenic flexure, allowing detection of up to 70% of cancers and almost all that cause fresh rectal bleeding. Finding left-sided colonic polyps or cancer mandates subsequent completion colonoscopy.

Colonoscopy is the investigation of choice if colorectal cancer is suspected (***Figure 77.5***). It has the advantage of not only securing histological diagnosis of a primary cancer but also detecting synchronous polyps or carcinomas, which occur in 3–5% of cases. There is a small risk of perforation (1:1000).

Radiology

Double-contrast barium enema has now been largely replaced by computed tomography (CT) colonography, which is extremely sensitive in picking up polyps to a size of 6 mm (***Figure 77.6***). It has the advantage of being less invasive than colonoscopy but, if a biopsy is required, an endoscopy will still be needed. CT is used as a diagnostic tool in patients with a palpable abdominal mass. CT of the thorax, abdomen and pelvis now represents the standard means of staging colorectal cancer; patients with rectal cancer require magnetic resonance imaging (MRI) for local staging (see ***Chapter 79***).

Surgical treatment

Preoperative preparation

With the advent of perioperative enhanced recovery after surgery (ERAS) protocols, mechanical bowel preparation fell out of favour. However, there is evidence that preoperative mechanical bowel preparation in combination with preoperative oral antibiotics not only reduces surgical site infection rates but also rates of anastomotic leak, postoperative ileus, reoperation and even mortality. Further research is required

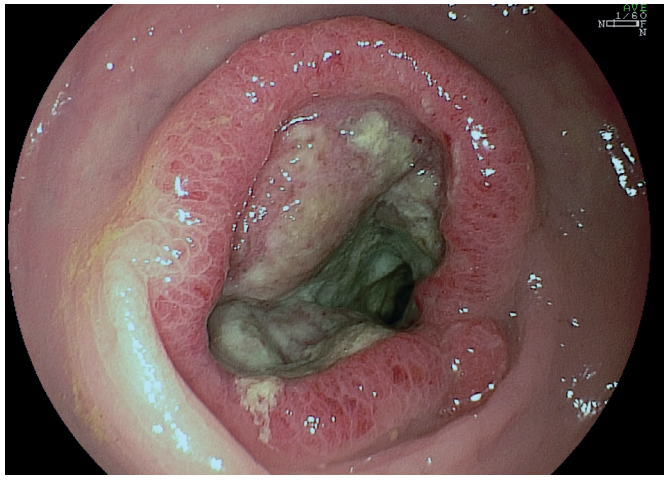

Figure 77.5 Colon cancer seen at colonoscopy (courtesy of Dr Adolfo Parra-Blanco, Nottingham University Hospitals, Nottingham, UK).

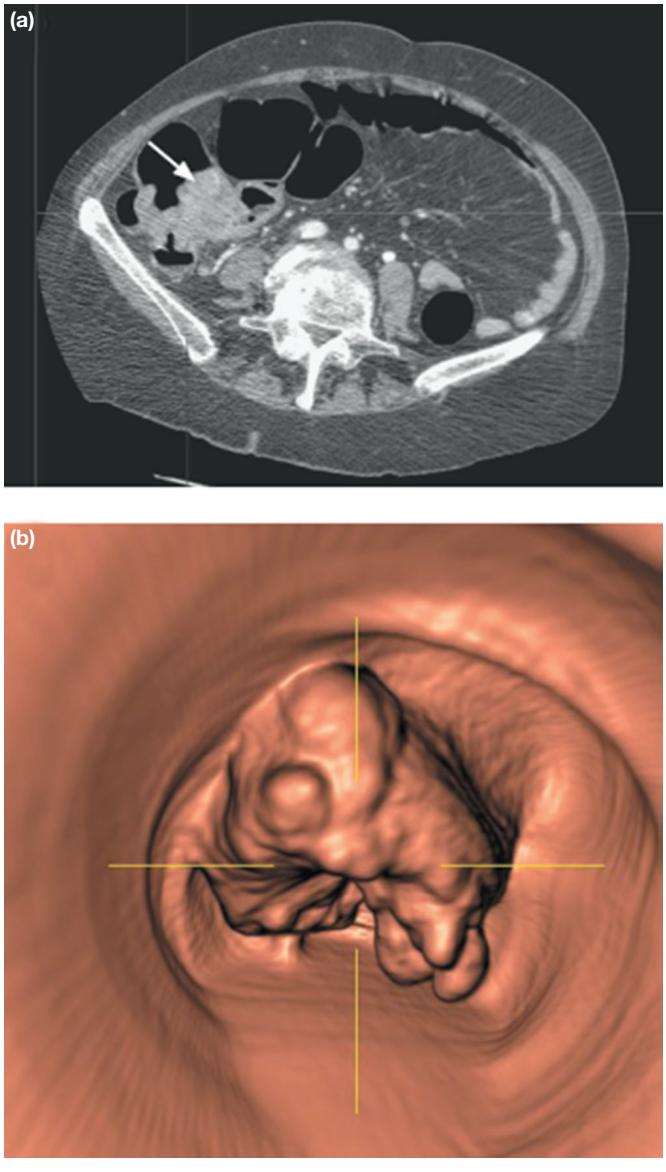

Figure 77.6 Virtual colonoscopy of the right colon. **(a)** Computed tomography scan of the abdomen showing a caecal tumour (arrow). **(b)** Formatted 'virtual' image of the same lesion as in **(a)** (courtesy of Dr A Slater, John Radcliffe Hospital, Oxford, UK).

but mechanical bowel preparation with oral antibiotics appears safe and could reasonably be used in combination with a surgical site infection bundle. This bundle should contain common and variable components such as preoperative bathing, intravenous prophylactic antibiotics given before surgical incision, maintenance of normoglycaemia and normothermia and use of wound protection devices. Antithrombotic stockings should be fitted, and the patient started on prophylactic subcutaneous low-molecular-weight heparin. Manual compression boots may be used perioperatively. In all cases where a stoma is anticipated, careful preoperative counselling and marking of an appropriate site by an enterostomal therapist is essential. ERAS programmes are widely used to reduce the physiological insult of surgery and improve postoperative outcomes (***Summary box 77.7***).

Summary box 77.7

Key elements of an ERAS programme

- Preadmission counselling
- Preoperative carbohydrate loading
- Avoidance of preoperative dehydration
- Avoidance of nasogastric tubes
- Short, transverse incisions (or laparoscopic procedure)
- Short-acting anaesthetic drugs
- Avoidance of perioperative fluid/salt overload
- Avoidance of opiate analgesia
- Maintenance of perioperative temperature
- Prevention of postoperative nausea and vomiting
- Early mobilisation
- Early introduction of oral fluids/diets/supplements
- Early removal of urinary catheters
- Continual audit of outcomes

Operations

The operations described are designed to remove the primary tumour and its draining locoregional lymph nodes. It is unusual to find unsuspected metastases at laparotomy (or laparoscopy) after CT staging, but the presence of peritoneal metastases may predicate a palliative strategy with a segmental resection and less aggressive lymphadenectomy. Similarly, a complete preoperative colonoscopy or CT colonography will have excluded synchronous bowel lesions. The use of stapling and hand-suturing techniques for colonic anastomoses have been compared, and there is probably little difference in leak rate. It is more important that healthy bowel, free of tension or distal obstruction, is used to construct an anastomosis and that patients are adequately nourished and free from active infection if anastomotic leakage is to be avoided.

Right hemicolectomy Carcinoma of the caecum or ascending colon (***Figure 77.7***) is treated by right hemicolectomy (***Figure 77.8***). At open surgery the peritoneum lateral to the ascending colon is incised, and the incision is continued

Figure 77.7 Right hemicolectomy specimen showing an ascending colon cancer (courtesy of Dr Philip Kaye, Nottingham University Hospitals, Nottingham, UK).

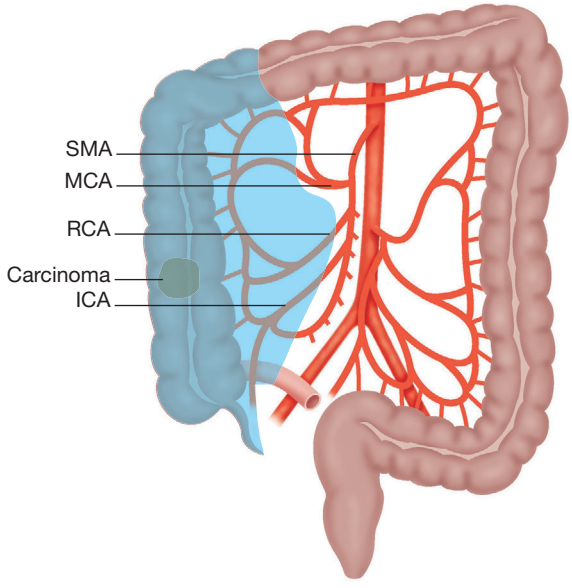

Figure 77.8 Schematic showing right hemicolectomy. This shows the basic plane of dissection for a complete mesocolic excision. ICA, ileocolic artery; MCA, middle colic artery; RCA, right colic artery; SMA, superior mesenteric artery.

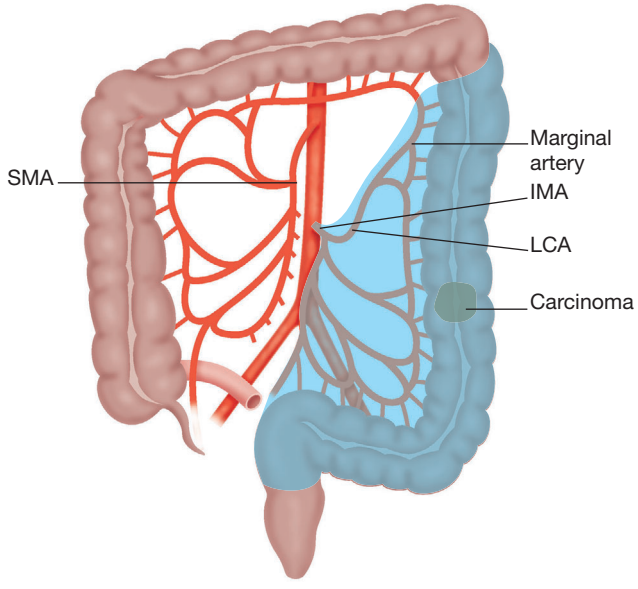

Figure 77.9 Schematic showing left hemicolectomy. This shows the basic plane of dissection for a complete mesocolic excision. IMA, inferior mesenteric artery; LCA, left colic artery; SMA, superior mesenteric artery.

around the hepatic flexure. The right colon and mesentery are elevated, taking care not to injure the ureter, gonadal vessels or the duodenum. The ileocolic artery is ligated close to its origin from the superior mesenteric artery ('high-tie') and divided. Complete mesocolic excision with dissection along embryological planes (see ***Chapter 65***) and removal of the lymphovascular supply of the resected colon with flush ligation of the ileocolic and right colic vessels at their origin from the superior mesenteric artery may improve survival in node-positive disease (Hohenburger). The mesentery of the distal 10 cm of the ileum and the mesocolon as far as the proximal third of the transverse colon is divided. The greater omentum is divided up to the point of intended division of the transverse colon. When it is clear that there is an adequate blood supply at the resection margins, the right colon is resected and an anastomosis is fashioned between the ileum and the transverse colon. If the tumour is at the hepatic flexure the resection must be extended further along the transverse colon and will involve dividing the right branch of the middle colic artery.

Extended right hemicolectomy Carcinomas of the transverse colon and splenic flexure are most commonly treated by an extended right hemicolectomy. The mobilisation is as for a right hemicolectomy but dissection continues to include the tumour, this may include taking down the splenic flexure and excising the whole transverse mesocolon. Some surgeons prefer to perform a left hemicolectomy for a splenic flexure cancer.

Left hemicolectomy This is the operation of choice for descending colon and sigmoid cancers (***Figure 77.9***). The left half of the colon is mobilised completely along the 'white line' that marks the lateral attachment of the mesocolon (see ***Chapter 65***). As the sigmoid mesentery is mobilised, the left ureter and gonadal vessels must be identified and protected. The splenic flexure may be mobilised by extending the lateral dissection from below and completed by entering the lesser sac. The inferior mesenteric artery below its left colic branch, together with the related paracolic lymph nodes, is included in the resection by ligating the inferior mesenteric artery close to its origin ('high-tie'). For full mobility the inferior mesenteric vein is also ligated and divided at the lower border of the pancreas. The bowel and mesentery can then be resected to allow a tension-free anastomosis. A temporary diverting stoma may be fashioned proximally, usually by formation of a loop ileostomy. This is usually undertaken if the anastomosis is below the peritoneal reflection of the rectum, because of the greater risk of anastomotic leakage.

Laparoscopic surgery

Laparoscopic surgery for colon cancer has been shown to have equivalent overall and cancer-related outcomes to open surgery. Lymph node harvests are equivalent to open surgery and initial concerns about reports of port-site recurrence have been dispelled as world experience has grown. In the UK, the National Institute for Health and Care Excellence (NICE) has stated that laparoscopic colorectal surgery should be offered to suitable patients. Operation times are longer but wound infection rates, blood loss and postoperative pain scores are lower than for open surgery. The costs of laparoscopic surgery are, however, generally higher and this may be particularly relevant where funds are limited.

Werner Hohenburger, contemporary, surgeon, Erlangen, Germany.

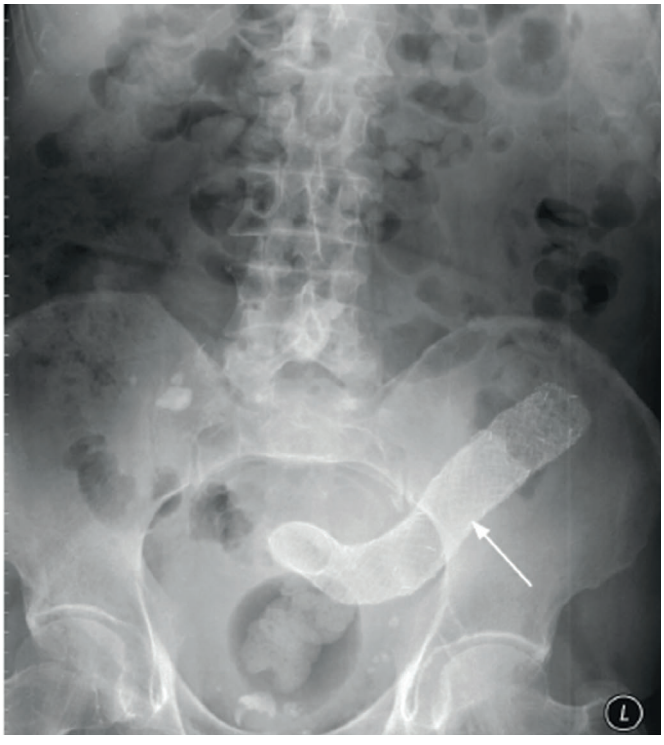

Figure 77.10 Abdominal radiograph demonstrating a colonic stent in position (arrow) (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

If laparoscopic surgery is planned it is useful to tattoo the lesion at prior colonoscopy as it not possible to locate lesions by palpation. The laparoscopic operation has particular advantages if performed in a medial to lateral manner, i.e. starting the dissection by controlling and dividing the major vascular pedicles and only taking the lateral peritoneal reflection once the mesocolon is completely free. Specimen retrieval and bowel anastomosis can then be performed via a small incision. Dedicated training in laparoscopic colorectal surgery is important as there is a relatively long learning curve.

Emergency surgery

In the UK, 20% of patients with colonic cancer will present as an emergency, the majority with obstruction, but occasionally with haemorrhage or perforation. If the lesion is right sided, it is usually possible to perform a right hemicolectomy and anastomosis in the usual manner. If there has been perforation with substantial contamination or if the patient is unstable, it may be advisable to bring out an ileocolostomy following resection of the lesion rather than forming an anastomosis. For a left-sided lesion the decision lies between a Hartmann's procedure and a resection and anastomosis. An on-table washout may be necessary to remove residual faecal content in the proximally obstructed bowel. Alternatively, removal of the whole proximal bowel may be required if the colon is markedly distended or if there is concern regarding its viability. Where endoscopic and radiological facilities are present an obstructing left-sided lesion can often be treated initially with an expanding metal stent (***Figure 77.10***). This allows decompression of the obstructed bowel and may allow conversion of an emergency operation with a high chance of a stoma to a situation that can be managed semielectively by resection and anastomosis. Although early studies cast doubt on the benefits of colorectal stenting, more recently evidence has emerged that stenting leads to a reduction in stoma rates.

Postoperative care

Patients should be closely monitored after colonic resection as there is a small incidence of postoperative bleeding. Antithrombosis measures should be continued and as currently recommended for 28 days postoperatively. There is no advantage to placing intra-abdominal drains after colonic surgery. Wound infections are relatively common after colonic surgery and may well be more frequent than the 10% usually quoted. Anastomotic leaks occur in 4–8% of ileocolic or colocolic anastomoses. The possibility should be borne in mind in any patient not progressing as expected or with unexplained cardiac abnormalities, fever or worsening abdominal pain. Early investigation with contrast-enhanced CT scan is appropriate. In the presence of sepsis or peritonitis, early return to theatre and taking down the leaking anastomosis with the formation of stomas is usually advised.

Prolonged nasogastric drainage, intravenous fluid therapy and cautious introduction of oral fluid and diet represented traditional postoperative practice. ERAS programmes that include preoperative, intraoperative and postoperative components have been shown to reduce length of hospital stay from 10–14 days to as little as 3–5 days by modulating the surgical stress response and reducing postoperative ileus (***Summary box 77.7***). It is important to appreciate that these programmes require multiple interventions and considerable time, effort and education from the surgical, anaesthetic and ward teams.

Adjuvant therapy

In most patients with colon cancer preoperative chemotherapy is not required; however, a recent research study (FOxTROT) has shown that it is safe and further work on case selection has been recommended. Adjuvant chemotherapy improves survival after surgery in patients with node-positive colon cancer (stage III/Dukes' C). Fluoropyrimidine regimes are often used, with the addition of oxaliplatin in patients who are otherwise fit and have high-risk stage III disease. Patients with stage II disease show less benefit in overall survival with adjuvant chemotherapy, thus it is reserved for those with high-risk stage II disease. Presence of MSI (in the tumour histology) also affects tumour recurrence and is taken into account when making decisions with patients about chemotherapy (see ***Chapter 12***).

Metastatic disease

Hepatic and pulmonary metastases can be resected and series have demonstrated 5-year survival of around 40% in resectable disease. CT, MRI and positron emission tomography (PET) scanning are all used to identify colorectal metastases and assess patients' suitability for further resection (***Figure 77.11***).

Henri Albert Antoine Hartmann, 1860–1952, Professor of Clinical Surgery in the Faculty of Medicine, University of Paris, Paris, France.

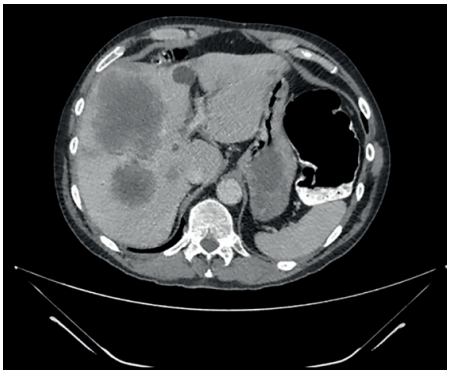

Figure 77.11 Computed tomography scan of the liver showing multiple metastases from carcinoma of the colon (courtesy of Dr Rajpal Dhingsa, Nottingham University Hospitals, Nottingham, UK).

The role of chemotherapy and the timing of colonic and hepatic surgery in synchronous metastases is still a matter of debate and such cases should be carefully discussed by a multidisciplinary team. Many centres offer adjuvant chemotherapy as standard and neoadjuvant therapy also in those with high-risk disease.

Isolated lung metastases may be suitable for resection or stereotactic radiofrequency ablation, but they are more commonly accompanied by metastases elsewhere. In patients with widespread disease, palliative chemotherapy is offered alongside symptomatic treatment and support by a palliative care team.

Prognosis

Overall 5-year survival for colorectal cancer is approximately 58%. While there are numerous factors that may predict prognosis (***Summary box 77.8***) the most important determinant is tumour stage and, in particular, lymph node status. Patients with disease confined to the bowel wall (TNM stage 1, Dukes' stage A) will usually have cure by surgical resection alone and around 95% will have disease-free survival at 5 years. Spread beyond the bowel wall (TNM stage 2, Dukes' B) reduces 5-year disease-free survival to approximately 85% with surgery alone. Patients with lymph node metastases (TNM stage 3, Dukes' C) have a 5-year disease-free survival of around 45–50% with surgery alone.

Adjuvant chemotherapy based on 5-fluorouracil (5-FU) and folinic acid (leucovorin) usually in combination with oxaliplatin (FolFox) is used on an individual basis for those with stage II disease (Dukes' stage B), although the benefit is uncertain. In those with stage III disease adjuvant chemotherapy increases the chance of 5-year disease-free survival by approximately 20% to 67–70%. Those presenting with unresectable metastatic disease at diagnosis have a 5-year survival of approximately 10%.

In metastatic disease chemotherapy based on 5-FU and folinic acid in combination with irinotecan (FolFiri) is often used as first-line treatment. Second-line therapy may include introduction of a monoclonal antibody such as a vascular endothelial growth factor (VEGF) inhibitor (bevacizumab) or an epidermal growth factor receptor (EGFR) inhibitor in *KRAS* wild-type tumours (cetuximab, panitumumab). Recently immunotherapy (pembrolizumab) has been shown to have a role in MSI tumours. Tumours exhibiting the *BRAF* V660E mutation (approximately 10%) have a poor prognosis but may respond to treatment with combined BRAF (encorafenib) and MAP kinase (binimetinib) inhibitors.

Summary box 77.8

Histopathological factors that influence prognosis

- Tumour stage
- Histological grade
- Degree of mucin secretin
- Presence of signet cells
- Venous invasion
- Perineural invasion
- Pushing versus infiltrative margin
- Tumour infiltrating lymphocytes
- Presence of MSI

Colorectal cancer follow-up

Since the advent of safe liver resection for metastases the outcome benefit of follow-up has been clearly demonstrated. Follow-up aims to identify synchronous bowel tumours (present in 3%) that were not identified at the time of original diagnosis. Similarly, 3% of patients will develop a metachronous (at a different time) colonic cancer. Up to a half of all patients with colorectal cancer will develop liver metastases at some point. Regular imaging of the liver (CT scan) and measurement of carcinoembryonic antigen (CEA) is designed to diagnose this early, in order to allow curative metastectomy. Optimum follow-up pathways continue to be developed. NICE guidelines recommend CT scans of the abdomen, pelvis and thorax as well as CEA measurements during the first 3 years after treatment of colon cancer with curative intent but identified no clinically important difference in colorectal cancer-specific survival with a more intensive follow-up schedule compared with a less intensive follow-up.

Palliative care

About 20% of patients present with metastatic disease and about one-fifth of these patients are suitable for potentially curative management. For the rest, quality of residual life is the main outcome but it should be borne in mind that with the combination of interventions including chemotherapy, metastectomy, cytoreductive surgery and intraperitoneal chemotherapy some colonic disease may 'convert to resectable'. For those whose disease remains incurable colonic surgery may still be offered, particularly if symptomatic. This may be non-resectional (defunctioning stoma or internal bypass) or resectional (procedures detailed earlier but with a smaller segmental resection and less aggressive lymphadenectomy). Non-surgical techniques include palliative chemotherapy, stenting for obstruction, intraluminal laser, argon plasma coagulation and radiotherapy for bleeding and pain (especially in rectal cancers).

Malignant: miscellaneous cancers

Gastrointestinal stromal tumours

Gastrointestinal stromal tumours (GISTs) are extremely rare, constituting less than 0.1% of all colorectal tumours. They appear to arise from the interstitial cells of Cajal and are mainly due to a mutation in a specific gene called *c-kit*. This allows a specific marker to be used to diagnose most tumours as well as targeted chemotherapy with imatinib. Thirty per cent are malignant with mitotic rate, Ki-67 (>10%), size (>5 cm), local invasion and cellularity the best indicators of malignant potential. Diagnosis is by CT or MRI and endoscopic biopsy. Surgical resection is the mainstay of treatment with imatinib for those tumours that are unresectable, have metastasised or recurred. Adjuvant imatinib may be used for tumours felt to be at high risk of recurrence.

Carcinoid

'Carcinoids' are well-differentiated neuroendocrine tumours of the colon and are part of a spectrum of disease with poorly differentiated neuroendocrine carcinomas at the most aggressive end of this spectrum.

They constitute around 50% of all neuroendocrine tumours of the gut and about 5% of all colonic tumours. Fewer than 10% of colonic carcinoid tumours present with carcinoid syndrome (skin erythema, diarrhoea, cardiorespiratory symptoms) owing to release of hormones. Surgery remains the only potentially curative treatment and, since the possibility of metastatic disease is directly related to the size of the primary tumour, the extent of resection should be determined accordingly. Tumours greater than 2 cm require en bloc resection of adjacent mesenteric lymph nodes. In the midgut (the area receiving its blood supply from the superior mesenteric artery) even lesions less than 1 cm have been shown to metastasise and radical resection is also indicated. Small (<1 cm) hindgut tumours (the area receiving its blood supply from the inferior mesenteric artery) can be safely locally excised (see ***Chapters 74 and 76***).

Lymphoma

Primary lymphoma of the colon is rare, accounting for less than 1% of all colonic malignancies. The caecum is the most common site of occurrence, usually with non-Hodgkin's type lymphoma (NHL). Patients present with abdominal pain, a mass, change in bowel habit, per rectal bleeding, obstruction or intussusception. These tumours may occasionally perforate. The lack of specific complaints and rarity of intestinal obstruction probably accounts for the often delayed diagnosis. CT and colonoscopy with submucosal biopsy are required for diagnosis. Treatment is combination surgery with systemic chemotherapy, although surgery alone may be considered adequate treatment for low-grade NHL disease that does not infiltrate beyond the submucosa.

Metastatic disease to colon

Metastatic disease to the colon from other primary sites constitutes about 1% of all colorectal cancers. There is often a known primary, usually lung, ovary, breast, kidney, skin, stomach or hepatobiliary system tumours. In most cases multiple lesions are seen and one-third may be asymptomatic. The most common pathway of spread is through peritoneal seeding (typical of ovarian cancer), although haematological and lymphatic dissemination is described in breast and lung cancer and melanoma. Patients may present with obstruction, per rectal bleeding (especially melanoma), anaemia and weight loss. CT and colonoscopic biopsy are required for diagnosis and treatment should be individualised to patient symptoms and prognosis.

COLITIS

There are two types of colitides: IBD (discussed in ***Chapter 75***) and non-IBD. The non-IBD causes can be grouped into infective and non-infective causes, with infective being by far the most common. The majority of non-IBD colitides present acutely with severity ranging from a self-limiting illness to severe disease necessitating emergency colectomy.

A careful history of acute onset and potential predisposing factors, including the use of antibiotics, is often key. Investigations include stool culture, serology and inflammatory markers. Supine abdominal radiographs may demonstrate bowel oedema, colonic distension or, in severe cases, gas in the bowel wall. CT may determine the extent of disease, presence of alternative pathology or resultant complications. In a deteriorating patient awaiting cultures, endoscopic biopsies may also be helpful.

Infective colitides

Infective causes may be classified as bacterial, protozoal, viral and fungal. Common infections include the following.

Escherichia coli

E. coli is a Gram-negative bacillus transmitted via the faecooral route from contaminated food or water. Symptoms vary according to strain, with the most common form – enterotoxigenic *E. coli* – causing 'traveller's' diarrhoea (diarrhoea, vomiting and colicky pain). In adults, infection is usually brief and self-limiting. A more severe form – enteroinvasive *E. coli* – causes a more systemic illness and haematochezia. A very severe form – enterohaemorrhagic *E. coli* – results in colonic oedema, ulceration and haemorrhage with the very ill requiring colectomy.

Campylobacter

Infection with *Campylobacter jejuni* (a Gram-negative rod with a distinctive spiral shape) is the most common form of gastroenteritis in resource-rich countries, typically acquired from eating infected poultry. It causes diarrhoea and abdominal pain. Severe cases may resemble ulcerative colitis. The organism

Santiago Ramon y Cajal, 1852–1934, Spanish neuroscientist, pathologist and Nobel prize winner (1906) for studies of cellular anatomy of the nervous system.
Thomas Hodgkin, 1798–1866, pathologist, Guy's Hospital, London, UK, described 'Morbid appearances of the absorbent glands and spleen' in 1832.

may take several days to isolate on stool culture. Treatment is supportive as it usually resolves without antibiotics, but severe colitis and even perforation may occur.

Salmonellosis, typhoid and paratyphoid

Salmonella are a family of Gram-negative rods that can cause a range of enteric infections. Salmonella gastroenteritis is typically caused by *Salmonella enteritidis* from poultry and is most often a self-limiting illness comprising headache, fever and watery diarrhoea. When severe, antibiotics, hospitalisation and intravenous fluids may be needed. The diagnosis is based on stool culture. *Shigella* and enteropathogenic strains of *E. coli* may cause similar diarrhoeal illnesses.

Typhoid fever is caused by *Salmonella enterica* Typhi and paratyphoid fever by *Salmonella enterica* Paratyphi A, B or C. The clinical differences between these infections are subtle. They present with fever and abdominal pain after a 10- to 20-day incubation period. Over the next week, the patient can develop distension, diarrhoea, splenomegaly and characteristic 'rose spots' on the abdomen caused by a vasculitis. A number of surgical complications can result:

- paralytic ileus;
- intestinal haemorrhage;
- perforation;
- cholecystitis.

In addition, invasion of the systemic circulation, which is a characteristic feature of salmonellosis, can cause severe Gram-negative sepsis and septic shock may develop. Occasionally patients develop metastatic sepsis, including septic arthritis, osteomyelitis, meningitis, encephalitis and pancreatitis.

Yersinia

Yersinia, Gram-negative coccobacilli, infection results from ingestion of contaminated food, typically meat, water and dairy products. Invasion typically occurs in the ileocaecal region and may mimic Crohn's disease. Treatment is usually supportive with antibiotics reserved for severe infection or in the immunocompromised.

Shigella (bacillary dysentery)

Dysentery results from the ingestion of contaminated food or water, with only a small dose of infective agent required. The Gram-negative bacilli invade the colonic epithelium, causing cell death, ulceration and necrosis. Exotoxins cause a brief period of watery diarrhoea before the onset of classical severe, bloody diarrhoea.

Clostridium difficile

Clostridium difficile is a toxin-producing Gram-positive bacillus that is of increasing concern in many hospitals. Although normally present in around 2% of the population, it proliferates after antibiotic treatment (especially with cephalosporins). Clinically, *C. difficile* infection presents with diarrhoea, abdominal pain and fever. Infection may progress to pseudomembranous colitis, so called because on endoscopic visualisation of the bowel plaques of inflammatory exudate between oedematous mucosa are seen. Diagnosis is usually made by detection of the toxin in stool samples, rather than by culture. Treatment is by metronidazole or vancomycin alongside supportive care. In refractory cases, faecal transplantation to restore a healthy microbiota may be tried. If toxic dilatation occurs, an emergency subtotal colectomy and ileostomy may be necessary.

Recently more virulent strains have stressed the importance of prevention. Suspicion of the disease should prompt source isolation, protective equipment for health staff, vigorous disinfection and scrupulous hand washing.

Intestinal amoebiasis

Entamoeba histolytica has a worldwide distribution and is transmitted mainly in contaminated drinking water. It can cause colonic ulcers, described as 'bottlenecked' because they have considerably undermined edges. The ulcers typically also have a yellow necrotic floor, from which blood and pus exude. In the majority they are confined to the distal sigmoid colon and the rectum. Clinically amoebiasis can mimic ulcerative colitis, most commonly causing bloody diarrhoea. Severe colonic complications can occur, including haemorrhage, stricture formation or perforation. A pericolitis is not uncommon and results in adhesions that may cause intestinal obstruction. Amoebiasis may cause liver abscesses or an amoebic mass ('amoeboma') of the caecum or sigmoid, which is difficult to distinguish from a carcinoma. Surgery is fraught with danger as the bowel is extremely friable.

Endoscopic biopsies or fresh stools are examined to look for the presence of amoebae (***Figure 77.12***). It is important to emphasise, however, that the presence of the parasite does not indicate that it is pathogenic. It is especially important to exclude amoebic infection in patients suspected of having ulcerative colitis. Treatment is by metronidazole in the acute phase. Diloxanide furoate is effective against chronic infections associated with the passage of cysts in stools.

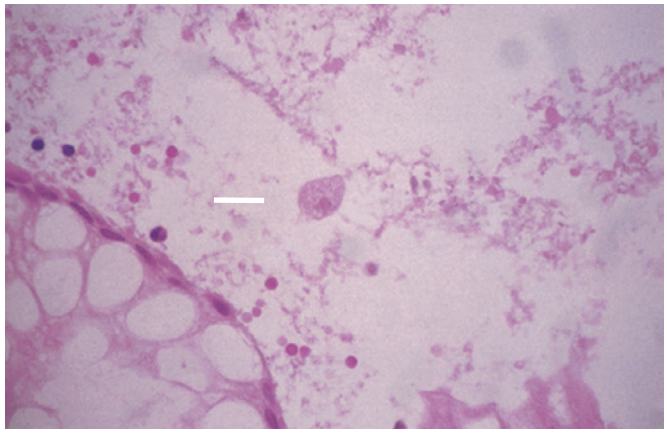

Figure 77.12 An amoeba in a rectal biopsy (arrow).

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932 along with Leon Ginzburg and Gordon Oppenheimer.

Cytomegalovirus

Cytomegalovirus (CMV) is present asymptomatically in 40–100% of adults. It usually remains latent within the host but can reactivate in immunocompromised patients. Commonly affected are those with acquired immunodeficiency syndrome (AIDS) (where it is the most common indication for colectomy) and patients on immunosuppressive therapy for IBD. Symptoms include profuse bloody diarrhoea and colicky pain. Severe disease may lead to perforation. Treatment is with ganciclovir with surgery necessary for severe disease or complications.

Human immunodeficiency virus

Intestinal complications are common after the development of AIDS when opportunistic organisms can cause gastroenteritis (***Summary box 77.9***). Human immunodeficiency virus 1 (HIV1) may also cause a specific enteropathy. Treatment is directed towards the responsible organism and surgery should be avoided.

Summary box 77.9

Opportunistic intestinal infections in patients with AIDS

- Bacteria
  - *Salmonella*
  - *Shigella*
  - *Yersinia*
  - *Campylobacter*
  - *Mycobacterium avium–intracellulare* (MAI)
- Viral
  - *Cytomegalovirus*
- Protozoa
  - *Cryptosporidium*
  - *Giardia*
- Fungal
  - *Candida albicans*

Non-infective colitides

Diverticular colitis

Diverticular colitis is a clinicopathological entity distinct from acute diverticulitis (see ***Diverticular disease***). The term refers to colonic mucosal inflammation, resembling IBD, in a segment of colon affected by diverticula. Symptoms of diarrhoea, pain and bleeding may occur, and the histology overlaps with that of IBD. It is usually self-limiting, with a short clinical course and low rate of recurrence. It is important to differentiate diverticular colitis from IBD to avoid further unnecessary tests and treatment. Localisation near to diverticula, a previous history of diverticulitis and rectal sparing should raise suspicion.

Diversion colitis

Diversion colitis is an iatrogenic process that occurs when a colon/rectum is defunctioned with a proximal stoma. Although the majority of patients with defunctioned bowel will develop typical changes of diffuse inflammation with friable mucosa and spontaneous bleeding, less than 50% will develop symptoms of lower abdominal pain, blood and mucus per rectum. The aetiology is likely to be multifactorial with alteration of the bacterial flora and a reduction in the bioavailability of short chain fatty acids (the predominant metabolic substrate of colonic mucosa). Diagnosis is by endoscopy and treatment includes reassurance and, if feasible, restoration of the bowel continuity.

Microscopic colitis

See ***Chapter 75***.

Radiation colitis

Radiation colitis refers to the characteristic acute and chronic morphological changes that occur following radiation treatment. Although most commonly occurring in the rectum (proctitis) these changes can affect the colon if any portion falls within the radiation field. Acute inflammatory changes manifest a few days to 6 weeks after treatment, whereas chronic colonic changes leading to fibrosis and stenosis occur up to years later. Obstructive symptoms require appropriate radiological and possibly endoscopic assessment and may lead to resectional surgery. After resection care must be taken to ensure healthy non-irradiated bowel is used for any anastomosis. As the rectum is the most commonly affected part of the large bowel, further details are given in ***Chapter 79***.

Graft-versus-host disease colitis

Graft-versus-host disease colitis (GVHD) is a common complication occurring about 3–6 weeks after haematopoietic stem cell transplantation and is the result of severe immune-mediated toxicity against host cells. The patient develops diarrhoea and vomiting with colicky abdominal pain. Inflammation is evident on endoscopy. Treatment is complex and difficult. Once established the prognosis is poor.

Drug-induced colitis

A wide range of medications may induce colitis (***Summary box 77.10***) and recognition is essential as cessation of the medication often leads to prompt resolution of symptoms. Patients with the *DPYD* (*dihydropyrimidine dehydrogenase*) gene mutation are particularly prone to colitis if treated with 5-FU during treatment for colon cancer. Dose reduction should be employed.

Summary box 77.10

Drugs that may result in colitis

- Non-steroidal anti-inflammatory drugs
- Proton pump inhibitors and H2 antagonists
- Cardiac drugs (digoxin, diuretics, dopamine)
- Immunosuppressants
- Antibiotics (owing to increasing the likelihood of *C. difficile* infection)
- Statins
- Chemotherapy
- Antidepressants (selective serotonin reuptake inhibitors)
- Anti-migraine drugs (ergotamine)
- Cocaine

Ischaemic colitis

Ischaemia of the colon typically results from thrombosis or embolism. Sudden embolic events leading to acutely ischaemic bowel present with severe pain out of proportion to the degree of peritonism, bloody diarrhoea, haemodynamic instability and shock. Resuscitation and laparotomy are required with

resection of gangrenous bowel and exteriorisation of viable bowel ends. Mortality is extremely high.

Thrombotic occlusion usually occurs in the context of global atherosclerosis. The presentation of this ischaemic colitis tends to be less dramatic with abdominal pain, a raised white cell count and rectal bleeding. A plain abdominal radiograph may show 'thumb-printing' and endoscopy may demonstrate haemorrhagic oedema. The left colon and, in particular, the splenic flexure are usually the worst affected (the 'watershed' area of blood flow). Symptoms usually settle spontaneously. In some cases, ulceration at the splenic flexure associated with ischaemic colitis may heal with stricturing and present with subsequent large bowel obstruction.

Bowel ischemia is a well-known but uncommon complication following both open and endovascular abdominal aortic aneurysm repair due to sacrifice of the inferior mesenteric artery.

DIVERTICULAR DISEASE

Diverticula (hollow outpouchings) are a common structural abnormality of the gastrointestinal tract. They can be classified as:

- **congenital**: all three coats of the bowel are present in the wall of the diverticulum (e.g. Meckel's diverticulum).
- **acquired**: there is no muscularis layer present in the diverticulum (e.g. sigmoid diverticular disease).

Diverticula are found in the left colon in around 75% of those over 70 years of age in the Western world. The condition is overwhelmingly found in the sigmoid colon but can affect the whole colon. In South East Asia right-sided diverticular disease is more common. Diverticula are most often asymptomatic (diverticulosis) and found incidentally, but they can present clinically with sepsis or haemorrhage.

Aetiology

Epidemiological studies suggest that diverticular disease is a consequence of a refined Western diet, deficient in dietary fibre. The combination of altered collagen structure with ageing, disordered motility and increased intraluminal pressure, most notably in the narrow sigmoid colon, results in herniation of mucosa through the circular muscle at the points where blood vessels penetrate the bowel wall. The rectum has a complete muscular coat and a wider lumen and is thus very rarely affected. Diverticular disease is rare in Africa and Asia, where the diet is high in natural fibre (Burkitt).

Complications of diverticular disease

The majority of patients with diverticulosis are asymptomatic but historical studies suggest that somewhere between 10% and 30% will have symptomatic complications (***Summary box 77.11***).

Summary box 77.11

Complications of diverticular disease

- Diverticulitis
- Abscess
- Peritonitis
- Intestinal obstruction
- Haemorrhage
- Fistula formation

Clinical features

In mild cases, symptoms such as distension, flatulence and a sensation of heaviness in the lower abdomen may be indistinguishable from those of irritable bowel syndrome. These symptoms are thought to result from a combination of increased luminal pressure affecting wall tension and increased visceral hypersensitivity. Surgical treatment is rarely, if ever, appropriate for diverticular disease in the absence of complications.

Diverticulitis typically presents as persistent lower abdominal pain. There may be accompanying diarrhoea or constipation. The lower abdomen is tender, especially over the left iliac fossa, but occasionally also on the right side if the sigmoid loop lies across the midline. The sigmoid colon may be tender and thickened on palpation and rectal examination may reveal a tender mass if an abscess has formed. Distinguishing between diverticulitis and abscess formation is difficult on clinical grounds alone and radiological imaging is essential. Generalised peritonitis as a result of free perforation presents in the typical manner with systemic upset and generalised tenderness and guarding.

Classification of contamination

The degree of infection has a major impact on outcome in acute diverticulitis. Patients with inflammatory masses have a lower mortality than those with perforation (3% versus 33%). Classification systems have been developed for complicated diverticulitis to try to rationalise the literature, the most commonly used being the Hinchey classification (***Table 77.2***).

Haemorrhage from colonic diverticula is typically painless and profuse. Bleeding from the sigmoid will be bright red with

TABLE 77.2 Hinchey classification of complicated diverticulitis.

Grade I	Mesenteric or pericolic abscess
Grade II	Pelvic abscess
Grade III	Purulent peritonitis
Grade IV	Faecal peritonitis

Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.
Denis Parsons Burkitt, 1911–1993, Irish surgeon who practised in Uganda, observed that many Western diseases were rare in Africa as a result of diet and lifestyle.
Edward John Hinchey, b. 1934, surgeon, Montreal General Hospital, Montreal, Canada.

clots, whereas right-sided bleeding will be darker. Torrential bleeding is fortunately rare and, in fact, more commonly due to angiodysplasia, but diverticular bleeding may persist or recur, requiring transfusion and resection. The presentation of a fistula resulting from diverticular disease depends on the site. The most common colovesical fistula results in recurrent urinary tract infections and pneumaturia (flatus in the urine) or even faeces in the urine. Colovaginal fistulae are more common after hysterectomy. Colocutaneous fistulation is unusual in the absence of prior intervention (e.g. radiological drainage). Rarely, diverticular disease may perforate into the retroperitoneum, leading to a psoas abscess, and even fistulation to the groin.

Investigation

Radiology

Plain radiographs can demonstrate a pneumoperitoneum. Spiral CT has excellent sensitivity and specificity for identifying bowel wall thickening, abscess formation and extraluminal disease and has revolutionised the assessment of complicated diverticular disease (***Figure 77.13***). On identification of abscesses in stable patients, drainage, under interventional radiology guidance, may be carried out percutaneously, avoiding the need for laparotomy/laparoscopy. Contrast studies and endoscopy are usually avoided for 6 weeks after an acute attack for fear of causing perforation. They are used subsequently, however, to exclude a coexisting carcinoma and assess the extent of diverticular disease. Contrast examination or CT can demonstrate a fistula.

Colonoscopy

Endoscopic assessment may demonstrate the necks of diverticula within the bowel lumen (***Figure 77.14***). A narrowed area of diverticular disease may be impassable because of the severity of disease and there is a significant risk of endoscopic perforation. Colonoscopy in these circumstances requires judgement and experience. Biopsies may be taken if possible and corroboration with CT virtual colonoscopy or occasionally contrast enema is required. Excluding a carcinoma may not always be possible and may represent an indication for resection.

Management

Patients are frequently recommended a high-fibre diet and bulk-forming laxatives, although the evidence for their effectiveness in diverticulosis or after an attack of diverticulitis is limited. Antispasmodics may have a role if recurrent pain is a problem. Acute diverticulitis has been traditionally treated with intravenous antibiotics and bowel rest. More recently, in recognition that diverticulitis may be a more inflammatory process than an infective one, many have advocated selective use of antibiotics. Essentially, antibiotic therapy may not be needed in immunocompetent people with uncomplicated diverticulitis who have no signs of systemic infection, as this may be a self-limiting condition. Uncomplicated disease should be confirmed by CT. For disease complicated by a localised abscess, intravenous antibiotics and image-guided drainage is indicated.

Operative procedures for diverticular disease

The aim of emergency surgery is to control peritoneal infection; indications are generalised peritonitis and failure to respond to optimum medical management. Laparotomy for diverticular disease in the acute setting has considerable risk with mortality in most series of 15%; in the case of faecal peritonitis, mortality approaches 50%.

Traditionally laparotomy and thorough washout of contamination are performed and then a choice has to be made between a Hartmann's procedure (sigmoid resection with formation of a left iliac fossa colostomy and closure of the rectal stump; ***Figure 77.15***) and resection with colonic washout and primary anastomosis (with consideration of a defunctioning

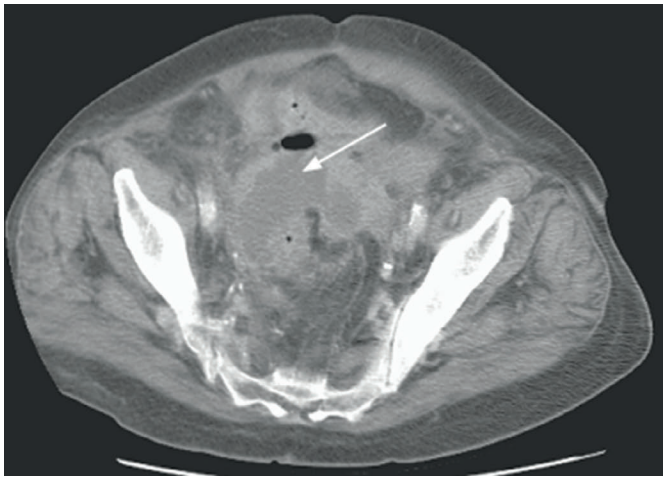

Figure 77.13 Computed tomography scan demonstrating an abscess associated with diverticulitis (arrow) (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

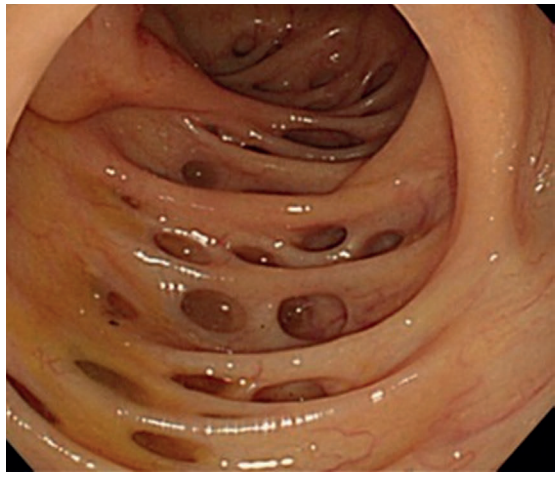

Figure 77.14 Colonoscopic view of right-sided diverticula. (From Niikura R, Nagata N, Akiyama J *et al*. Hypertension and concomitant arteriosclerotic diseases are risk factors for colonic diverticular bleeding: a case–control study. *Int J Colorectal Dis* 2012; **27**: 1137–43.)

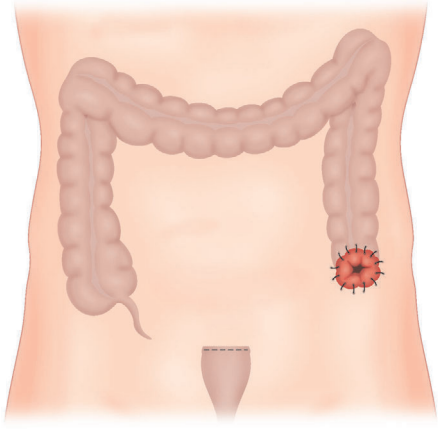

Figure 77.15 Hartmann's procedure with an oversewn rectal stump and an end left-sided colostomy following resection of the diseased segment of sigmoid colon.

loop ileostomy). Primary anastomosis should be used selectively but is appealing in a young fit patient without gross contamination or overwhelming sepsis. There is evidence that simple defunctioning with a proximal stoma is associated with higher mortality than a resection of the affected colon.

There may be a role for emergency laparoscopy in diverticular disease in expert hands. It allows assessment of the disease and in very selected cases a simple but thorough washout and drainage. The patient must have minimal comorbidity, be relatively stable, have no visible perforation and no gross faecal contamination. While this may avoid sigmoid resection in a select few, it remains controversial.

Elective surgery is usually undertaken for management of complications. Diverticular fistulae can only be cured by resecting the affected bowel, although a defunctioning stoma can ameliorate symptoms. In a colovesical fistula, once cancer has been excluded, the sigmoid can often be pinched off the bladder, the sigmoid colon resected and the bladder drained with an indwelling catheter for 7–10 days. If an anastomosis is performed, it is wise to place an omental pedicle between the bowel and bladder to prevent recurrent fistulation. These procedures can be technically challenging and ureteric stents may be advisable to reduce the risk of ureteric injury. Partial cystectomy may be required and assistance from a urological surgeon is often very helpful.

Haemorrhage from diverticular disease should be distinguished from angiodysplasia. It usually responds to conservative management and only occasionally requires resection. Where available, CT angiography is helpful to localise bleeding points and selective embolisation may control active bleeding. Rarely, colonoscopy may be necessary to localise the bleeding site. If the source cannot be located and bleeding continues, subtotal colectomy and ileostomy is the safest option.

Indications for surgery in an elective setting, in the absence of complications of the disease, are controversial. There is undoubtedly a small number of patients with recurrent attacks who should be offered an elective sigmoid colectomy (with anastomosis). This could be performed laparoscopically in experienced hands with a likely swifter recovery as well as improved cosmesis. Cohort studies suggest that of patients under 50 years old admitted with diverticulitis, 25% will have a further episode. The data may be used as an argument for offering elective resection but equally indicate that 75% will not get another severe attack. Many surgeons would discuss the pros and cons of elective surgery after two emergency admissions, although comorbidities must be carefully considered. However, there is an increasing tendency to treat even patients with recurrent attacks of diverticulitis conservatively in the absence of complications.

Summary box 77.12

Principles of surgical management of diverticular disease

- Hartmann's procedure is often the safest option in an emergency setting
- Primary anastomosis (with or without proximal diversion) can be considered in selected patients
- Elective resection may be considered for recurrent attacks or complications
- Laparoscopy has advantages in the elective setting but use in the emergency setting is more controversial

VASCULAR ANOMALIES OF THE INTESTINE

Angiodysplasia

Angiodysplasia is a vascular malformation that commonly causes haemorrhage from the colon in patients over the age of 60. The malformations consist of dilated tortuous submucosal veins.

Clinical features

In the majority of cases, the symptoms are subtle and patients can present with anaemia. About 10–15% have brisk bleeds, which may present as melaena or significant rectal bleeding. Many patients in whom rectal bleeding has been attributed to diverticular disease have probably bled from angiodysplasia. There is an association with aortic stenosis (Heyde's syndrome).

Investigation

Colonoscopy may show the characteristic lesion in the right colon. The lesions are only a few millimetres in size and appear as reddish, raised areas at endoscopy. CT angiography shows the site and extent of the lesion by a 'blush' of contrast, provided bleeding is more rapid than 1 mL/min. If this fails, a ^{99m}Tc-labelled red cell scan may confirm and localise the source of haemorrhage.

Edward Heyde, 1911–2004, American internist, published his findings on the association between aortic valve stenosis and angiodysplasia in a letter to the *New England Journal of Medicine* in 1958.

Treatment

In the context of a massive lower gastrointestinal bleed the first principle is to stabilise the patient. Following this, the bleeding needs to be localised. CT angiography allows not only localisation if bleeding is rapid but also therapeutic embolisation. If angiography fails or is unavailable careful colonoscopy (with copious lavage) may allow cauterisation to be carried out and an argon laser can be helpful. In severe uncontrolled bleeding, surgery becomes necessary. If preoperative localisation has not been successful, on-table colonoscopy is carried out to confirm the site of bleeding. Angiodysplastic lesions are sometimes demonstrated by transillumination through the caecum. If it is still not clear exactly which segment of the colon is involved a subtotal colectomy may be necessary. The management algorithm in ***Summary box 77.13*** is adapted from the diagnosis and management acute lower gastrointestinal bleeding guidelines from the British Society of Gastroenterology.

Summary box 77.13

Management of acute lower gastrointestinal bleeding

Patients with active bleeding and features of hypovolaemic shock

- CT angiogram and embolisation
- Bleeding treated: inpatient colonoscopy
- Bleeding continues: consider therapeutic endoscopy or surgery

Patients without features of hypovolaemic shock

- Significant bleeding: inpatient colonoscopy and consider oesophagogastroduodenoscopy; if normal consider capsule endoscopy, CT angiogram, nuclear medicine scanning
- Minor bleeding: arrange outpatient investigations

All patients: consider withholding anticoagulants and transfuse blood products as required

VOLVULUS

A volvulus is a twist of the intestine and the mesentery that supplies it (***Figure 77.16***). It is most commonly seen in the sigmoid colon, where elongation of the colon and mesentery with a narrow posterior attachment exists in some patients. It can, however, occur in patients with a hypermobile caecum and rarely in the transverse colon. Patients with sigmoid volvulus tend to be elderly and institutionalised; however, in West African countries it is more commonly seen in younger patients. Patients presenting with a caecal volvulus are usually younger and otherwise well. Predisposing factors include adhesions, gastric banding, pelvic masses and pregnancy.

Clinical features

Given the frailty of typical patients with sigmoid volvulus a history is not always forthcoming. Massive distension is key but pain is unusual and if present is a warning sign of ischaemia.

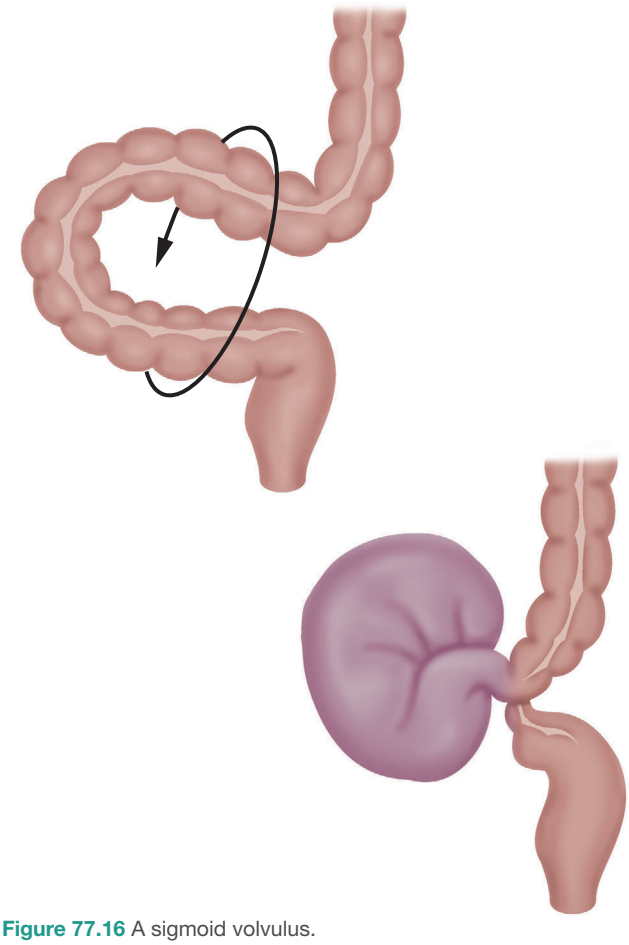

Figure 77.16 A sigmoid volvulus.

Investigation

A supine abdominal radiograph is useful but not always diagnostic (***Figure 77.17***). CT is the mainstay of diagnosis.

Treatment

For sigmoid volvulus the initial management is non-operative decompression using either a rigid sigmoidoscope or a colonoscope. Direct vision allows assessment of mucosal viability and derotation. With successful derotation a well-lubricated flatus tube should be inserted and left for 2–5 days. Bloody bowel contents or discoloured mucosa suggest ischaemia and the need for urgent surgery. Attempted derotation in this situation should be abandoned as it could lead to circulatory collapse and death.

Careful consideration of definitive surgery on a case-by-case basis in this, often elderly and frail, patient group is required. Although they would be subject to significant perioperative risk there is a very high recurrence rate for sigmoid volvulus. Such surgery should involve at least resection of the whole of the sigmoid colon and can be carried out laparoscopically. Given that there is very little need for colonic mobilisation and a large utility incision is required because of the bowel size, some of the benefits of a laparoscopic approach are negated. It is therefore reasonable to carry out surgery through a minilaparotomy

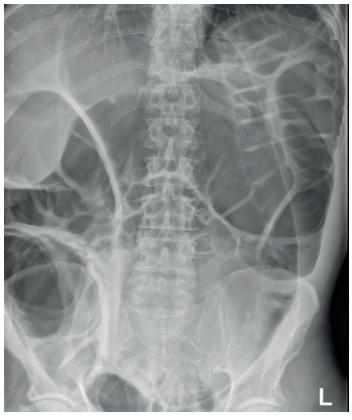

Figure 77.17 Plain abdominal radiograph showing colonic distension associated with a sigmoid volvulus (courtesy of Dr Rajpal Dhingsa, Nottingham University Hospitals, Nottingham, UK).

incision with the same recovery outcomes. An alternative to surgical resection in the very unfit patient is a percutaneous endoscopic colostomy, using a colonoscope to place a drainage tube through the abdominal wall into the sigmoid to fix the bowel in an untwisted position.

In the emergency situation where there is evidence of necrosis it may be wise to ligate the mesenteric vessels before untwisting the volvulus to theoretically avoid the systemic release of ischaemic toxins. It may also be prudent to avoid anastomosis. Instead, a Hartmann's-type approach or a Paul–Mikulicz double-barrelled stoma should be considered. For caecal volvulus endoscopic decompression is often unsuccessful and leads to treatment delay. Instead, urgent right hemicolectomy is indicated.

ENDOMETRIOSIS

This is mainly covered in ***Chapter 87***. It tends to be found deep in the pelvis and therefore relates more to the rectum. On the rare occasion it is found in the colon, it may be a cause of fibrosis and obstruction.

COLOSTOMIES

A colostomy is a planned opening made in the colon to divert faeces and flatus through the abdominal wall, where they can be collected in an external appliance. Ileostomies are discussed in ***Chapter 74***. Depending on the purpose for which the diversion has been necessary, a stoma may be temporary or permanent. Indications for stomas are shown in ***Summary box 77.14***.

In elective surgery stoma counselling and siting should be performed by a trained stoma nurse. The patient should be examined lying, standing and sitting to determine the optimum site, which should be away from scars, skin creases and bony prominences. In obese patients the stoma should be sited higher so that it can be easily seen. Clothing preference and patient disability (hand dexterity and vision) should also be considered. In the emergency setting siting may be difficult with a sick and immobile patient, particularly if the abdomen is distended.

Summary box 77.14

Indications for colostomy formation

- To protect a distal anastomosis or allow healing away from the faecal flow
- Following resection when anastomosis is unsafe or not possible
- To relieve obstruction when resection is not feasible
- To reduce disease activity (e.g. Crohn's disease)
- To allow alternative bowel control (incontinence)

Types of colostomy

Loop colostomy

Loop stomas are most commonly used to temporarily divert the faecal stream; for instance, to protect an anastomosis (usually by a loop ileostomy) following traumatic injury to the rectum, to facilitate the operative treatment of a high anal fistula, for incontinence and to defunction an obstructing low rectal cancer prior to long-course chemoradiotherapy. A mobilised loop of colon is brought out onto the anterior abdominal wall. Once the abdomen has been closed, the colostomy is opened and the edges of the colonic incision are sutured to the adjacent skin margin (***Figure 77.18***). A rod or bridge is sometimes placed under the loop to prevent retraction in the early postoperative period, being removed after a few days. Colostomy function should be expected in 2–7 days after operation.

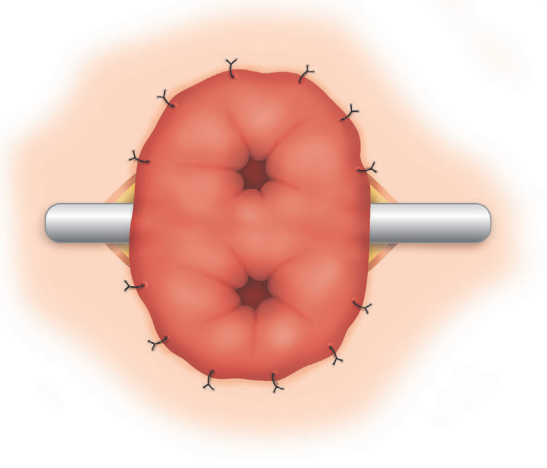

Figure 77.18 Loop colostomy with a bridge.

Frank T Paul, 1851–1941, surgeon, Liverpool, UK.
Johannes von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Poland.

If there is resolution of the indication for which the temporary stoma was constructed, the colostomy can usually be closed without recourse to a laparotomy/laparoscopy. Conventionally a water-soluble contrast enema is performed to assess the distal bowel before closure, particularly for pelvic anastomoses. Approximately 25% of temporary diverting stomas are never closed because of complications or changes in medical comorbidity.

End-colostomy

This is formed after an abdominoperineal excision of the rectum or as part of a Hartmann's procedure, bringing the divided colon through a left iliac fossa trephine in rectus abdominis and the skin. The colonic margin is then sutured usually flush or slightly everted on the adjoining skin (***Figure 77.19***).

Double-barrelled colostomy (Paul–Mikulicz)

Occasionally, when resection of a section of colon has occurred but the patient is too ill to undergo a safe reanastomosis it is possible and appropriate to bring up both ends of the bowel to the abdominal wall (see ***Volvulus***). This aids subsequent closure as the ends can simply be mobilised locally and reanastomosed rather than the patient requiring a relaparotomy.

Figure 77.19 A colostomy in the left iliac fossa.

Summary box 77.15

Stomas

- May be colostomy or ileostomy
- May be temporary or permanent
- Temporary or defunctioning stomas are usually fashioned as loop stomas
- An ileostomy is spouted; a colostomy is flush or slightly everted
- Ileostomy effluent is usually liquid whereas colostomy effluent is usually solid
- Ileostomy patients are more likely to develop fluid and electrolyte problems
- An ileostomy is usually sited in the right iliac fossa
- End-colostomy is usually sited in the left iliac fossa
- Whenever possible patients should be counselled and sited by a stoma care nurse before their operation

Stoma bags and appliances

Stoma output is collected in disposable adhesive bags. Colostomy appliances are simply changed as necessary. A wide range of such bags is currently available. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

Complications of stomas

Stoma complications are common (***Summary box 77.16***). The vast majority of these complications can be dealt with by a suitably experienced stoma nurse but on occasion revision surgery is needed. Stoma ischaemia is usually evident in the early postoperative period and it is essential to inspect the stoma the day after surgery to assess mucosal viability. If the stoma looks ischaemic a proctoscope is useful to assess viability below the fascia. Urgent surgery is required if the mucosa below the fascia is also ischaemic. Conversely if the mucosa of the bowel immediately proximal to the stoma is viable, the patient can be managed expectantly in the hope that the non-viable mucosa will slough and the worst late result is a stenosis that can be managed with a more local procedure. This may be preferable to an immediate, difficult relaparotomy. Mucocutaneous separation can usually be managed conservatively with intensive stoma care.

Prolapse is more common in loop stomas, particularly transverse colon loop stomas. If recurrent and causing problems with stoma care the most effective solution is reversal. Other options include conversion to an end-stoma and/or resection of redundant bowel. Retraction is mostly a problem in obese patients and may require, what can sometimes be difficult, revision. Minor degrees of stenosis may respond to simple dilatation with more severe or recurrent issues requiring revision surgery.

Repair of parastomal hernias is particularly technically challenging and the recurrence rate is high. Simple sutured repair is associated with an almost 100% risk of recurrence and transfer to the opposite side of the abdomen, or insertion of a piece of prosthetic material within the abdominal wall around the stoma may be necessary. There is some evidence that stoma trephine reinforcement with mesh at the time of initial stoma formation may reduce the incidence of parastomal herniation, which may be as high as 50% over the long term. There are however complications associated with parastomal meshes including recurrence, mesh infection, fistulation and bowel obstruction.

Summary box 77.16

Stoma complications

- Skin irritation
- Prolapse
- Retraction
- Ischaemia
- Stenosis
- Parastomal hernia
- Bleeding
- Fistulation

PART 11 | Abdominal

CHAPTER 78

Intestinal obstruction

Learning objectives

To understand:

- The pathophysiology of dynamic and adynamic intestinal obstruction
- The cardinal features on history and examination
- The causes of small and large bowel obstruction
- The indications for surgery and other treatment options in bowel obstruction

CLASSIFICATION

Intestinal obstruction may be classified into two types:

- **Dynamic**, in which peristalsis is working against a mechanical obstruction. It may occur in an acute or a chronic form (*Figure 78.1*).
- **Adynamic**, in which there is no mechanical obstruction; peristalsis is absent or inadequate (e.g. paralytic ileus or pseudo-obstruction).

Summary box 78.1

Causes of intestinal obstruction

Dynamic

- Intraluminal
  - Faecal impaction
  - Foreign bodies
  - Bezoars
  - Gallstones
- Intramural
  - Stricture
  - Malignancy
  - Intussusception
  - Volvulus
- Extramural
  - Bands/adhesions
  - Hernia

Adynamic

- Paralytic ileus
- Pseudo-obstruction

PATHOPHYSIOLOGY

Irrespective of aetiology or acuteness of onset, in dynamic (mechanical) obstruction the bowel proximal to the obstruction dilates and the bowel below the obstruction exhibits normal peristalsis and absorption until it becomes empty and collapses. Initially, proximal peristalsis is increased in an attempt to overcome the obstruction. If the obstruction is not relieved, the bowel continues to dilate; ultimately there is a reduction in peristaltic strength, resulting in flaccidity and paralysis.

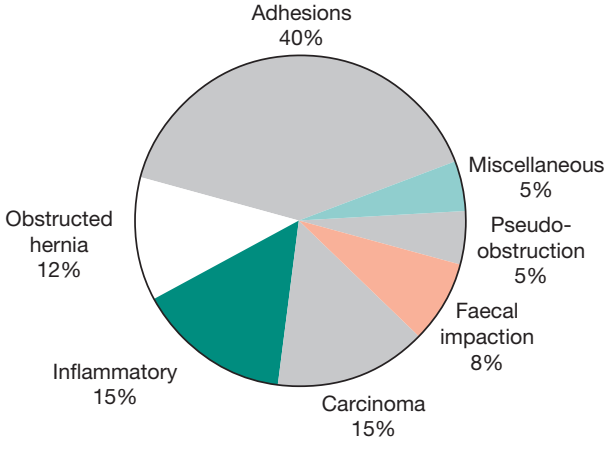

Figure 78.1 Pie chart showing the common causes of intestinal obstruction and relative frequencies.

The distension proximal to an obstruction is caused by two factors:

- **Gas**: there is a significant overgrowth of both aerobic and anaerobic organisms, resulting in considerable gas production. Following the reabsorption of oxygen and carbon dioxide, the majority is made up of nitrogen (90%) and hydrogen sulphide.
- **Fluid**: this is made up of the various digestive juices (saliva, 500 mL; bile, 500 mL; pancreatic secretions, 500 mL; gastric secretions, 1 litre; all per 24 hours). This accumulates in the gut lumen as absorption by the obstructed gut is retarded. Dehydration and electrolyte loss are therefore due to:
  - reduced oral intake;
  - defective intestinal absorption;
  - losses as a result of vomiting;
  - sequestration in the bowel lumen;
  - transudation of fluid into the peritoneal cavity.

STRANGULATION

It is important to appreciate that the consequences of intestinal obstruction are not immediately life-threatening unless there is superimposed strangulation. When strangulation occurs, the blood supply is compromised and the bowel becomes ischaemic.

Summary box 78.2

Causes of strangulation

Direct pressure on the bowel wall

- Hernial orifices
- Adhesions/bands

Interrupted mesenteric blood flow

- Volvulus
- Intussusception

Increased intraluminal pressure

- Closed-loop obstruction

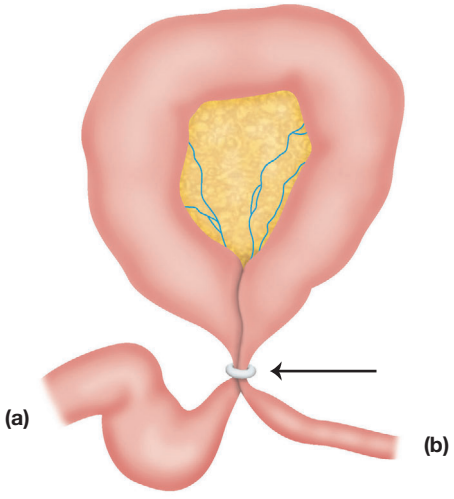

Figure 78.2 Distension. Closed-loop obstruction around a constricting band (arrow) with impending strangulation, mild distension of the proximal limb **(a)** and collapse of the distal limb **(b)** of small bowel.

Ischaemia from direct pressure on the bowel wall from a constricting band such as a hernial orifice is easy to understand.

Distension of the obstructed segment of bowel results in high pressure within the bowel wall. This can happen when only part of the bowel wall is obstructed, as seen in a Richter's hernia (see ***Chapter 64***). Venous return is compromised before the arterial supply. The resultant increase in capillary pressure leads to impaired local perfusion and, once the arterial supply is impaired, haemorrhagic infarction occurs. As the viability of the bowel is compromised, translocation and systemic exposure to anaerobic organisms and endotoxin occurs.

The morbidity and mortality associated with strangulation are largely dependent on the duration of the ischaemia and its extent. Elderly patients and those with comorbidities are more vulnerable to its effects. Although in strangulated external hernias the segment involved is often short, any length of ischaemic bowel can cause significant systemic effects secondary to sepsis. Bowel distension and fluid sequestration proximal to the obstruction can result in significant dehydration. When bowel involvement is extensive circulatory failure is common.

Closed-loop obstruction

This occurs when the bowel is obstructed at both the proximal and distal points (***Figure 78.2***). The distension is principally confined to the closed loop; distension proximal to the obstructed segment is not typically marked.

A classic form of closed-loop obstruction is seen in the presence of a malignant stricture of the colon with a competent ileocaecal valve (present in up to one-third of individuals). This can occur with lesions as far distally as the rectum. The inability of the distended colon to decompress itself into the small bowel results in an increase in luminal pressure, which is greatest at the caecum, with subsequent impairment of blood flow in the wall. Unrelieved, this results in necrosis and perforation (***Figure 78.3***).

SPECIAL TYPES OF MECHANICAL INTESTINAL OBSTRUCTION

Internal hernia

Internal herniation occurs when a portion of the small intestine becomes entrapped in one of the retroperitoneal fossae or in a congenital mesenteric defect.

The following are potential sites of internal herniation (all are very rare):

- the foramen of Winslow;
- a defect in the mesentery;
- a defect in the transverse mesocolon;
- defects in the broad ligament;
- congenital or acquired diaphragmatic hernia;
- duodenal retroperitoneal fossae;
- caecal/appendiceal retroperitoneal fossae;
- intersigmoid fossa.

Internal herniation in the absence of adhesions is rare and a preoperative diagnosis is unusual. The standard treatment of an obstructed hernia is to release the constricting agent by division. This should not be undertaken in cases of herniation involving the foramen of Winslow, mesenteric defects and paraduodenal/duodenojejunal fossae as major blood vessels run in the edge of the constriction ring. The distended loop in such circumstances must first be decompressed (minimising contamination) and then reduced.

August Gottlieb Richter, 1742–1812, lecturer in surgery, Göttingen, Germany, described this form of hernia in 1777.
Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic and Surgery, Paris, France.

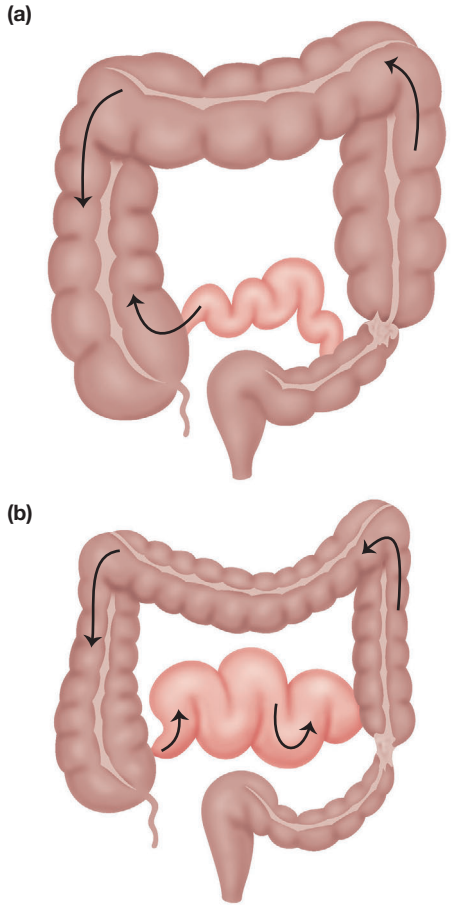

Figure 78.3 Obstructing stricture of the distal descending colon in the presence of **(a)** a competent ileocaecal valve, resulting in gross caecal distension, and **(b)** an incompetent ileocaecal valve, allowing decompression into the distal small bowel without gross caecal distension.

Obstruction from enteric strictures

Small bowel strictures usually occur secondary to tuberculosis or Crohn's disease. Malignant strictures associated with lymphoma are uncommon; carcinoma and sarcoma are rare. Presentation is usually subacute or chronic. Standard surgical management consists of resection and anastomosis. Resection is important to establish a histological diagnosis as this can be uncertain clinically. In Crohn's disease, strictureplasty may be considered in the presence of short multiple strictures without active sepsis (see ***Chapter 75***).

Bolus obstruction

Bolus obstruction in the small bowel may be caused by gallstones, food, trichobezoar, phytobezoar, stercoliths and worms.

Gallstones

This type of obstruction tends to occur in the elderly secondary to erosion of a large gallstone directly through the gallbladder into the duodenum. Classically, there is impaction about 60 cm proximal to the ileocaecal valve. The patient may have recurrent attacks as the obstruction may be incomplete or relapsing as a result of a ball-valve effect. The characteristic radiological sign of gallstone ileus is Rigler's triad, comprising: small bowel obstruction, pneumobilia and an atypical mineral shadow on radiographs of the abdomen. The presence of two of these radiological signs has been considered pathognomonic of gallstone ileus and is encountered in 40–50% of the cases (note that pneumobilia is a common finding following endoscopic retrograde cholangiopancreatography with sphincterotomy). At laparotomy, the stone should be milked proximally away from the site of impaction. It may be possible to crush the stone within the bowel lumen; if not, the intestine is opened at this point and the gallstone removed. If the gallstone is faceted, a careful check for other enteric stones should be made. The region of the gallbladder should not be explored (see ***Chapter 71***).

Food

Bolus obstruction may occur after partial or total gastrectomy when unchewed articles can pass directly into the small bowel. Fruit and vegetables are particularly liable to cause obstruction. The management is similar to that for gallstones, with intraluminal crushing usually being successful.

Trichobezoars and phytobezoars

These are firm masses of undigested hair ball and fruit/vegetable fibre, respectively. The former is due to persistent hair chewing or sucking and may be associated with an underlying psychiatric abnormality. Predisposition to phytobezoars results from a high fibre intake, inadequate chewing, previous gastric surgery, hypochlorhydria and loss of the gastric pump mechanism. When possible, the lesion may be kneaded into the caecum; otherwise, open removal is required. A preoperative diagnosis is difficult even with high-resolution computed tomography (CT) scanning.

Stercoliths

These are usually found in the small bowel in association with a jejunal diverticulum or ileal stricture. Presentation and management are identical to that of gallstones.

Worms

Ascaris lumbricoides may cause low small bowel obstruction, particularly in children, the institutionalised and those near the tropics. An attack may follow the initiation of anthelmintic therapy. Debility is frequently out of proportion to that produced by the obstruction. If worms are not seen in the stool or vomitus the diagnosis may be indicated by eosinophilia or the sight of worms within gas-filled small bowel loops on a plain radiograph. At laparotomy it may be possible to knead the tangled mass into the caecum; if not, it should be removed. Occasionally, worms may cause a perforation and peritonitis, especially if the enteric wall is weakened by such conditions as amoebiasis (see ***Chapter 6***).

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.
Leo George Rigler, 1896–1979, Professor of Radiology, University of California, Los Angeles, CA, USA.

Obstruction by adhesions and bands

Adhesions

In western countries adhesions and bands are the most common cause of intestinal obstruction. The lifetime risk of requiring an admission to hospital for adhesional small bowel obstruction subsequent to abdominal surgery is approximately 4% and the risk of requiring a laparotomy around 2%. Adhesions start to form within hours of abdominal surgery. In the early postoperative period, the onset of such a mechanical obstruction may be difficult to differentiate from paralytic ileus.

The causes of intraperitoneal adhesions are shown in *Table 78.1*. Any source of peritoneal irritation results in local fibrin production, which produces adhesions between apposed surfaces. Early fibrinous adhesions may disappear when the cause is removed or they may become vascularised and be replaced by mature fibrous tissue.

There are several factors that may limit adhesion formation.

TABLE 78.1 The common causes of intra-abdominal adhesions.

Acute inflammation	Sites of anastomoses, reperitonealisation of raw areas, trauma, ischaemia
Foreign material	Talc, starch, gauze, silk
Infection	Peritonitis, tuberculosis
Chronic inflammatory conditions	Crohn's disease
Radiation enteritis	

Summary box 78.3

Prevention of adhesions

Factors that may limit adhesion formation include:

- Good surgical technique
- Washing of the peritoneal cavity with saline to remove clots
- Minimising contact with gauze
- Covering anastomoses and raw peritoneal surfaces

Numerous substances have been instilled in the peritoneal cavity to prevent adhesion formation, including hyaluronidase, hydrocortisone, silicone, dextran, polyvinylpropylene (PVP), chondroitin, streptomycin, anticoagulants, antihistamines, non-steroidal anti-inflammatory drugs and streptokinase. Currently, no single agent or combination of agents has been convincingly shown to be effective. It is hoped that with more widespread use of laparoscopic surgery the incidence of intra-abdominal adhesions will reduce.

Adhesions may be classified into various types by virtue of whether they are early (fibrinous) or late (fibrous) or by underlying aetiology. From a practical perspective there are only two types: 'easy' flimsy ones and 'difficult' dense ones (*Figure 78.4*).

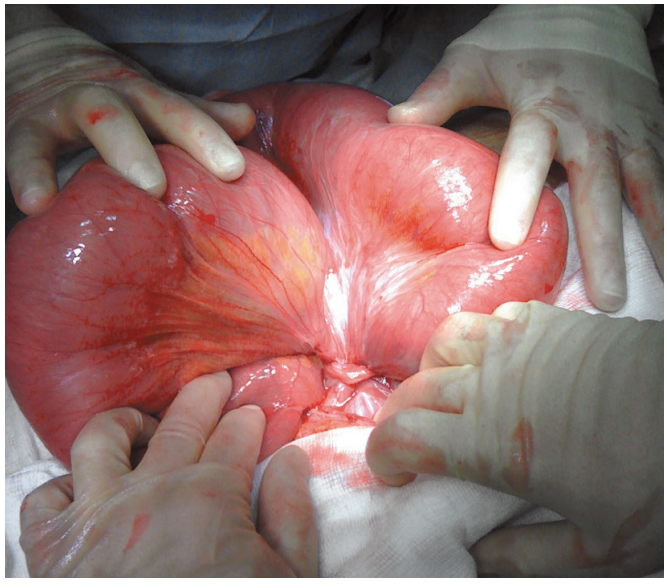

Figure 78.4 Band adhesion causing a closed-loop obstruction.

Postoperative adhesions giving rise to intestinal obstruction usually involve the lower small bowel and less commonly the large bowel.

Bands

Usually only one band is culpable. This may be:

- congenital, e.g. obliterated vitellointestinal duct;
- a string band following previous abdominal surgery or peritoneal inflammation;
- a portion of greater omentum, usually adherent to the parietes.

Acute intussusception

This occurs when one portion of the gut invaginates into an immediately adjacent segment; almost invariably, it is the proximal into the distal.

The condition is encountered most commonly in children, with a peak incidence between 5 and 10 months of age. About 90% of cases are idiopathic but an associated upper respiratory tract infection or gastroenteritis may precede the condition. It is believed that hyperplasia of Peyer's patches in the terminal ileum may be the initiating event. Weaning, loss of passively acquired maternal immunity and common viral pathogens have all been implicated in the pathogenesis of intussusception in infancy (see *Chapter 17*).

Children with intussusception associated with a pathological lead point such as Meckel's diverticulum, polyp, duplication, Henoch–Schönlein purpura or appendix are usually older than those with idiopathic disease. After the age of 2 years, a

Johann Conrad Peyer, 1653–1782, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.
Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.
Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, gave his account of this disease in 1837.

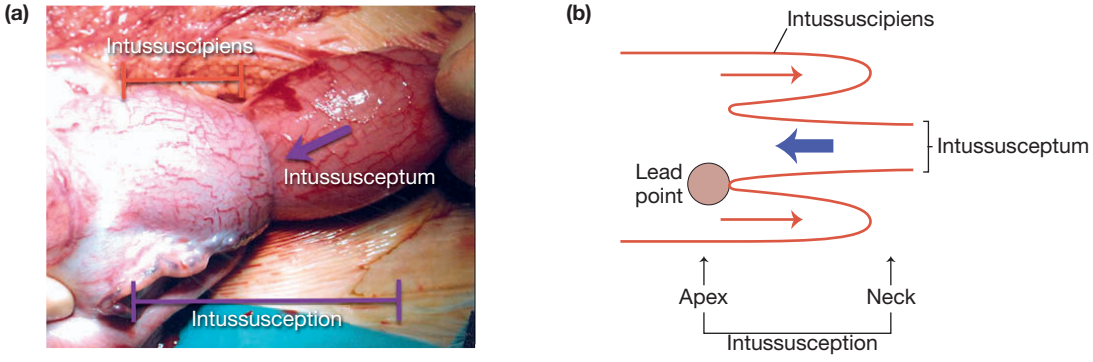

Figure 78.5 Small bowel intussusception showing components: intussusceptum (purple arrow); intussuscipiens; lead point; middle tube (red arrows).

pathological lead point is found in at least one-third of affected children. In adults, cases are almost invariably associated with a lead point, which is usually a polyp (e.g. Peutz–Jeghers syndrome), a submucosal lipoma or other tumour.

The phenomenon of transient intussusception in younger patients is now recognised. Imaging of the small bowel (with CT scanning, capsule endoscopy or enteroscopy) is required to exclude intraluminal disease.

Pathology

An intussusception is composed of three parts (***Figure 78.5***):

- the entering or inner tube (intussusceptum);
- the returning or middle tube;
- the sheath or outer tube (intussuscipiens).

The part that advances is the apex, the mass is the intussusception and the neck is the junction of the entering layer with the mass.

Intussusception may be anatomically defined according to the site and extent of invagination (***Table 78.2***). In most children, the intussusception is ileocolic. In adults, colocolic intussusception is more common. The degree of ischaemia is dependent on the tightness of invagination, which is usually greatest as it passes through the ileocaecal valve.

TABLE 78.2 Types of intussusception in children (after RE Gross) (n = 702).

	Percentage of series
Ileoileal	5
Ileocolic	77
Ileoileocolic	12
Colocolic	2
Multiple	1
Retrograde	0.2
Others	2.8

On CT scanning the target sign may be evident and, if present, is pathognomonic (***Figure 78.6***). It is worth noting that occasionally an asymptomatic intussusception can be observed on CT scanning in adults. This may be transient or intermittent.

Summary box 78.4

Intussusception

- Most common in children
- Adult cases are secondary to intestinal pathology, e.g. polyp, Meckel's diverticulum
- Ileocolic is the most common variety
- Can lead to an ischaemic segment
- Radiological reduction is indicated in most paediatric cases
- Adults who present acutely require surgery

Figure 78.6 Abdominal computed tomography scan illustrating the 'target sign' of the ileocolic intussusception seen in ***Figure 78.5***.

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John's Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.
Robert Edward Gross, 1905–1988, paediatric surgeon, Harvard Medical School, Boston, MA, USA.

Volvulus

A volvulus is a twisting or axial rotation of a portion of bowel about its mesentery. The rotation causes obstruction to the lumen (>180° torsion) and if tight enough also causes vascular occlusion in the mesentery (>360° torsion). Bacterial fermentation adds to distension and increasing intraluminal pressure impairs capillary perfusion. Mesenteric veins become obstructed as a result of the mechanical twisting; thrombosis results and contributes to ischaemia.

Volvuli may be primary or secondary. The primary form is caused by congenital malrotation of the gut, abnormal mesenteric attachments or congenital bands. Examples include volvulus neonatorum, caecal volvulus and sigmoid volvulus (see *Chapter 65*). A secondary volvulus, which is the more common variety, is due to rotation of a segment of bowel around an acquired adhesion or stoma.

Summary box 78.5

Volvulus

- May involve the small intestine, caecum or sigmoid colon
- Neonatal midgut volvulus secondary to midgut malrotation is life-threatening
- The most common spontaneous type in adults is sigmoid volvulus
- Sigmoid volvulus can be relieved by decompression per anum
- Surgery may be required to prevent or relieve ischaemia

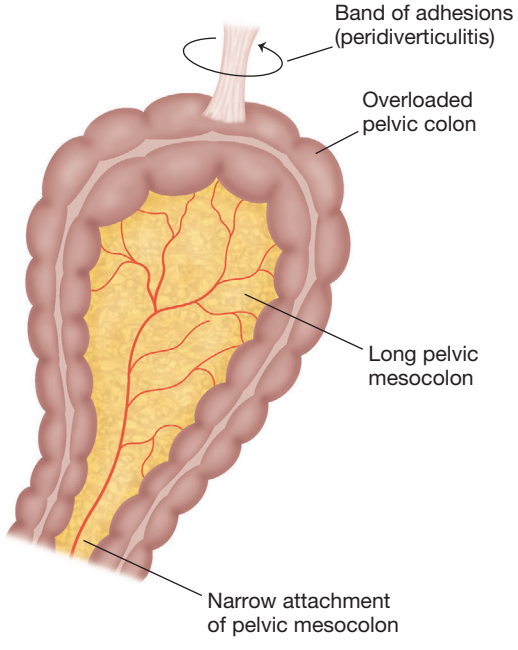

Figure 78.7 Causes predisposing to volvulus of the sigmoid colon. Idiopathic megacolon usually precedes the volvulus in African people.

Volvulus neonatorum

This occurs secondary to intestinal malrotation (see *Chapters 17 and 65*) and is potentially catastrophic.

Sigmoid volvulus

This is uncommon in Europe and the USA but more common in eastern Europe and Africa. Indeed, it is the most common cause of large bowel obstruction in the indigenous black African population. Rotation nearly always occurs in the anticlockwise direction. The predisposing clinical features are summarised in *Figure 78.7*. Other predisposing factors include a high-residue diet and constipation. In western populations, the condition is seen most often in elderly patients with chronic constipation; comorbidities are common and chronic psychotropic drug use is associated with this condition. Younger patients present earlier and the prognosis is inversely related to the duration of symptoms.

Presentation with volvulus can be classified as:

- **fulminant**: sudden onset, severe pain, early vomiting, rapidly deteriorating clinical course;
- **indolent**: insidious onset, slow progressive course, less pain, late vomiting.

Compound volvulus

This is a rare condition that is also known as ileosigmoid knotting. The long pelvic mesocolon allows the ileum to twist around the sigmoid colon, resulting in gangrene of either or both segments of bowel. The patient presents with acute intestinal obstruction, but distension is comparatively mild. Plain radiography reveals distended ileal loops in a distended sigmoid colon. At operation, decompression, resection and anastomosis are required.

CLINICAL FEATURES OF INTESTINAL OBSTRUCTION

Dynamic obstruction

The diagnosis of dynamic intestinal obstruction is based on the classic quartet of pain, distension, vomiting and absolute constipation. Obstruction may be classified clinically into two types:

- small bowel obstruction – high or low;
- large bowel obstruction.

The nature of the presentation will also be influenced by whether the obstruction is:

- complete;
- incomplete.

A complete small bowel obstruction has all the cardinal features. In cases of complete large bowel obstruction there is often a surprising lack of preceding symptoms. Both small and large bowel obstruction can present with more chronic symptoms in which the symptoms and signs are intermittent or the obstruction is incomplete. Incomplete obstruction is also referred to as partial or subacute.

Summary box 78.6

Features of obstruction

- In **high small bowel obstruction**, vomiting occurs early, is profuse and causes rapid dehydration. Distension is minimal with little evidence of dilated small bowel loops on abdominal radiography
- In **low small bowel obstruction**, pain is predominant with central distension. Vomiting occurs later. Multiple dilated small bowel loops are seen on radiography
- In **large bowel obstruction**, distension is early and pronounced. Pain is less severe and vomiting and dehydration are later features. The colon proximal to the obstruction is distended on abdominal radiography. The small bowel will be dilated if the ileocaecal valve is incompetent (***Figure 78.3***)

Summary box 78.7

Cardinal clinical features of acute obstruction

- Abdominal pain
- Distension
- Vomiting
- Absolute constipation

Presentation will be further influenced by whether the obstruction is:

- simple – in which the blood supply is intact;
- strangulating/strangulated – in which there is interference to blood flow.

The common causes of intestinal obstruction in western countries and their relative frequencies are shown in ***Figure 78.1***. The underlying mechanisms are shown in ***Summary box 78.2***.

The clinical features vary according to:

- the location of the obstruction;
- the duration of the obstruction;
- the underlying pathology;
- the presence or absence of intestinal ischaemia.

Late manifestations of intestinal obstruction that may be encountered include dehydration, oliguria, hypovolaemic shock, pyrexia, septicaemia, respiratory embarrassment and peritonism. In all cases of suspected intestinal obstruction, the hernial orifices must be examined.

Pain

Pain is the first symptom encountered; it occurs suddenly and is usually severe. It is colicky in nature and usually centred on the umbilicus (small bowel) or lower abdomen (large bowel) (see ***Chapter 63***). The pain coincides with increased peristaltic activity. With increasing distension, the colicky pain is replaced by a more constant diffuse pain. If there is no ischaemia and the obstruction persists over several days, pain reduces and can disappear.

The development of severe pain is suggestive of strangulation, especially if the pain is continuous. Beware the patient whose pain is not controlled with intravenous opiates. Colicky pain may not be a significant feature in postoperative simple mechanical obstruction and colicky pain does not usually occur in paralytic ileus.

Vomiting

The more distal the obstruction, the longer the interval between the onset of symptoms and the appearance of nausea and vomiting. As obstruction progresses the character of the vomitus alters from digested food to faeculent material, as a result of enteric bacterial overgrowth.

Distension

In the small bowel the degree of distension is dependent on the site of the obstruction and is greater the more distal the lesion. Visible peristalsis may be present in thin patients (***Figure 78.8***). This can sometimes be provoked by 'flicking' the abdominal wall. Distension is a later feature in colonic obstruction and may be minimal or absent in the presence of mesenteric vascular occlusion.

Constipation

This may be classified as absolute (i.e. neither faeces nor flatus is passed) or relative (where only flatus is passed). Absolute constipation is a cardinal feature of complete intestinal obstruction. Some patients may pass flatus or faeces after the onset of obstruction as a result of the evacuation of the distal bowel contents. The administration of enemas should be avoided in cases of suspected obstruction. This merely stimulates evacuation of bowel contents distal to the obstruction and confuses the clinical picture.

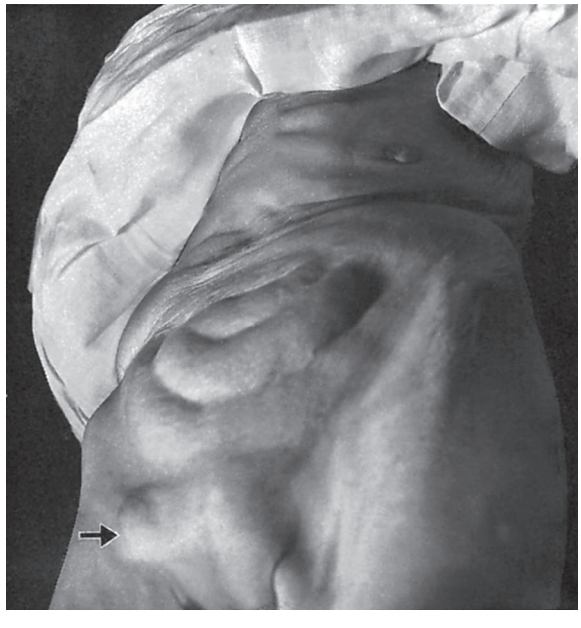

Figure 78.8 Visible peristalsis. Intestinal obstruction due to a strangulated right femoral hernia (arrow).

The rule that absolute constipation is present in intestinal obstruction does not apply in:

- Richter's hernia;
- gallstone ileus;
- mesenteric vascular occlusion;
- functional obstruction associated with pelvic abscess;
- all cases of partial obstruction (in which diarrhoea may occur).

Other manifestations

Dehydration

Dehydration is seen most commonly in small bowel obstruction because of repeated vomiting and fluid sequestration. It results in dry skin and tongue, poor venous filling and sunken eyes with oliguria. The blood urea level and haematocrit rise, giving a secondary polycythaemia.

Hypokalaemia

Hypokalaemia is not a common feature in simple mechanical obstruction. An increase in serum potassium, amylase or lactate dehydrogenase may be associated with the presence of strangulation, as may leukocytosis or leukopenia.

Pyrexia

Pyrexia in the presence of obstruction may indicate:

- the onset of ischaemia;
- intestinal perforation;
- inflammation or abscess associated with the obstructing disease.

Hypothermia indicates septicaemic shock or neglected cases of long duration.

Abdominal tenderness

Localised tenderness indicates impending or established ischaemia. The development of peritonism or peritonitis indicates impending or established infarction and/or perforation. In cases of large bowel obstruction, it is important to elicit these findings in the right iliac fossa as the caecum is most vulnerable to ischaemia.

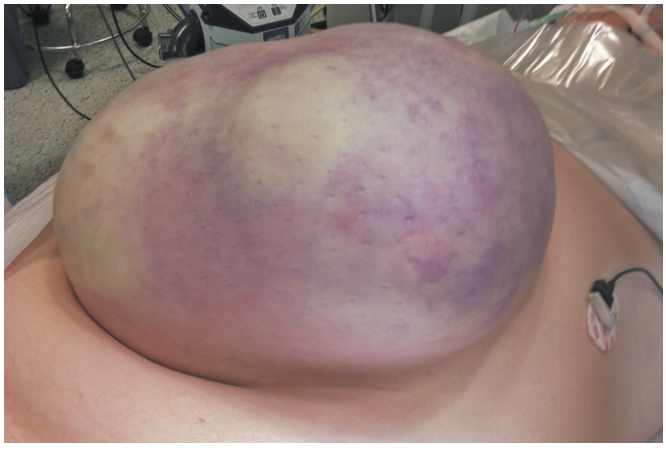

Figure 78.9 Skin discoloration over a strangulated incisional hernia.

Figure 78.10 Ischaemic small and large bowel in a strangulated incisional hernia.

Bowel sounds

High-pitched bowel sounds are present in the vast majority of patients with intestinal obstruction. Normal bowel sounds are of negative predictive value. Bowel sounds may be scanty or absent if the obstruction is longstanding and the small bowel has become inactive.

Clinical features of strangulation

It is vital to distinguish strangulating from non-strangulating intestinal obstruction because the former is a surgical emergency. The diagnosis is clinical but may be aided by CT scanning as long as this does not delay surgical intervention.

Summary box 78.8

Clinical features of strangulation

- Constant pain, severe pain
- Tenderness with rigidity and peritonism
- Shock

In addition to the features in ***Summary box 78.8***, it should be noted that:

- The presence of shock suggests underlying ischaemia.
- In impending or established strangulation, pain is never completely absent.
- The presence and character of any local tenderness are of great significance and, however mild, tenderness requires frequent reassessment.
- Generalised tenderness and the presence of rigidity indicates the need for early laparotomy.
- When pain persists despite conservative management, even in the absence of the above signs, strangulation should be presumed.
- When strangulation occurs in an external hernia, the lump is tense, tender and irreducible and there is no expansile cough impulse. Skin changes with erythema or purplish discoloration are associated with underlying ischaemia (***Figures 78.9 and 78.10***).

Clinical features of intussusception

The classic presentation of intussusception is with episodes of screaming and drawing up of the legs in a previously well male infant. The attacks last for a few minutes and recur repeatedly. During attacks the child appears pale and between episodes may be listless. Vomiting may or may not occur at the outset but becomes conspicuous and bile-stained with time. Initially, the passage of stool may be normal, whereas, later, blood and mucus are evacuated – the 'redcurrant jelly' stool.

Whenever possible, examination should be undertaken between episodes of colic, without disturbing the child. Classically, the abdomen is not initially distended; a lump that hardens on palpation may be discerned but this is present in only 60% of cases (***Figure 78.11***). There may be an associated feeling of emptiness in the right iliac fossa (the sign of Dance). On rectal examination, blood-stained mucus may be found on the finger. Occasionally, in extensive ileocolic or colocolic intussusception, the apex may be palpable or even protrude from the anus.

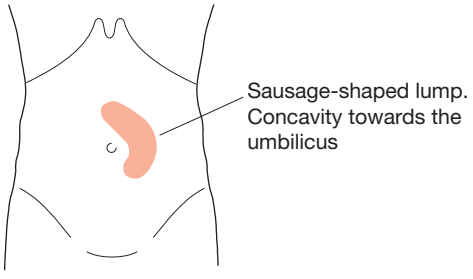

Figure 78.11 The physical signs as recorded by Hamilton Bailey in a typical case of intussusception in an infant.

Unrelieved, progressive dehydration and abdominal distension from small bowel obstruction will occur, followed by peritonitis secondary to gangrene. Rarely, natural cure may occur as a result of sloughing of the intussusception.

Differential diagnosis

Acute gastroenteritis

Although abdominal pain and vomiting are common in acute gastroenteritis, with occasional blood and mucus in the stool, diarrhoea is a leading symptom and faecal matter or bile is always present in the stool.

Henoch–Schönlein purpura

Henoch–Schönlein purpura is associated with a characteristic rash and abdominal pain; intussusception may occur.

Clinical features of volvulus

Volvulus of the small intestine

This may be primary or secondary and usually occurs in the lower ileum. It may occur spontaneously in African people, particularly following the consumption of a large volume of vegetable matter, whereas in western countries it is usually secondary to adhesions passing to the parietes or female pelvic organs.

Caecal volvulus

This may occur as part of volvulus neonatorum or *de novo* and is usually a clockwise twist. It is more common in females in the fourth and fifth decades and usually presents acutely with the classic features of obstruction. Ischaemia is common. At first the obstruction may be partial, with the passage of flatus and faeces. In 25% of cases, examination may reveal a palpable tympanic swelling in the midline or left side of the abdomen. The volvulus typically results in the caecum lying in the left upper quadrant. The diagnosis is not usually made preoperatively.

Sigmoid volvulus

The symptoms are of large bowel obstruction. Presentation varies in severity and acuteness, with younger patients appearing to develop the more acute form. Abdominal distension is an early and progressive sign, which may be associated with hiccough and retching. Constipation is absolute. In the elderly, a more chronic form may be seen. In some patients the grossly distended torted left colon is visible through the abdominal wall.

IMAGING

Erect abdominal films are no longer routinely obtained and the radiological diagnosis is based on a supine abdominal film (***Figure 78.12***). An erect film may subsequently be requested when further doubt exists.

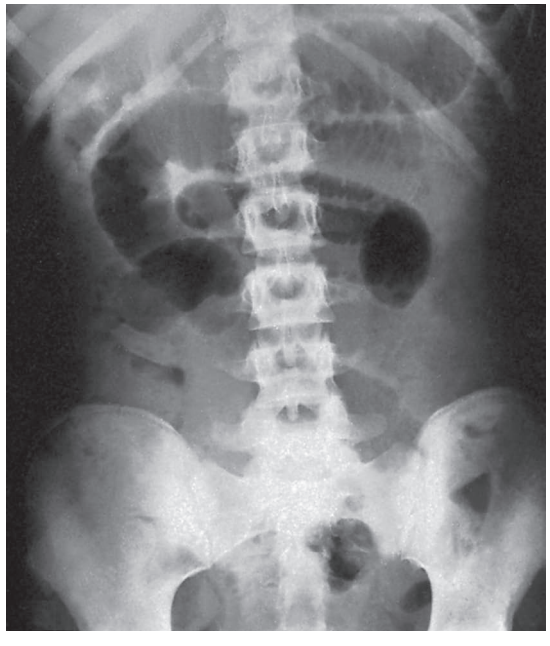

Figure 78.12 Gas-filled small bowel loops illustrating valvulae conniventes; patient supine.

Henry Hamilton Bailey, 1894–1961, surgeon, The Royal Northern Hospital, London, UK.
Jean Baptiste Hippolyte Dance, 1797–1832, physician, Hôpital Cochin, Paris, France.

When distended with gas, the jejunum, ileum, caecum and remaining colon have a characteristic appearance in adults and older children that allows them to be distinguished radiologically.

Summary box 78.9

Radiological features of obstruction (on plain radiograph)

- The obstructed small bowel is characterised by straight segments that are generally central and lie transversely. No/minimal gas is seen in the colon
- The jejunum is characterised by its valvulae conniventes, which completely pass across the width of the bowel and are regularly spaced, giving a 'concertina' or ladder effect
- Ileum – the distal ileum is featureless
- A distended caecum appears as a rounded gas shadow in the right iliac fossa
- Large bowel, except for the caecum, shows haustral folds, which, unlike valvulae conniventes, are spaced irregularly, do not cross the whole diameter of the bowel and do not have indentations placed opposite one another
- Small bowel fluid levels may be seen on an erect abdominal radiograph

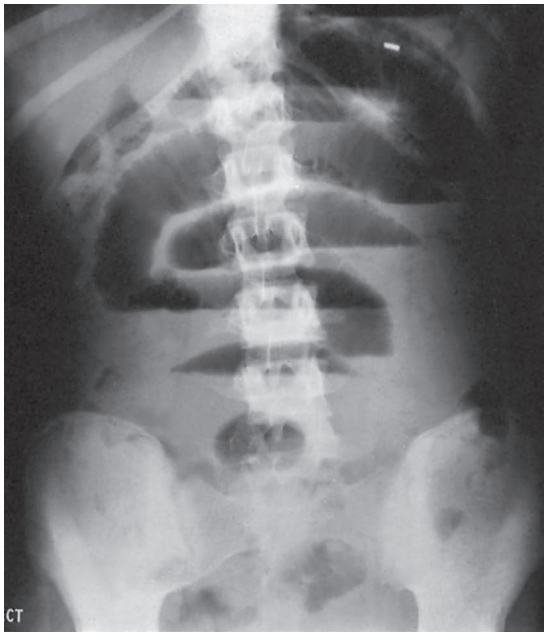

Figure 78.13 Fluid levels with gas above; 'stepladder pattern'. Ileal obstruction caused by adhesions (erect abdominal radiograph).

Fluid levels seen radiologically appear later than gas shadows as it takes time for gas and fluid to separate (***Figure 78.13***). These are most prominent on an erect abdominal radiograph or cross-sectional imaging. In adults, two inconstant fluid levels – one at the duodenal cap and the other in the terminal ileum – may be regarded as normal. In infants (less than 1 year old), a few fluid levels in the small bowel may be physiological. In this age group it is difficult to distinguish large from small bowel in the presence of obstruction because the characteristic features seen in adults are not present or are unreliable.

During the obstructive process, fluid levels become more conspicuous and more numerous when paralysis has occurred. When fluid levels are pronounced, the obstruction is advanced. In the small bowel, the number of fluid levels is directly proportional to the degree of obstruction and to its site, the number increasing the more distal the lesion.

In patients without evidence of strangulation there is a role for other imaging modalities. The appearance of contrast in the colon 4–24 hours after administration of 50–100 mL of water-soluble contrast agent had a sensitivity of 96% and a specificity of 98% in predicting resolution of small bowel obstruction. If contrast does not reach the colon, surgery is required in approximately 90% of patients. Administration of a water-soluble agent was also effective in reducing the need for surgery and shortening the duration of hospital stay.

Low colonic obstruction does not commonly give rise to small bowel fluid levels unless advanced, whereas high colonic obstruction may do so in the presence of an incompetent ileocaecal valve. Colonic obstruction is usually associated with a large amount of gas in the caecum. A limited water-soluble enema can be undertaken to differentiate large bowel obstruction from pseudo-obstruction. A barium follow-through is contraindicated in the presence of acute obstruction and may be life-threatening.

CT scanning is now used very widely to investigate all forms of intestinal obstruction. It is highly accurate and its only limitations are in diagnosing ischaemia. Two features may be helpful when looking for intestinal ischaemia: reduced enhancement of the bowel wall and absence of mesenteric oedema. It is important to remember that, even with the best imaging techniques, the diagnosis of strangulation remains primarily clinical.

Summary box 78.10

CT features of strangulation

- Reduced bowel wall enhancement on CT increases the probability of strangulation
- Absence of mesenteric fluid on CT decreases the probability of strangulation
- The clinical reliability of other CT signs is doubtful for predicting strangulation

Impacted foreign bodies may be seen on abdominal radiographs. It is noteworthy that gas-filled loops and fluid levels in the small and large bowel can also be seen in established paralytic ileus and pseudo-obstruction (see ***Chapter 73***). The former can, however, normally be distinguished on clinical grounds whereas the latter can be confirmed radiologically. Fluid levels may also be seen in non-obstructing conditions such as gastroenteritis, acute pancreatitis and intra-abdominal sepsis.

Imaging in intussusception

A plain abdominal field usually reveals evidence of small or large bowel obstruction with an absent caecal gas shadow in

ileocolic cases. A soft-tissue opacity is often visible in children. A barium enema may be used to diagnose the presence of an ileocolic intussusception but does not demonstrate small bowel intussusception. Abdominal ultrasonography has a high diagnostic sensitivity in children, demonstrating the typical doughnut appearance of concentric rings in transverse section. CT scanning is currently considered the most sensitive radiological method to confirm intussusception, with a reported diagnostic accuracy of 58–100%. The characteristic features of CT scan include a 'target'- or 'sausage'-shaped soft-tissue mass with a layering effect (***Figure 78.6***); mesenteric vessels within the bowel lumen are also typical.

Imaging in volvulus

- In caecal volvulus, radiological abnormalities are identifiable in nearly all patients but are often non-specific, with caecal dilatation (98–100%), a single air–fluid level (72–88%), small bowel dilatation (42–55%) and absence of gas in distal colon (82–91%) reported as the most common abnormalities. A barium enema may be used to confirm the diagnosis if there are no concerns about ischaemia, with an absence of barium in the caecum and a bird's beak deformity. CT scanning is now the imaging of choice.
- In sigmoid volvulus, a plain radiograph shows massive colonic distension. The classic appearance is of a dilated loop of bowel; the two limbs are seen running diagonally across the abdomen from right to left (***Figure 78.14***) with two fluid levels seen, one within each loop of bowel (if an erect film is taken).
- In volvulus neonatorum, the abdominal radiograph shows a variable appearance. Initially, it may appear normal or show evidence of duodenal obstruction but, as the intestinal strangulation progresses, the abdomen becomes relatively gasless.

TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

There are three main measures used to treat acute intestinal obstruction.

Summary box 78.11

Treatment of acute intestinal obstruction

- Gastrointestinal drainage via a nasogastric tube
- Fluid and electrolyte replacement
- Relief of obstruction
- Surgical treatment is necessary for most cases of intestinal obstruction but should be delayed until resuscitation is complete, provided there is no sign of strangulation or evidence of closed-loop obstruction

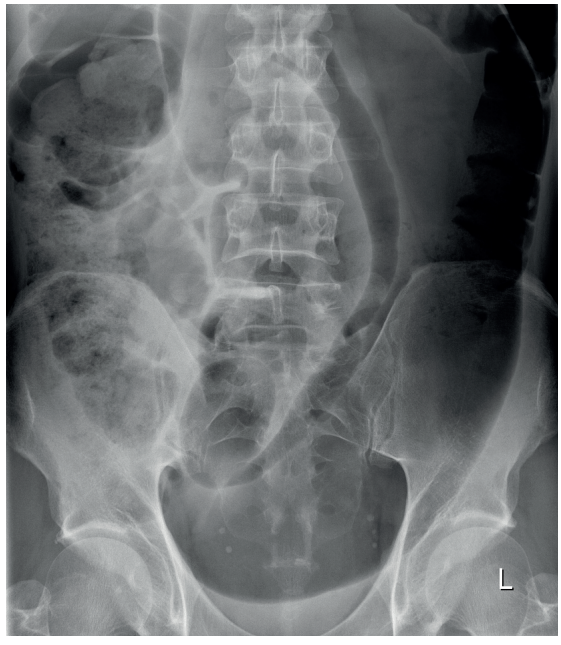

Figure 78.14 Supine abdominal radiograph showing sigmoid volvulus.

The first two steps are always necessary before attempting surgical relief of obstruction and are the mainstay of postoperative management.

Summary box 78.12

Principles of surgical intervention for obstruction

Management of:

- The segment at the site of obstruction
- The distended proximal bowel
- The underlying cause of obstruction

Supportive management

Nasogastric decompression is achieved by the passage of a non-vented (Ryle) or vented (Salem) tube. The tubes are normally placed on free drainage with 4-hourly aspiration but may be placed on continuous or intermittent suction. As well as facilitating decompression proximal to the obstruction, they are essential to reducing the risk of subsequent aspiration during induction of anaesthesia and after extubation.

The basic biochemical abnormality in intestinal obstruction is sodium and water loss, and therefore the appropriate replacement is Hartmann's solution or normal saline. The volume required varies and should be determined by clinical haematological and biochemical criteria.

John Alfred Ryle, 1889–1950, Regius Professor of Physic, University of Cambridge, and later Professor of Social Medicine, University of Oxford, UK, introduced the Ryle's tube in 1921.

Henri Albert Charles Antoine Hartmann, 1860–1952, Professor of Clinical Surgery, University of Paris, Paris, France.

Surgical treatment

The timing of surgical intervention is dependent on the clinical picture. There are several indications for early surgical intervention.

Summary box 78.13

Indications for early surgical intervention

- Obstructed external hernia
- Clinical features of intestinal strangulation
- Obstruction in a previously unoperated abdomen

The classic clinical advice that 'the Sun should not both rise and set' on a case of unrelieved acute intestinal obstruction was based on the concern that intestinal ischaemia would develop while the patient was waiting for surgery. If there is complete obstruction, but no evidence of intestinal ischaemia, it is reasonable to defer surgery until the patient has been adequately resuscitated. Where obstruction is likely to be secondary to adhesions, conservative management may be continued for up to 72 hours in the hope of spontaneous resolution.

If the site of obstruction is unknown, adequate exposure is best achieved by a midline laparotomy incision. Assessment is directed to:

- the site of the obstruction;
- the nature of the obstruction;
- the viability of the gut.

In cases of small bowel obstruction, the first manoeuvre is to deliver the distended small bowel into the wound. This permits access to the site of obstruction. The small bowel should be covered with moist swabs and the weight of the fluid-filled bowel supported such that the blood supply to the mesentery is not impaired.

Operative decompression should be performed whenever possible. The simplest and safest method is to insert a large-bore orogastric tube and to milk the small bowel contents in a retrograde manner to the stomach for aspiration. Great care must be taken not to tear the mesentery or injure the small bowel, which will be distended and oedematous. It is important to ensure that the stomach is empty at the end of the procedure to reduce the incidence of postoperative aspiration. Decompression using Savage's decompressor within a seromuscular purse-string suture may be required. Its benefits should be balanced against the potential risk of septic complications from spillage and the risk of leakage from the suture line postoperatively.

The type of surgical procedure required will depend upon the cause of obstruction: division of adhesions (enterolysis), excision, bypass or proximal decompression. If resection is performed, Savage's decompressor can be inserted into this segment to obviate the risk of a suture line.

Following relief of obstruction, the viability of the involved bowel should be carefully assessed (***Table 78.3***). Although frankly infarcted bowel is obvious, viability in many cases may be difficult to discern. If in doubt, the bowel should be wrapped in hot packs for 10 minutes and then reassessed. The state of the mesenteric vessels and pulsation in adjacent arcades should be sought. Viability is also confirmed by colour, sheen and peristalsis. If, at the end of this period, there is still uncertainty about bowel viability, it should be resected unless there is concern that the extent of resection may lead to short bowel syndrome (see ***Chapter 74***). In which case, or in the case of a critically unwell patient, consideration should be given to resecting necrotic bowel and raising both residual ends as stomas. This avoids anastomosis in unfavourable circumstances. When no resection has been undertaken or there are multiple ischaemic areas (mesenteric vascular occlusion), a second-look laparotomy at 24–48 hours may be required.

Intestinal ischaemia/reperfusion injury has been described following reperfusion of ischaemic bowel with remote lung injury resulting from the release of inflammatory mediators. This should be borne in mind when dealing with ischaemic bowel. For example, if there is a volvulus with established infarction, detorsion should be avoided until the affected mesentery has been clamped and thus reperfusion injury prevented.

TABLE 78.3 Differentiation between viable and non-viable intestine.

	Viable	Non-viable
Circulation	Dark colour becomes lighter Visible pulsation in mesenteric arteries	Dark colour remains No detectable pulsation
General appearance	Shiny	Dull and lustreless
Intestinal musculature	Firm	Flabby, thin and friable
	Peristalsis may be observed	No peristalsis

Special attention should always be paid to the sites of constriction at each end of an obstructed segment. If of doubtful viability, they should be infolded using a seromuscular suture (***Figure 78.15***).

The surgical management of massive infarction is dependent on the patient's overall prognostic criteria. In the elderly, infarction of the small bowel from the duodenojejunal flexure to the right colon may be considered incurable, whereas in the young, with the potential for long-term intravenous alimentation and small bowel transplantation, a policy of excision may be justified.

Whenever the small bowel is resected, the exact site of resection, the length of the resected segment and that of the residual bowel should be recorded.

As laparoscopic surgery is now so common, it is important to note that small bowel obstruction and strangulation occur in relation to port-site hernias. The risk of port-site herniation is related to older age, higher body mass, trocar diameter and extension of the port site for tissue extraction.

Paul Thwaites Savage, 1916–2013, surgeon, Whittington Hospital, London, UK.

For laparoscopic cholecystectomy, the hernia rate is reported to be around 2%. Obstruction and strangulation have even been reported through 5-mm port sites. Complications from these hernias may present in the early postoperative period and as a Richter's hernia. They can be easily overlooked and careful examination of port sites in patients with small bowel obstruction is essential.

Treatment of adhesions

Initial management is based on intravenous rehydration and nasogastric decompression; occasionally, this treatment is curative. Although an initial conservative regimen is considered appropriate, regular assessment is mandatory to ensure that strangulation does not occur. Conservative treatment should not usually be prolonged beyond 72 hours.

When laparotomy is required, although multiple adhesions may be found, only one may be causative. If there is absolute certainty that this is the cause of the obstruction, this should be divided and the remaining adhesions can be left *in situ* unless severe angulation is present. Division of these adhesions will only cause further adhesion formation.

When obstruction is caused by multiple adhesions, the adhesions should be freed by sharp dissection from the duodenojejunal junction to the caecum. Following the release of band obstruction, the constriction sites that have suffered direct compression should be carefully assessed and, if they show residual colour changes, invaginated with a seromuscular suture (***Figure 78.15***).

Laparoscopic adhesiolysis may be considered in highly selected cases of small bowel obstruction. This is classed as an advanced laparoscopic procedure and should only be undertaken by surgeons with advanced laparoscopic skills.

Summary box 78.14

Treatment of adhesive obstruction

- Initially treat conservatively provided there are no signs of strangulation; should rarely continue conservative treatment for longer than 72 hours
- At operation, divide only the causative adhesion(s) and limit dissection
- Repair serosal tears; invaginate (or resect) areas of doubtful viability
- Laparoscopic adhesiolysis should only be performed by surgeons with advanced laparoscopic skills

Treatment of recurrent intestinal obstruction caused by adhesions

Several procedures may be considered in the presence of recurrent obstruction including:

- repeat adhesiolysis (enterolysis) alone;
- Noble's plication operation;

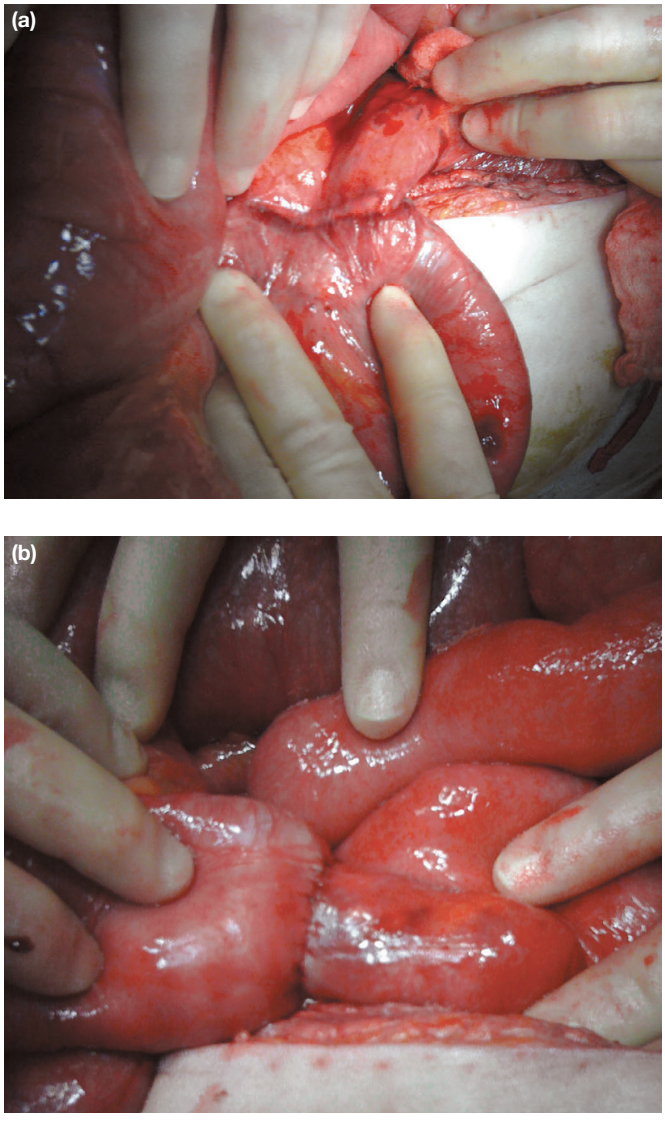

Figure 78.15 (a, b) Wall injury resulting from band compression, oversewn with an absorbable seromuscular suture.

- Childs–Phillips transmesenteric plication;
- intestinal intubation.

The last three operations are now very rarely performed and can probably be consigned to the history books (they have never been required by the author).

Postoperative intestinal obstruction

Differentiation between persistent paralytic ileus and early mechanical obstruction may be difficult in the early postoperative period. Mechanical obstruction is more likely if the patient has regained bowel function postoperatively that subsequently stops. Obstruction is usually incomplete and the majority settle with continued conservative management. Postoperative

Thomas Benjamin Noble, 1895–1965, surgeon, The Community Hospital, Indianapolis, IN, USA.
Wesley A Childs, 1915–2005, surgeon, University of Colorado, Denver, CO, USA.
Richard B Phillips, surgeon, Albuquerque, NM, USA.

intra-abdominal sepsis is a potent cause of postoperative obstruction; CT scanning with oral contrast is of particular value in the assessment of the postoperative abdomen.

Treatment of intussusception

In the infant with ileocolic intussusception, after resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction can be attempted using an air or barium enema. Successful reduction can only be accepted if there is free reflux of air or barium into the small bowel, together with resolution of symptoms and signs in the patient. Non-operative reduction is contraindicated if there are signs of peritonitis or perforation, there is a known pathological lead point or in the presence of profound shock. In experienced units, more than 70% of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic or hydrostatic reduction is a recognised hazard but is rare. Recurrent intussusception occurs in up to 10% of patients after non-operative reduction.

Surgery is required when radiological reduction has failed or is contraindicated. After resuscitation, a transverse right-sided abdominal incision provides good access. Reduction is achieved by gently compressing the most distal part of the intussusception towards its origin, making sure not to pull. The last part of the reduction is the most difficult (***Figure 78.16***). After reduction, the terminal part of the small bowel and the appendix will be seen to be bruised and oedematous. The viability of the whole bowel should be checked carefully. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

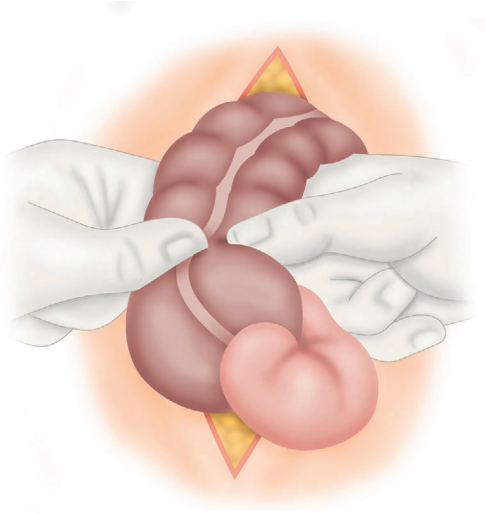

Figure 78.16 Reducing the terminal part of the intussusception (after RE Gross).

Acute intestinal obstruction of the newborn

Neonatal intestinal obstruction has many potential causes. Congenital atresia and stenosis are the most common. Intestinal malrotation with midgut volvulus, meconium ileus, Hirschsprung's disease, imperforate anus, necrotising enterocolitis and an incarcerated inguinal hernia may also be responsible. Many of these conditions are discussed in ***Chapters 17 and 18***.

Intestinal atresia

Duodenal atresia and stenosis are the most common forms of intestinal obstruction in the newborn (see ***Chapter 18***). Jejunal or ileal atresias are next in frequency whereas colonic atresia is rare. The possibility of multiple atresias makes intraoperative assessment of the whole small and large bowel mandatory. As with all congenital anomalies, associated malformations are common and should be excluded.

There are four main types of jejunal/ileal atresia, ranging from an obstructing membrane with continuity of the bowel wall through blind-ended segments of bowel separated by a fibrous cord or V-shaped mesenteric defect (including the so-called apple-peel atresia) (***Figure 78.17***), to multiple atresias ('string of sausages'). The obstructed proximal bowel is at risk of perforation, which may happen prenatally, causing meconium peritonitis in the fetus.

Small bowel atresias present with intestinal obstruction soon after birth. Bilious vomiting is the dominant feature in jejunal atresia whereas abdominal distension is more prominent with ileal atresia. A small amount of pale meconium may be passed despite the atresia.

Plain abdominal radiographs show a variable number of dilated loops of bowel and fluid levels according to the level of obstruction. In a stable infant, a contrast enema may be required to clarify the cause of a distal bowel obstruction.

Figure 78.17 Apple-peel jejunal bowel atresia with obstructed proximal jejunum and collapsed distal ileum coiled round a remnant ileocolic artery (courtesy of MD Stringer, Leeds, UK).

Harald Hirschsprung, 1830–1916, physician, The Queen Louise Hospital for Children, Copenhagen, Denmark, described congenital megacolon in 1887.

Surgery

Duodenal atresia is corrected by a duodenoduodenostomy. In most cases of jejunal/ileal atresia, the distal end of the dilated proximal small bowel is resected and a primary end-to-end anastomosis is possible. If the proximal bowel is extremely dilated it may need to be tapered to the distal bowel before anastomosis. Occasionally, a temporary stoma is required before definitive repair.

Meconium ileus

Cystic fibrosis is almost always the underlying cause of this condition. Meconium is normally kept fluid by the action of pancreatic enzymes. In meconium ileus the terminal ileum becomes filled with thick viscid meconium, resulting in progressive intestinal obstruction. A sterile meconium peritonitis may have occurred *in utero*.

Visibly dilated loops of bowel are often palpable in the newborn with meconium ileus. An abdominal radiograph may show a dilated small intestine with mottling. Fluid levels are generally not seen. Unlike ileal atresia there is no abrupt termination of the gas-filled intestine. A contrast enema shows an unused microcolon. As the condition is caused by an autosomal recessive genetic defect, a family history may be present. Further assessment includes gene mutation analysis and, beyond the neonatal period, a sweat test, which shows elevated sodium and chloride levels (>70 mmol/L).

Uncomplicated meconium ileus may respond to treatment with a hyperosmolar Gastrografin enema; this draws fluid into the gut lumen and also has detergent properties, which help to liquefy the meconium. Infants treated in this way need extra intravenous fluids to compensate for fluid shifts. Meconium ileus complicated by intestinal perforation, volvulus or atresia, or unresponsive to enemas, demands surgery. Various surgical procedures are used, including intestinal resection and temporary stoma formation, resection and primary anastomosis, and, in uncomplicated cases, enterotomy and irrigation of the bowel. The Bishop–Koop operation (***Figure 78.18***) with its irrigating stoma is now rarely used.

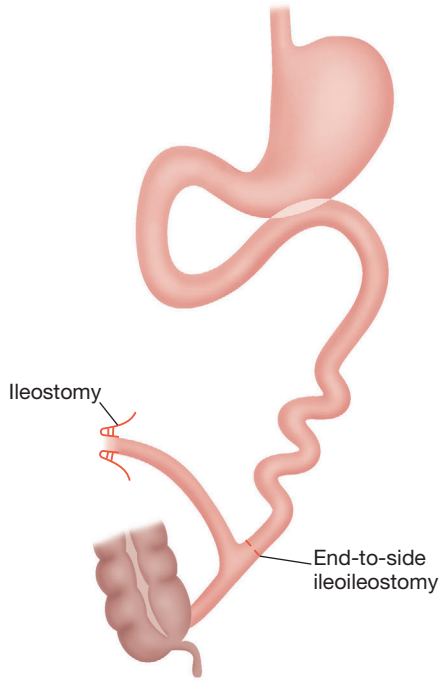

Figure 78.18 Bishop–Koop operation. This shows the completed procedure after a grossly distended ileum has been resected. Because intestinal continuity is preserved, early closure of the ileostomy is not essential.

TREATMENT OF ACUTE LARGE BOWEL OBSTRUCTION

Large bowel obstruction is caused by an underlying carcinoma or less commonly diverticular disease and presents in an acute or chronic form. The condition of pseudo-obstruction should always be considered and excluded by a limited contrast study or CT scan to confirm mechanical obstruction.

After full resuscitation, the abdomen should be opened through a midline incision. Care should be taken to ensure that the loss of tamponade of the abdominal wall does not lead to increased caecal distension and rupture (this starts with splitting along the line of the taenia coli on the antimesenteric border). Distension of the caecum will confirm large bowel involvement. Identification of a collapsed distal segment of the large bowel and its sequential proximal assessment will readily lead to identification of the cause. As surgery for malignant bowel cancer is technically challenging, wherever possible a suitably trained surgeon should perform the procedure. When a removable lesion is found in the caecum, ascending colon, hepatic flexure or proximal transverse colon, an emergency right hemicolectomy should be performed. A primary anastomosis is safe if the patient's general condition is reasonable (see ***Chapter 77***). If the lesion is not resectable a proximal stoma (colostomy or ileostomy if the ileocaecal valve is incompetent) or ileotransverse bypass should be considered. Obstructing lesions at the splenic flexure should be treated by an extended right hemicolectomy with ileo-descending colonic anastomosis.

For obstructing lesions of the left colon or rectosigmoid junction, immediate resection should be considered unless there are clear contraindications. In rare instances or when caecal perforation is imminent, additional time to improve the patient's clinical condition can be bought by performing an emergency caecostomy or loop transverse colostomy (loop ileostomy in the presence of an incompetent ileocaecal valve).

In the absence of senior clinical staff, it is safest to bring the proximal colon to the surface as a colostomy. When possible the distal bowel should be brought out at the same time (Paul–Mikulicz procedure) to facilitate subsequent closure. In the majority of cases, the distal bowel will not reach and is

Harry C Bishop, 1921–2009, Professor of Surgery, University of Philadelphia, Philadelphia, PA, USA.

Johann von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Germany (now Wrocław, Poland).

closed and returned to the abdomen (Hartmann's procedure). A second-stage colorectal anastomosis can be planned when the patient is fit.

If an anastomosis is to be considered using the proximal colon, it may be decompressed and cleaned by an on-table colonic lavage.

In a palliative situation or if a patient is unfit for major surgery insertion of a self-expanding metal stent may be preferable as it offers reduced mortality and morbidity and stoma formation (see ***Chapter 77***). Technical and clinical success rates for stenting are of the order of 80–90% (***Figure 78.19***).

For patients with potentially curative disease, stenting as a bridge to surgery (usually performed 1–4 weeks post stenting) has been shown to reduce stoma formation but not to reduce postoperative mortality. Recent guidelines from the European Society of Gastrointestinal Endoscopy recommend stenting as a bridge to surgery to be discussed, within a shared decision-making process, as a treatment option in patients with potentially curable left-sided obstructing colon cancer as an alternative to emergency resection. This is a strong recommendation based on high-quality evidence. Colonic stenting should be performed or directly supervised by an operator who can demonstrate competence in both colonoscopy and fluoroscopic techniques and who performs colonic stenting on a regular basis. A time interval of 2–4 weeks is generally employed prior to definitive surgery. This period allows treatment of comorbidities and completion of staging investigations. A decompressing stoma as a bridge to elective surgery is a valid option if the patient is not a candidate for colonic stenting or when stenting expertise is not available.

Treatment of caecal volvulus

At operation the volvulus is frequently found to be ischaemic and needs resection. If viable, the volvulus should be reduced. Sometimes, this can only be achieved after decompression of the caecum using a needle. Further management consists of either resection or fixation of the caecum to the right iliac fossa (caecopexy) and/or a caecostomy in those considered unfit for resection. Recurrence of volvulus after caecopexy has been reported in up to 40% of cases.

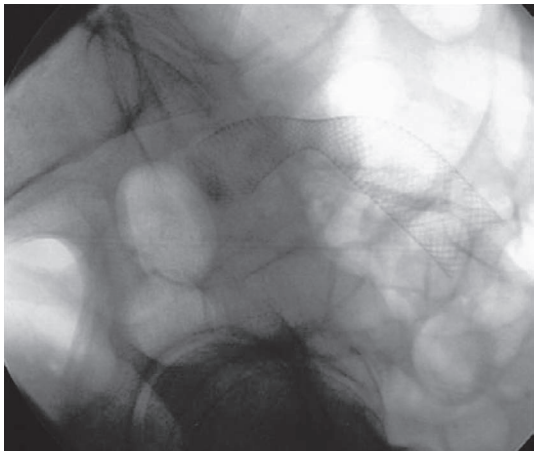

Figure 78.19 Radiograph of a stent inserted for malignant colonic obstruction.

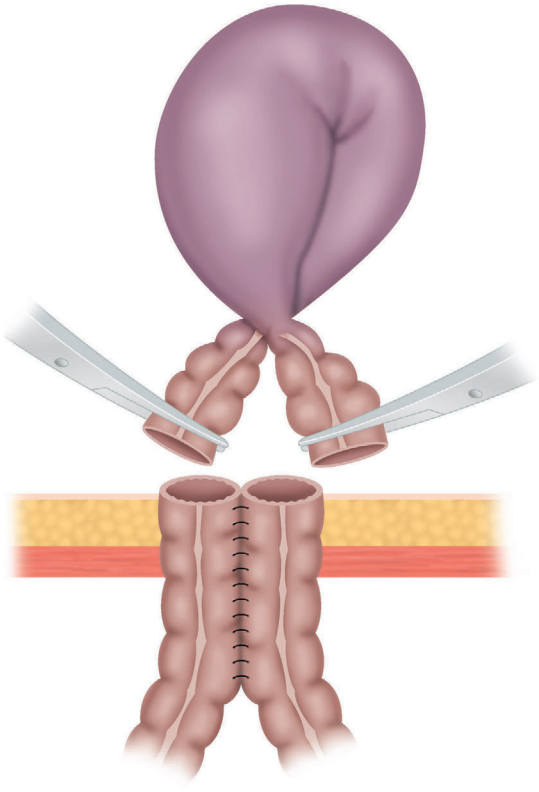

Figure 78.20 The Paul–Mikulicz operation applied to volvulus of the pelvic colon.

Treatment of sigmoid volvulus

Flexible sigmoidoscopy or rigid sigmoidoscopy and insertion of a flatus tube should be carried out to allow deflation of the gut. The tube should be secured in place with tape for 24 hours and a repeat radiograph taken to ensure that decompression has occurred. Success, as long as ischaemic bowel is excluded, will resolve the acute problem.

In fit patients, an elective sigmoid colectomy is required. It may not be reasonable to offer any further treatment following successful endoscopic decompression in elderly or unfit patients; however, if there are recurrent episodes of volvulus, the options are resection or two-point fixation with combined endoscopic/percutaneous tube insertion (gastrostomy tubes are frequently used for this purpose).

When the bowel is viable, fixation of the sigmoid colon to the posterior abdominal wall may be a safer manoeuvre in inexperienced hands. Resection is preferable if it can be achieved safely. A Paul–Mikulicz procedure is useful, particularly if there is suspicion of impending gangrene (***Figure 78.20***); an alternative procedure is a sigmoid colectomy and, when anastomosis is considered unwise, a Hartmann's procedure with subsequent reanastomosis can be carried out.

CHRONIC LARGE BOWEL OBSTRUCTION

The symptoms of chronic intestinal obstruction may arise from two sources: the cause and the subsequent obstruction.

The causes of obstruction may be organic:

- intraluminal (rare) – faecal impaction;
- intrinsic intramural – strictures (Crohn's disease, ischaemia, diverticular), anastomotic stenosis;
- extrinsic intramural (rare) – metastatic deposits (ovarian), endometriosis, stomal stenosis;

or functional:

- Hirschsprung's disease, idiopathic megacolon, pseudo-obstruction.

The symptoms of chronic obstruction differ in their predominance, timing and degree from acute obstruction. In functional cases, the symptoms may have been present for months or years. Constipation appears first. It is initially relative and may become absolute, associated with distension. In the presence of large bowel disease, the point of greatest distension is in the caecum, and this is heralded by the onset of pain. Vomiting is a late feature and therefore dehydration is less severe. Examination is unremarkable, save for confirmation of distension, which can be profound (***Figure 78.21***) and the onset of peritonism in late cases. Rectal examination may confirm the presence of faecal impaction or a tumour.

Figure 78.21 Gross functional colonic distension.

Investigation

Plain abdominal radiography confirms the presence of large bowel distension. All such cases should be investigated by a subsequent single-contrast water-soluble enema study, CT scan or endoscopic assessment to rule out functional disease.

Organic disease requires decompression with either a laparotomy or stent. Stomal stenosis can usually be managed at the abdominal wall level. Surgical management after resuscitation depends on the underlying cause and the relevant chapters in this book should be consulted.

Functional disease requires colonoscopic decompression in the first instance and conservative management. Intestinal perforation can occur in patients with functional obstruction (see ***Chapter 73***).

ADYNAMIC OBSTRUCTION

Paralytic ileus

This may be defined as a state in which there is failure of transmission of peristaltic waves secondary to neuromuscular failure (i.e. in the myenteric [Auerbach's] and submucous [Meissner's] plexuses). The resultant stasis leads to accumulation of fluid and gas within the bowel, with associated distension, vomiting, absence of bowel sounds and absolute constipation.

Varieties

The following varieties are recognised:

- **Postoperative**: a degree of ileus usually occurs after any abdominal procedure and is self-limiting, with a variable duration of 24–72 hours. Postoperative ileus may be prolonged in the presence of hypoproteinaemia or metabolic abnormality.
- **Infection**: intra-abdominal sepsis may give rise to localised or generalised ileus.
- **Reflex ileus**: this may occur following fractures of the spine or ribs, retroperitoneal haemorrhage or even the application of a plaster jacket.
- **Metabolic**: uraemia and hypokalaemia are the most common contributory factors.

Clinical features

Paralytic ileus takes on a clinical significance if, 72 hours after laparotomy:

- there has been no return of bowel sounds on auscultation;
- there has been no passage of flatus.

Abdominal distension becomes more marked and tympanitic. Colicky pain is not a feature. Distension increases pain from the abdominal wound. In the absence of gastric aspiration, effortless vomiting may occur. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels (if an erect film is felt necessary).

Management

Nasogastric tubes are not required routinely after elective intra-abdominal surgery. Paralytic ileus is managed with the use of nasogastric suction and restriction of oral intake until bowel sounds and the passage of flatus return. Electrolyte balance must be maintained. The use of an enhanced recovery programme with early introduction of fluids and solids is, however, becoming increasingly popular (see ***Chapter 73***).

Specific treatment is directed towards the cause, but the following general principles apply:

- If a primary cause is identified this must be treated.
- Gastrointestinal distension must be relieved by decompression.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wrocław, Poland), described the myenteric plexus in 1862.
Georg Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucous plexus of the alimentary tract in 1852.

- Close attention to fluid and electrolyte balance is essential.
- There is no convincing evidence for the use of prokinetic drugs to treat postoperative adynamic ileus.
- If paralytic ileus is prolonged CT scanning will demonstrate any intra-abdominal sepsis or mechanical obstruction and therefore guide any requirement for laparotomy.

The decision to take a patient back to theatre in these circumstances is always difficult. The need for a laparotomy becomes increasingly likely the longer the bowel inactivity persists, particularly if it lasts for more than 7 days or if bowel activity recommences following surgery and then ceases.

Pseudo-obstruction

This condition describes an obstruction, usually of the colon, that occurs in the absence of a mechanical cause or acute intra-abdominal disease. It is associated with a variety of syndromes in which there is an underlying neuropathy and/or myopathy and a range of other factors.

Small intestinal pseudo-obstruction

This condition may be primary (i.e. idiopathic or associated with familial visceral myopathy) or secondary. The clinical picture consists of recurrent subacute obstruction. The diagnosis is made by the exclusion of a mechanical cause. Treatment consists of initial correction of any underlying disorder. Metoclopramide and erythromycin may be of use.

Colonic pseudo-obstruction

This may occur in an acute or a chronic form. The former, also known as Ogilvie's syndrome, presents as acute large bowel obstruction. Abdominal radiographs show evidence of colonic obstruction, with marked caecal distension being a common feature. Indeed, caecal perforation is a well-recognised complication. The absence of a mechanical cause requires urgent confirmation by colonoscopy or a single-contrast water-soluble barium enema or CT. The aetiology, investigation and management are covered in detail in ***Chapter 73***.

PART 11 | Abdominal

CHAPTER
79 The rectum

Learning objectives

To understand:
- The anatomy of the rectum and its relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the rectum

To appreciate:
- That carcinoma of the rectum is common and can present with symptoms similar to benign disease. Careful evaluation is required
- The principles involved in the management of rectal pathologies

ANATOMY

Surgical anatomy

The rectum begins where the tinea coli of the sigmoid colon join to form a continuous outer longitudinal muscle layer at the level of the sacral promontory. The rectum follows the curve of the sacrum and ends at the anorectal junction. The puborectalis muscle encircles the posterior and lateral aspects of the junction, creating the anorectal angle (normally 120°). The rectum has three lateral curvatures; the upper and lower are convex to the right, and the middle is convex to the left. On the luminal aspect, these three curves are marked by semicircular folds (valves of Houston).

The adult rectum is approximately 12–18 cm in length and is conventionally divided into three equal parts: the upper third, which is mobile and has a peritoneal covering anteriorly and laterally; the middle third, where the peritoneum covers only the anterior and part of the lateral surfaces; and the lowest third, which lies deep in the pelvis below the peritoneal reflection.

The lower third of the rectum is separated by distinct fascial layers from the prostate/vagina anteriorly (Denonvilliers' fascia), and from the coccyx and lower two sacral vertebrae posteriorly (Waldeyer's fascia) (***Table 79.1***). These fascial layers are surgically important as they act as barriers to malignant invasion and form the anatomical envelope for total mesorectal excision (TME) to achieve complete oncological clearance of rectal cancer.

Summary box 79.1

Anatomy of the rectum
- The rectum measures approximately 15 cm in length
- It is divided into lower, middle and upper thirds
- The blood supply consists of superior, middle and inferior rectal vessels
- The lymphatic drainage follows the blood supply. The principal route of drainage is upwards along the superior rectal vessels to the para-aortic nodes, although the lower rectum can drain to lymphatics along the internal iliac pedicle and lateral pelvic side walls

TABLE 79.1 Anatomical relations of the rectum.

	Relation
Anterior	Bladder Seminal vesicles and prostate (males) Denonvilliers' fascia Pouch of Douglas and rectovaginal septum (females) Uterus and cervix (females) Ureters
Lateral	Lateral ligaments and middle rectal artery Obturator internus muscle and side wall of pelvis Pelvic autonomic plexus Levator ani muscle
Posterior	Sacrum and coccyx Waldeyer's fascial condensation Superior rectal artery and lymphatics Hypogastric nerves

John Houston, 1802–1845, physician, City of Dublin Hospital and Lecturer in Surgery, Dublin, Ireland.
Charles-Pierre Denonvilliers, 1808–1872, Professor of Anatomy and later of Surgery, Paris, France.
Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921, Professor of Pathological Anatomy, Berlin, Germany.
James Douglas, 1675–1742, Scottish anatomist and Physician Extraordinary to Queen Caroline.

Embryology

The embryological hindgut forms the upper rectum, while the lower rectum is derived from the cloaca and is surrounded by extraperitoneal connective tissue. The primitive gut tube is suspended dorsally by a mesentery throughout its length, to form the mesorectum. The muscular layers of the rectum are derived from the mesenchyme that accompanies the endodermal part of the anorectum, with the inner circular layer preceding the outer longitudinal layer in the seventh week of embryonic development.

The levator ani muscles and external anal sphincter muscles form within the surrounding mesenchyme and grow to make contact with each other and with bundles of smooth muscle cells from the outer longitudinal layer of the rectal wall. A layer of undifferentiated mesenchyme separates the rectal muscle layers from the levator ani muscle and the muscle layer of the future anal canal.

Blood supply

The superior rectal artery is the direct continuation of the inferior mesenteric artery and is the main arterial supply of the rectum (***Figure 79.1***). The arteries and their accompanying lymphatics lie within the loose fatty tissue in the mesorectum, surrounded by a sheath of connective tissue (the mesorectal fascia). The middle rectal artery arises on each side from the internal iliac artery and passes to the rectum in the lateral ligaments. It is usually small and often only present on one side, and divides into several branches. The inferior rectal artery arises on each side from the internal pudendal artery as it enters Alcock's canal. It hugs the inferior surface of the levator ani muscle as it crosses the roof of the ischiorectal fossa to enter the anal muscles.

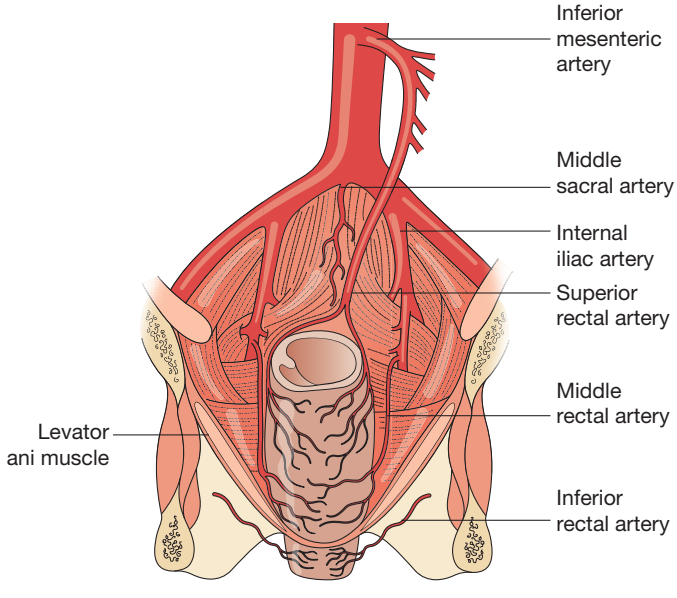

Figure 79.1 Blood supply to the rectum. The main blood supply comes from the superior rectal arteries, supplemented by middle rectal arteries in 20% of cases. The inferior rectal arteries are derived from the pudendal vessels and supply the anal canal and lower rectum.

Venous drainage

The superior haemorrhoidal veins draining the upper half of the anal canal above the dentate line pass upwards to become the rectal veins; these unite to form the superior rectal vein, which later becomes the inferior mesenteric vein. This forms part of the portal venous system and ultimately drains into the splenic vein. Middle rectal veins exist but are small, unimportant channels unless the normal paths are blocked.

Lymphatic drainage

The lymphatics of the rectal mucosa communicate freely with those of the muscle layers. The usual drainage flow is upwards, and only to a limited extent laterally and downwards. For this reason, surgical clearance of malignant disease concentrates mainly on achieving wide resection of proximal lymph nodes. However, if the usual upward routes are blocked, for example by metastatic disease, the flow can reverse and it is possible to find involved lymph nodes on the side walls of the pelvis (along the middle rectal vessels) or even in the inguinal region (along the inferior rectal artery).

CLINICAL FEATURES OF RECTAL DISEASE

Symptoms

Rectal diseases are common and can occur at any age. The symptoms of many of them overlap. In general, inflammatory conditions affect younger age groups, while tumours occur in the middle-aged and elderly.

Summary box 79.2

Main symptoms of rectal disease

- Fresh bleeding per rectum
- Altered bowel habit with loose stool
- Mucus discharge
- Tenesmus
- Prolapse
- Proctalgia (pain)

Bleeding

This is often painless and bright red in colour and should be carefully investigated at any age.

Altered bowel habit

Early morning stool frequency (spurious diarrhoea) is a symptom of rectal carcinoma, while blood-stained, frequent, loose stools characterise the inflammatory diseases.

Benjamin Alcock, 1801–?, first Professor of Anatomy, Queen's College (now University College), Cork, Ireland. Emigrated in 1859 following a resignation dispute over procurement of corpses for dissection.

Discharge
Mucus and pus are associated with rectal inflammation.

Tenesmus
Often described by the patient as 'I feel I want to go but nothing happens', this is normally an ominous symptom of rectal cancer, but can occur with other rectal conditions and is a common symptom of rectal prolapse.

Prolapse
This usually indicates either mucosal or full-thickness rectal wall protrusion from the anus. Internal prolapse or intussusception refers to a telescoping of the rectum into itself without protrusion from the anus.

Pain: 'proctalgia'
This is usually a severe and episodic pain resulting from spasm of the levator ani muscle. It may last for a few seconds to minutes then recur, or it can be constant (see ***Chapter 80***).

Signs
To examine the rectum the patient is most conveniently positioned in the left lateral or semi-prone (Sims) position.

Inspection
Visual examination of the anus precedes rectal examination to exclude the presence of anal disease, e.g. fissure or fistula. Evidence of rectal prolapse or abnormal pelvic floor descent can be elicited by asking the patient to strain.

Digital examination
The index finger used with gentleness and precision remains a valuable test for rectal disease (***Figure 79.2***). The anal sphincters are assessed for anatomical integrity, resting tone and squeeze. In females, a rectocele may be palpable as a herniation of the anterior rectal wall into the vagina. Tumours in the lower and middle thirds of the rectum can usually be felt. On removal, the finger should be examined for mucus, pus or blood. It is useful to note the normal, as well as the abnormal, findings on digital examination, e.g. the prostate in the male. Digital findings can be recorded as intraluminal (e.g. blood, pus), intramural (e.g. tumours, granular areas, strictures) or extramural (e.g. enlarged prostate, uterine fibroids). Intramural lesions can be described as fixed, tethered or mobile.

Proctoscopy
This procedure can be used to inspect the anus, anorectal junction and lower rectum. A lubricated proctoscope is inserted through the anus to provide views of the lower rectum and anal canal (***Figure 79.3***). Biopsy can be performed of any suspicious areas, provided it is above the sensitive anoderm. Proctoscopy is particularly useful for assessing the presence of haemorrhoids.

Sigmoidoscopy
In the past, the sigmoidoscope was a rigid stainless steel instrument of variable diameter and normally 25 cm in length, but this has been replaced by disposable plastic instruments. The rectum must be empty for proper inspection. Direct inspection of the rectal mucosa may alert the clinician to inflammation or tumours. This procedure can be performed in the outpatient setting.

Flexible sigmoidoscope
This is used as a supplement to rigid sigmoidoscopy or when views proximal to the rectum are required (***Figure 79.4***). The lower bowel needs to be cleaned out with preliminary enemas. In addition to the rectum, the whole sigmoid colon up to the splenic flexure is within visual reach. Flexible sigmoidoscopy

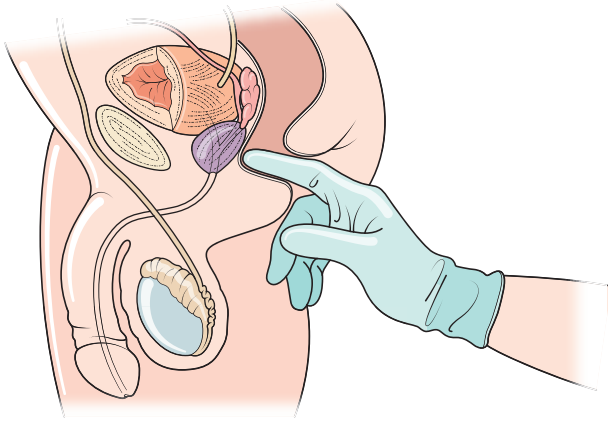

Figure 79.2 Digital rectal examination in the male. Assessment of the anal sphincter complex, lower rectum and prostate.

Figure 79.3 Proctoscope for visualisation of the anorectum.

James Marion Sims, 1813–1883, gynaecological surgeon, the State Hospital for Women, New York, NY, USA, introduced this position to give access to the anterior vaginal wall during operations for the closure of vesicovaginal fistula.

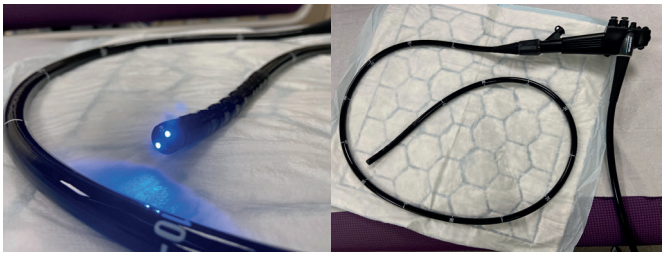

Figure 79.4 Flexible colonoscope.

is indicated to investigate underlying causes of fresh rectal bleeding or other bowel symptoms when full visualisation of the colon by colonoscopy is not required.

Summary box 79.3

Examination of the rectum

- Visual inspection of the perineum
- Digital examination
- Proctoscopy
- Sigmoidoscopy – rigid and/or flexible

INJURIES

The rectum or anal canal may be injured in a number of ways, all of which are uncommon:

- by falling in a sitting posture onto a pointed object;
- penetrating injury (including gunshots) to the buttocks;
- sexual assault or sexual activity involving anal penetration;
- by the fetal head during childbirth, especially forceps assisted.

Diagnosis

The anus should be inspected and the abdomen palpated. If abdominal rigidity or tenderness is present, early laparoscopy or laparotomy is indicated. A water-soluble contrast enema may help in delineating the injury, but a computed tomography (CT) scan is often preferred and will provide additional information on other pelvic injuries, such as accompanying urethral injury.

Treatment

The rectum is examined under general anaesthetic with a finger and a sigmoidoscope. If penetrating injury is confirmed, laparotomy or laparoscopy is required. If an intraperitoneal rupture of the rectum is found, the perforation is closed with sutures and the rectum defunctioned with a stoma. The defunctioned distal segment should be irrigated to remove all residual faecal matter. In the event that the rectal injury cannot be repaired, a Hartmann's procedure may be needed. If the rectal injury is below the peritoneal reflection, wide drainage from below is indicated, with rectal washout and a defunctioning colostomy. Care must be taken to preserve or restore anal sphincter integrity during debridement of the perineal wounds. Antibiotic cover must be provided against both aerobic and anaerobic organisms.

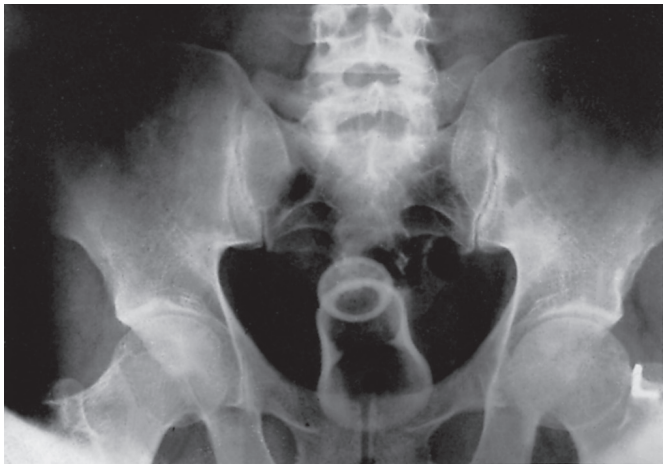

Figure 79.5 Foreign body in the rectum as seen on plain abdominal radiograph.

FOREIGN BODIES IN THE RECTUM

The variety of foreign bodies that have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (***Figure 79.5***). The difficulty lies in the creation of a vacuum effect when trying to extract the object through the anus. If insurmountable difficulty is experienced in grasping any foreign body in the rectum, laparotomy or laparoscopy is usually necessary. The object can be pushed from above into the assistant's fingers in the rectum or removed by means of a rectotomy in a proximal area of the rectum. If there is considerable laceration of the mucosa, a temporary colostomy is advisable.

Summary box 79.4

Injuries to the rectum are serious and invariably require surgery

- A temporary colostomy is often necessary
- There is a serious risk of associated necrotising fasciitis, and broad-spectrum antibiotics are mandatory
- There may be associated bladder or urethral damage

PROLAPSE

Mucosal prolapse

The mucosa and submucosa of the rectum may protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and the thumb, it is evident that it is composed of no more than a double layer of mucosa. This distinguishes mucosal prolapse

Henri Albert Hartmann, 1860–1952, Chief of Surgery, Hôtel Dieu, Paris, France.

from full-thickness rectal prolapse, in which the entire wall of the rectum protrudes through the anal canal.

In infants

The direct downward course of the rectum, owing to the as-yet undeveloped sacral curve, predisposes infants to this condition.

In children

Mucosal prolapse often commences after an attack of diarrhoea or from loss of weight and consequent loss of fat in the ischiorectal fossa. It may also be associated with cystic fibrosis, neurological disorder, Hirschsprung's disease, rectal polyps and maldevelopment of the pelvis.

Summary box 79.5

Rectal prolapse

- It may be mucosal or full thickness
- If full thickness, the whole wall of the rectum is included
- It may begin as a rectal intussusception (internal rectal prolapse)
- In children, the prolapse is usually mucosal and should be treated conservatively
- In adults, the prolapse is often full thickness and is frequently associated with constipation and incontinence
- Surgery is almost always necessary for full-thickness rectal prolapse
- The operation is performed either via the perineum or via the abdomen

In adults

Mucosal prolapse in adults is often associated with third-degree haemorrhoids, when it is referred to as mucohaemorrhoidal prolapse (***Figure 79.6***). In the female a perineum damaged at childbirth and in the male straining from urethral obstruction predispose to mucosal prolapse. In old age, both mucosal and full-thickness prolapse are associated with weakness of the pelvic floor and anal sphincters. Partial prolapse may follow an operation for fistula-*in-ano* where a large portion of muscle has been divided. Here, the prolapse is usually localised to the damaged quadrant and is seldom progressive.

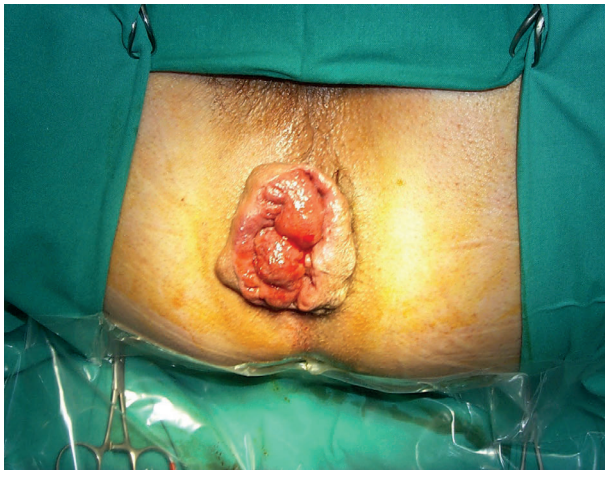

Figure 79.6 Mucohaemorrhoidal prolapse of the anorectum.

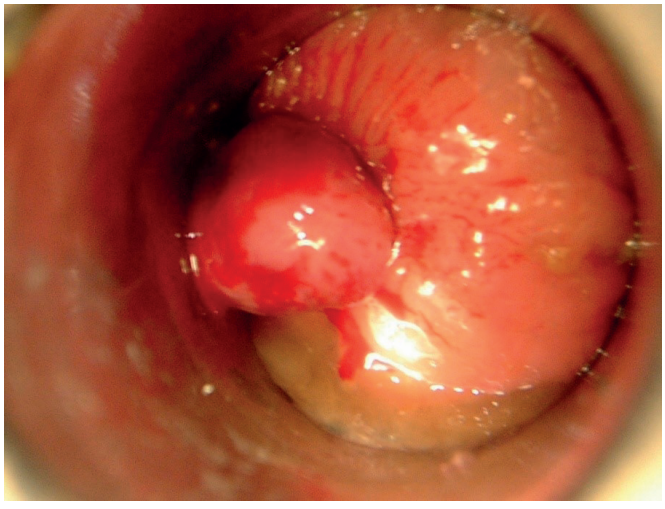

Figure 79.7 Through a proctoscope, a rubber band is applied to an area of mucohaemorrhoidal prolapse.

Treatment

In infants and young children

- **Digital repositioning**. The parents are taught to replace the protrusion, and any underlying causes are addressed.
- **Submucosal injection or banding**. If digital repositioning fails after a 6-week trial, injection of 5% phenol in almond oil or rubber band ligation under general anaesthetic can be tried (***Figure 79.7***).

In adults

- **Local treatments**. Submucosal injections of phenol in almond oil or the application of rubber bands may be successful in cases of mucosal prolapse.
- **Excision of the prolapsed mucosa**. When the prolapse is unilateral, the redundant mucosa can be excised or, if circumferential, an endoluminal stapling technique or internal Delorme's procedure can be used.

Internal rectal prolapse and solitary rectal ulcer syndrome

Internal rectal prolapse, or intussusception, refers to the invagination of the rectal tube during defecation. The prolapse descends towards the anal canal, where it can act as a blockage to defecation; a condition referred to as obstructed defecation. The patient describes the normal desire to defecate but an inability to satisfactorily evacuate the rectum, having to resort to excessive straining and sometimes digitation. Incomplete evacuation leads to a sensation of tenesmus, requiring repeated

Harald Hirschsprung, 1830–1916, Professor of Paediatrics, The Queen Louise Hospital for Children, Copenhagen, Denmark.
Edmond Delorme, 1847–1929, Professor of Surgery, Val-de-Grace Military Hospital, Paris, France.

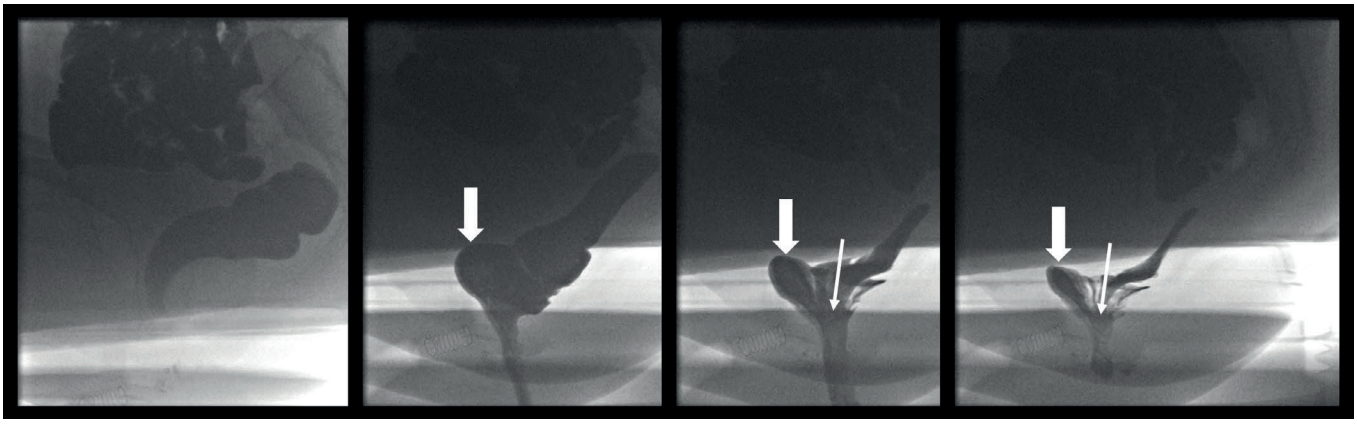

Figure 79.8 Defecating proctogram with selected images from left to right showing normal pelvic floor position at rest with development of a small anterior rectocele on evacuation (thick arrow) and a rectoanal intussusception entering the anal canal (thin arrow) (courtesy of Dr Damian Tolan, St James's Hospital, Leeds, UK).

returns to the toilet. Intussusception is often accompanied by other structural abnormalities of the rectum, including rectocele and enterocele, which can further add to evacuatory difficulty (***Figure 79.8***).

Treatment of internal rectal prolapse is indicated if it can be demonstrated on proctography and correlates with the patient's symptoms of obstructed defecation. Surgical options for treating internal rectal prolapse are the same as those for external rectal prolapse, namely internal Delorme's procedure (perineal approach) or laparoscopic ventral mesh rectopexy (LVMR) (abdominal approach).

Solitary rectal ulcer syndrome (SRUS) may also be another associated manifestation of obstructed defecation syndrome. Classically, SRUS takes the form of an ulcer on the anterior wall of the rectum, situated 6–8 cm from the anal verge. In this form, it can be mistaken for rectal carcinoma or inflammatory bowel disease, particularly Crohn's disease. It may heal, leaving a polypoid appearance. Proctographic studies may indicate accompanying rectal intussusception or anterior rectal wall prolapse. Histology will confirm the diagnosis. The condition is difficult to treat. Symptomatic relief from bleeding and discharge may sometimes be achieved by controlling any associated straining with re-coordination of defecation using biofeedback therapy. Transanal stapled resection of the intussusception (STARR procedure) or resuspension of the rectum by abdominal rectopexy may be beneficial, but the results are not as good as for internal or external rectal prolapse. In rare cases, rectal excision may be required with or without stoma.

Full-thickness prolapse

Complete rectal prolapse (synonym: procidentia) is less common than the mucosal variety. The protrusion consists of all layers of the rectal wall and is usually associated with a weak pelvic floor and/or chronic straining. The prolapse often commences as an intussusception of the rectum, which descends to protrude outside the anus. The process starts with the anterior wall of the rectum, where the supporting tissues are weakest, especially in women. It is more than 4 cm and commonly as much as 10–15 cm in length (***Figure 79.9***). On palpation between the finger and thumb, the prolapse feels much thicker than mucosal prolapse and consists of a double thickness of the entire wall of the rectum. Any prolapse over 5 cm in length will contain anteriorly, between its layers, a pouch of peritoneum. When large, the peritoneal pouch may contain small intestine or bladder. The anal sphincter is characteristically patulous and gapes widely on straining to allow the rectum to prolapse. Complete prolapse is uncommon in children but may occur as a result of malnutrition. In adults, it can occur at any age, but it is more common in the elderly and sometimes in patients with anorexia nervosa. Women are affected six times more often than men, and it is commonly associated with other pelvic organ prolapse. In approximately 50% of adults, faecal incontinence is also a feature. Complications of rectal prolapse include rectal ulceration and bleeding, incontinence and even incarceration with ischaemia and necrosis of the rectum.

Figure 79.9 Full-thickness rectal prolapse. The whole bowel wall protrudes through the anus.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA.

Differential diagnosis

In the case of a child with abdominal pain, the anus should be examined to exclude rectal prolapse as a cause. This should also be distinguished from intussusception protruding from the anus.

Treatment

Surgery is required for full-thickness rectal prolapse, and the operation can be performed via a perineal or abdominal approach. Abdominal operations can be by an open or laparoscopic approach. Abdominal rectopexy, either laparoscopic or open, has a lower rate of recurrence (<10%), but when the patient is elderly and very frail a perineal operation is usually safer and, if necessary, can be performed under regional anaesthetic blockade. As an abdominal procedure risks damage to the pelvic autonomic nerves, resulting in possible sexual dysfunction, a perineal approach may be preferred in young men.

Perineal approach

These procedures have been used most frequently:

- **Thiersch's operation**. In this procedure, a steel wire, or silastic or nylon tape, is placed around the anal canal. It has become largely obsolete owing to problems with chronic perineal sepsis, anal stenosis and obstructed defecation, but may be used to augment perineal repair in cases of severe pelvic floor weakness.
- **Delorme's operation**. In this procedure, the rectal mucosa is stripped circumferentially from the rectum over the length of the prolapse (***Figure 79.10***). The underlying muscle is plicated with a series of sutures, so that the rectal muscle is concertinaed towards the anal canal. The excess rectal mucosa is excised and a mucosal anastomosis performed. The resulting effect is to reduce the prolapse as a plicated ring of muscle above the anal canal. This operation may be preferred in patients with short segment full rectal prolapse, but recurrence rates are high, in the region of 30% over 5 years.

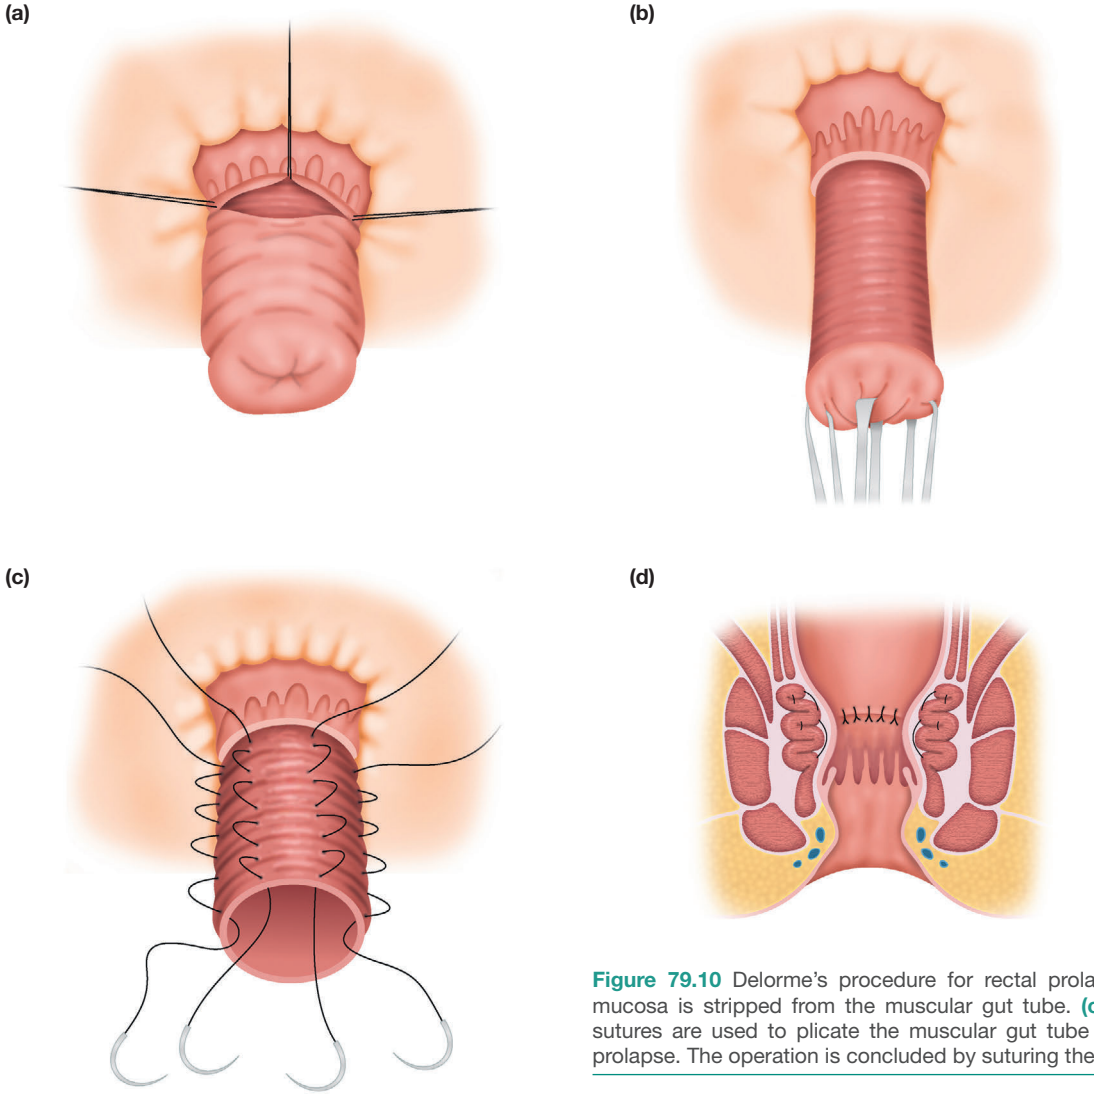

Figure 79.10 Delorme's procedure for rectal prolapse. **(a, b)** The mucosa is stripped from the muscular gut tube. **(c, d)** Interrupted sutures are used to plicate the muscular gut tube and reduce the prolapse. The operation is concluded by suturing the mucosa.

Karl Thiersch, 1822–1895, Professor of Surgery, Leipzig, Germany.

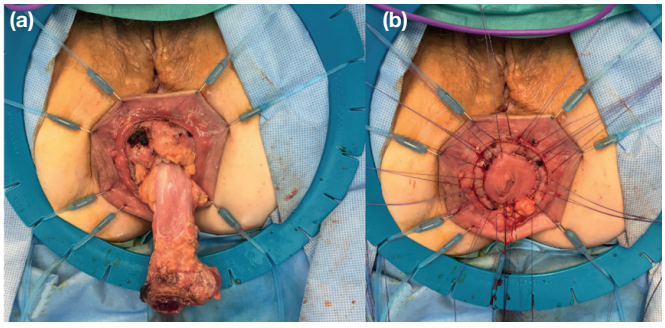

Figure 79.11 Altemeier's procedure showing **(a)** a full-thickness mobilisation of the prolapse and **(b)** a hand-sewn coloanal anastomosis following prolapse resection (courtesy of Ms Ann Hanly, FRCSI, Dublin, Ireland).

- **Altemeier's procedure**. In this procedure, the rectum is prolapsed through the anal canal and a full-thickness resection performed, incorporating any associated colonic prolapse (***Figure 79.11***). Restoration of colorectal continuity can be performed by either a hand-sewn or stapled anastomosis. This is the procedure of choice in patients presenting with incarcerated and strangulated prolapse. It is a good alternative perineal procedure to the Delorme's operation, particularly following recurrence. However, it is often complicated by poor bowel control with faecal soiling secondary to loss of the rectal reservoir. Recurrence rates range from 0% to 20%.

The advantages of a perineal approach include minimal postoperative pain, early mobility and low levels of morbidity. However, given the higher recurrence rates when compared with the abdominal operations, it is best reserved for patients at high risk of complications when undergoing a major operation.

Abdominal approach

The principle of all abdominal operations for rectal prolapse is to fix the rectum in its normal anatomical position. Many variations have been described, including inserting a sheet of polypropylene mesh between the rectum and the sacrum, hitching up the rectosigmoid junction with a Teflon sling to the front of the sacrum or simply suturing the mobilised rectum to the sacrum using four to six interrupted non-absorbable sutures – so-called 'sutured rectopexy' (Goldberg). Currently, the technique is most often performed laparoscopically, reducing the operative trauma, limiting the time in hospital and broadening its indication for higher risk patients.

As an abdominal rectopexy may lead to worsening constipation, some surgeons recommend combining this procedure with resection of the sigmoid colon, so-called 'resection rectopexy', but this adds an additional risk because of the anastomosis. An alternative is LVMR, which has become increasingly popular in western practice (D'Hoore). In this procedure, the plane between the rectum and vagina (or prostate) is dissected, and a strip of mesh sutured to the anterior rectum and posterior vaginal vault. The upper end of the mesh is secured to the sacral promontory with sutures or tacks, thus resuspending the rectum and preventing prolapse (***Figure 79.12***).

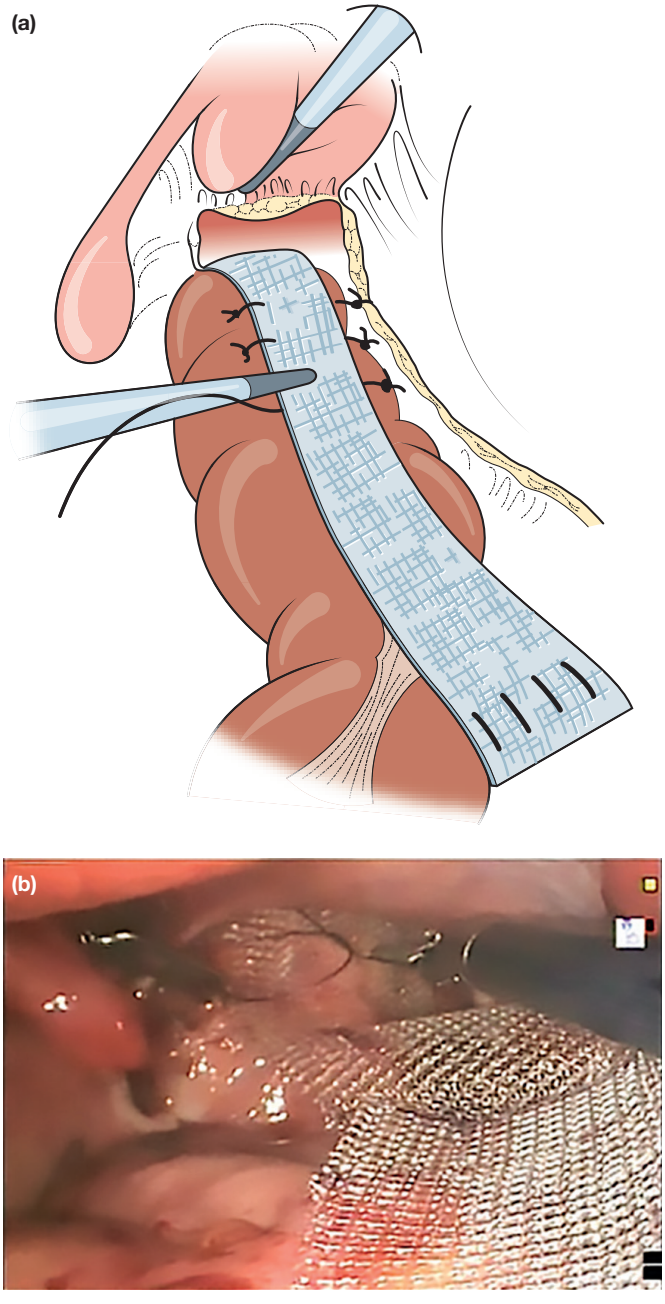

Figure 79.12 (a) Laparoscopic ventral mesh rectopexy: a prosthetic mesh is sutured to the front of the lower rectum and used to resuspend the rectum by securing the proximal end of the mesh to the sacral promontory. **(b)** Intraoperative image of a robotic ventral mesh rectopexy showing suturing of the mesh to the anterior rectum after dissection of the rectovaginal septum.

William Altemeier, 1910–1983, Professor of Surgery, Cincinnati, OH, USA.
Stanley M Goldberg, b. 1923, Emeritus Professor of Surgery, University of Minnesota, Minneapolis, MN, USA.
André D'Hoore, contemporary, Professor of Surgery, Catholic University Leuven, Leuven, Belgium.

The success of LVMR in treating external rectal prolapse and rectal intussusception has been variously reported between 70% and 80%, with improvement in both constipation and incontinence scores. It is a relatively safe procedure (overall complication rate 10%) with a quick recovery because of the laparoscopic approach. Possible complications include prolapse recurrence, bleeding, pelvic pain and dyspareunia. More recently, there has been concern regarding mesh complications when used more generally for pelvic organ prolapse surgery, culminating in the 2020 publication of the Cumberlege Report in the UK. As a result, the use of mesh for vaginal surgery has been restricted. When used for LVMR, mesh complications (infection and erosion) have been reported in 2–4% of cases and are higher when a polyester mesh is used.

PROCTITIS

The patient is usually middle-aged and complains of defecatory frequency with the passage of loose motions, often with blood mixed in the stools. Inflammation is sometimes limited to the rectum; in other cases, it is associated with a similar condition in the colon (proctocolitis). The inflammation can be acute or chronic. Although the patient has a frequent, intense desire to defecate, the amount of faeces passed at any time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination, there may be tenderness and blood on the glove. Proctoscopy is seldom sufficient and sigmoidoscopy is the more valuable method of examination. If the diagnosis is confirmed, colonoscopy with multiple biopsies is mandatory to determine the extent of the inflammatory process. Skilled pathological assessment is required to establish and classify the underlying pathology. Stool cultures should be sent routinely to exclude infective causes. If biopsy and histology are unable to establish an underlying inflammatory aetiology, the condition is frequently termed non-specific proctitis but may herald a subsequent diagnosis of inflammatory bowel disease (ulcerative colitis or Crohn's disease).

Treatment is usually medical and tailored to the underlying pathology. Non-specific colitis may be self-limiting, but treatment with topical 5-aminosalicylic acid (5-ASA) compounds in the form of suppositories or foam enemas is usually effective. In resistant cases, oral steroids may have to be used.

Ulcerative proctocolitis

Proctitis is present in most cases of ulcerative colitis, and the degree of rectal involvement may influence the type of operative procedure (see ***Chapter 75***).

Proctitis due to Crohn's disease

Crohn's disease can occasionally affect the rectum, although classically it is spared. Sigmoidoscopic appearances differ from those in non-specific proctitis. The inflammatory process tends to be patchy rather than confluent, and there may be fissuring, ulceration or even a cobblestone appearance. Rectal Crohn's disease is often associated with severe perineal disease characterised by fistulation, fissuring and haemorrhoids.

Summary box 79.6

Proctitis

- May be non-specific or related to a specific infective agent
- Non-specific proctitis usually remains confined to the distal bowel but can involve the proximal colon
- Symptoms include defecatory frequency, loose stools, bleeding and tenesmus
- Endoscopic assessment with biopsy is required to establish the diagnosis
- Treatment usually involves medical management

Coexistent disease is often present in the rest of the colon or small bowel, or both (see ***Chapter 75***).

Radiation proctitis

Radiation therapy is used in the treatment of cervical, prostate and rectal cancers. It can produce acute radiation proctitis with bleeding, pain, diarrhoea and defecatory frequency. Most symptoms settle within a few weeks, but some patients develop chronic proctitis with symptoms appearing months or even decades after the radiation exposure. Bleeding may require treatment with argon laser photocoagulation performed using a flexible sigmoidoscope.

Proctitis due to specific infections

Clostridium difficile

An acute form of proctocolitis caused by infection with *C. difficile* can follow broad-spectrum antibiotics. A membrane can sometimes be seen on sigmoidoscopy ('pseudomembranous' colitis).

Bacillary dysentery

The appearance is that of an acute purulent proctitis with multiple small, shallow ulcers.

Amoebic dysentery

The infection is more likely to be chronic, with exacerbations after a long period of symptom improvement. Proctoscopy and sigmoidoscopy are not painful.

Tuberculous proctitis

This is nearly always associated with active pulmonary tuberculosis or tuberculous ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

Gonococcal proctitis

Gonococcal proctitis occurs in both sexes as the result of rectal coitus and, in the female, from direct spread from the vulva.

In the acute stage, the mucous membrane is hyperaemic, and thick pus can be expressed as the proctoscope is withdrawn. In the early stages, the diagnosis can be readily established by bacteriological examination but later, when the infection is mixed, it is more difficult to recognise. Systemic treatment is so effective that local treatment is unnecessary.

Lymphogranuloma venereum

The modes of infection are similar to those of gonococcal proctitis but, in the female, chlamydial infection spreading from the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma venereum should be suspected when the inguinal lymph nodes are greatly enlarged, although nodal enlargement may be subsiding by the time proctitis commences.

Acquired immunodeficiency syndrome

Acquired immunodeficiency syndrome due to human immunodeficiency virus may present with a particularly florid type of proctitis. In such patients, unusual organisms including *Cytomegalovirus*, herpes simplex virus and parasites such as *Cryptosporidium* are often found.

Rectal bilharziasis

Rectal bilharziasis is caused by *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries and particularly in the Nile Delta. In stage 1, a cutaneous lesion develops at the site of entrance of the cercariae (parasites of freshwater snails). Stage 2 is characterised by pyrexia, urticaria and a high eosinophilia. Both these stages are frequently overlooked. Stage 3 results from deposition of the ova in the rectum (much more rarely in the bladder; see ***Chapter 83***) and is manifested by bilharzial dysentery. On examination in the later stages, papillomas are frequently seen. The papillomas, which are sessile or pedunculated, contain the ova of the trematode, the life cycle of which resembles that of *Schistosoma haematobium*. Untreated, the rectum becomes festooned and prolapse of the diseased mucous membrane is usual. Multiple fistulae-*in-ano* are prone to develop. The primary treatment is systemic and should be undertaken by a specialist in tropical medicine.

RECTAL POLYPS

The rectum, along with the sigmoid colon, is the most frequent site of polyps (and cancers) in the gastrointestinal tract. Adenomatous polyps of the colon and rectum have the potential to become malignant. The chance of developing invasive cancer is enhanced if the polyp is more than 1 cm in diameter. Removal of all polyps is recommended to allow complete histological diagnosis and exclude carcinoma. This is best done using endoscopic biopsy or snare polypectomy techniques. If one or more rectal polyps are discovered on sigmoidoscopic examination, a colonoscopy must be performed because further polyps are frequently found in the colon.

The rectum shares the same spectrum of polyps as the colon. Polyps are described in terms of their appearance (pedunculated, sessile, flat) or histological composition (tubular, villous, tubulovillous).

Polyps relevant to the rectum

Hyperplastic polyps

These are small, pinkish, sessile polyps, 2–4 mm in diameter and frequently multiple. They are usually an incidental finding, unless larger in size, when full colonoscopy is warranted to exclude hyperplastic polyposis syndrome.

Tubular adenomas

Tubular adenomas, or mixed tubulovillous adenomas, are the most common type of polyp. They have the potential to turn malignant, particularly if over 1 cm in diameter.

Villous adenomas

These have a characteristic frond-like appearance. They may be very large, occupying much of the circumference of the rectum. These tumours have an increased tendency to become malignant. Rarely, the profuse mucus discharge from these tumours, which is rich in potassium, causes electrolyte and fluid losses.

Serrated adenomas

These polyps are more commonly found in the right colon but may be present in the rectum. They are typically sessile lesions that have a distinct microscopic architecture and can give rise to cancers through an alternative 'serrated' pathway.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant inherited condition characterised by the development of multiple rectal and colonic adenomas around puberty. It is due to mutation in the adenomatous polyposis coli (*APC*) gene, allowing genetic testing in the 75% of families in which a mutation can be identified. A colonoscopy and biopsy will confirm the diagnosis. As this condition is premalignant, total colectomy is usually recommended within 10 years of disease onset. This may take the form of panproctocolectomy with permanent ileostomy. Rectal preservation may be an option if the rectal polyp load is not too severe, with colectomy and ileorectal anastomosis, but continuous rectal surveillance for synchronous polyps will be required. The alternative, if restoration of gastrointestinal continuity is desired, is to undertake restorative proctocolectomy with ileal pouch–anal anastomosis (see ***Chapter 77***).

Inflammatory pseudopolyps

These are oedematous islands of mucosa. They are usually associated with colitis in the UK, but most inflammatory diseases (including tropical diseases) can cause them. They are more likely to cause radiological difficulty, as the sigmoidoscopic appearance is usually associated with obvious signs of active or quiescent inflammation.

Theodor Maximilian Bilharz, 1825–1862, Professor of Zoology, Cairo, Egypt.

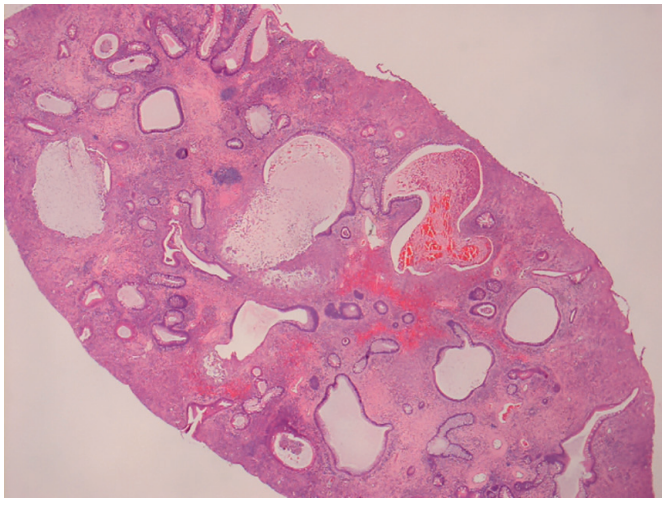

Figure 79.13 Microscopic appearance of a juvenile polyp (courtesy of Professor Kieran Sheahan, St Vincent's University Hospital, Dublin, Ireland).

Juvenile polyp

This is a bright red, glistening pedunculated sphere ('cherry tumour') that is found in infants and children that may persist into adult life. It can cause bleeding or pain if it prolapses during defecation. It often separates spontaneously but can be removed easily with forceps or a snare. A solitary juvenile polyp has virtually no tendency to malignant change but should be treated if symptomatic. Histological features typically consist of large mucus-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium (***Figure 79.13***). The rare autosomal dominant inherited syndrome juvenile polyposis does carry an increased risk of malignancy. It is characterised by multiple polyps and a positive family history.

Treatment of rectal polyps

All rectal polyps should be biopsied or removed for histological analysis. A range of techniques can be used, depending on polyp size and location. The majority are less than 1 cm in size, benign and amenable to endoscopic polypectomy. Polyps greater than 1 cm in size have a 10% chance of malignancy. The difficult polyp can be defined by a range of variables, including the number of polyps, a size greater than 15 mm or a certain shape, whether with a large pedicle or a flat appearance (see ***Chapter 72***). Endomucosal resection (EMR) and endoscopic submucosal dissection (ESD) are techniques to consider when use of biopsy forceps or a snare is not optimal. The resection plane for both EMR and ESD is the superficial submucosal layer. Both techniques utilise an injection into the submucosal layer (***Figure 79.14***). Importantly, if the mucosa does not lift, this may indirectly indicate deeper invasion of the lesion. A 'non-lift' sign may also occur because of fibrosis from previous resection attempts or tattooing (see ***Chapter 9***).

EMR is typically used for lesions up to 20 mm in size, although the piecemeal resection for lesions greater than 20 mm may obviate surgery at the risk of a higher recurrence rate. ESD was created to counter the shortcomings of EMR as en bloc resection allows assessment of both horizontal and

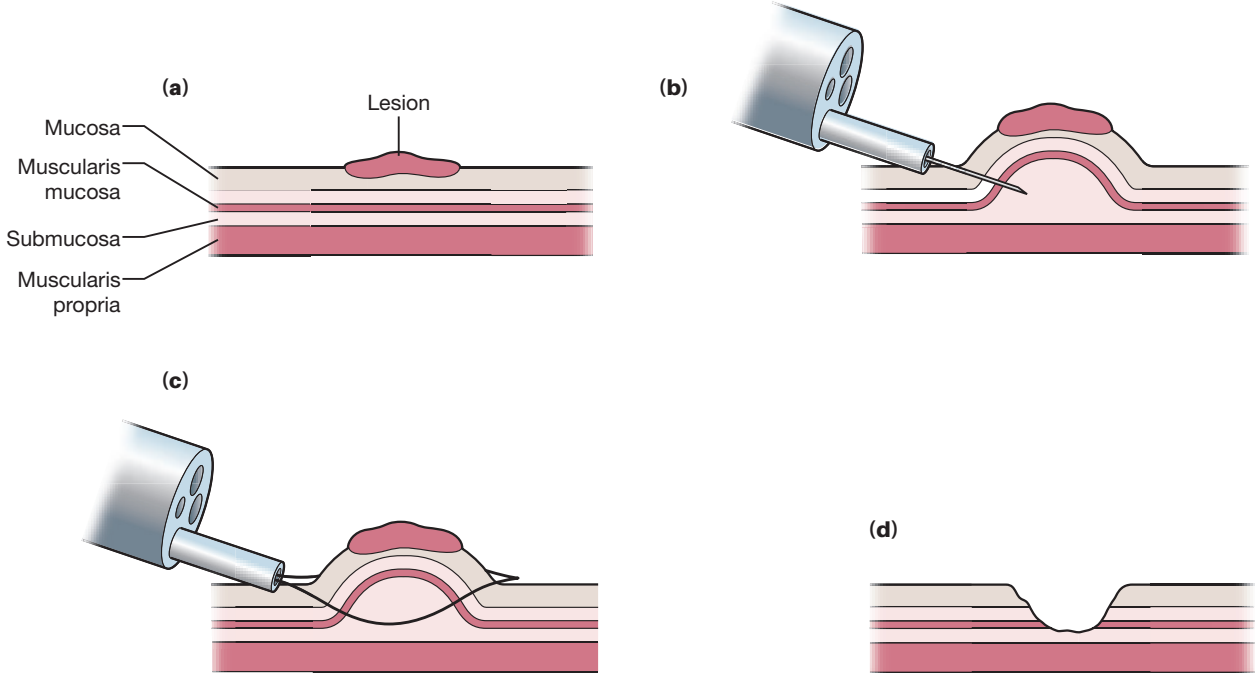

Figure 79.14 Endoscopic mucosal resection. The polyp is identified **(a)** and infiltration performed **(b)** to lift it from the underlying muscle layer. A diathermy snare is passed over the raised lesion **(c)** to achieve complete excision **(d)**.

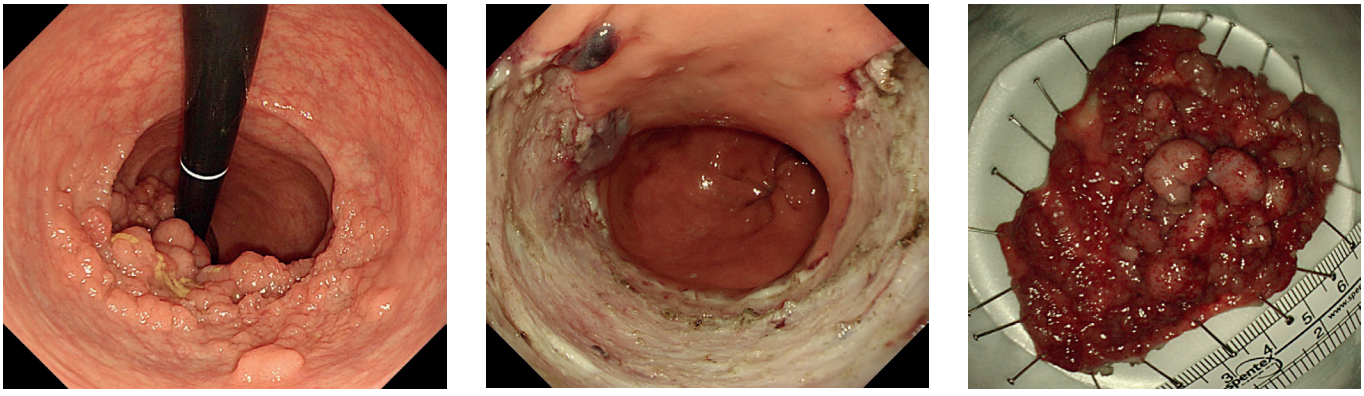

Figure 79.15 Endoscopic submucosal dissection of a rectal polyp (courtesy of Dr Noor Mohammed, St James's Hospital, Leeds, UK).

deep margins, which is not possible with a piecemeal resection (***Figure 79.15***). The submucosal injection is performed at the proximal border of the lesion, after which endoscopic knives are used to create an incision and dissect the submucosal layer free. ESD is informally indicated for lesions larger than 20 mm, when high-grade dysplasia or superficial submucosal invasion is suspected and when other endoscopic techniques have failed. The bleeding risks for EMR and ESD are roughly similar, whether immediate or delayed, with a reported incidence of 1–10%. Larger polyps are more difficult to remove by EMR and may require a transanal procedure, such as transanal endoscopic microsurgery (TEMS).

Summary box 79.7

Polyps in the rectum

- Adenomas are the most frequent histological type
- Villous adenomas may be extensive and undergo malignant change more commonly than tubular adenomas
- All adenomas must be removed to avoid malignant change
- All patients must undergo colonoscopy to determine whether further polyps are present
- Most polyps can be removed by endoscopic techniques, but sometimes major surgery is required

BENIGN RECTAL LESIONS

Endometrioma

Endometrioma is rare and may be misdiagnosed as a carcinoma. The focus of the ectopic endometrial tissue produces either a constricting lesion of the rectosigmoid or a tumour invading the rectum from the rectovaginal septum. The latter variety gives rise to a tender submucous elevation of the rectal wall. Endometrioma usually occurs between 20 and 40 years of age. Dysmenorrhoea and rectal bleeding (particularly coinciding with the menses) are the main symptoms. On sigmoidoscopy, endometriosis involving the rectosigmoid junction usually presents as a stricture, with the mucous membrane intact. Hormonal manipulation is the first-line therapy, but sometimes total abdominal hysterectomy and bilateral salpingo-oophorectomy and even bowel resection are required. The laparoscopic approach for resecting deep rectal endometriosis is becoming popular. Isolated endometrial deposits may be treated by diathermy ablation or local 'discectomy' incorporating the rectal wall.

Haemangioma

Haemangioma of the rectum is an uncommon cause of serious haemorrhage. The symptoms may mimic ulcerative colitis, and the diagnosis is often delayed, or it may be mistaken for a carcinoma. Selective angiography and embolisation may be helpful, but excision of the rectum is sometimes required.

Gastrointestinal stromal tumour

Smooth muscle tumours of the rectum are rare. If the mitotic rate is high, and if there is variation in nuclear number, size and shape, hyperchromasia and frequent bizarre cells, these tumours are likely to metastasise. In these circumstances, they should be classified as malignant gastrointestinal stromal tumours (GISTs) (formerly leiomyosarcomas). The uncertainty in their behaviour means that treatment should, whenever possible, be radical excision.

Neuroendocrine tumours

Neuroendocrine tumours (NETs) of the rectum constitute 19% of all gastrointestinal NETs. They are classified into well-differentiated (grades 1 and 2) and poorly differentiated (grade 3) tumours. Both tumour mitotic index and Ki-67 expression are important factors for histopathological classification. Grade 3 tumours include both small- and large-cell NETs. The majority of rectal NETs are grade 1, also known as carcinoid tumours, with a relatively good prognosis. These tumours are usually small (1–2 cm), solitary and clinically indolent; however, grade 3 NETs, while rare, metastasise at an early stage. Treatment depends on the size of the tumour, depth of tumour invasion and the presence or absence of metastasis. Small lesions (1 cm) can often be treated locally, either endoscopically or transanally. However, larger lesions (>2 cm) require formal oncological resection. Adjuvant therapy is indicated only for metastatic disease.

CARCINOMAS

Globally, colorectal cancer is the second most common malignancy, being the second most common cancer in women and the third most common cancer in men. It is the fourth most common cause of cancer death after lung, gastric and liver cancer. In western countries the incidence is rising, with an overall 14% increase since the 1970s, with the largest increase (20%) seen in males. Risk factors include diet, obesity, smoking and lack of physical exercise. Most colorectal cancers are due to old age, with around 60% of cases affecting patients 70 years or older. The rectum is the most frequently involved site, accounting for approximately one-third of the cancers.

Pathogenesis

Colorectal cancer originates from premalignant precursor lesions in the epithelial lining of the colon or rectum in a stepwise progression that results in increasing dysplasia due to an accumulation of genetic abnormalities. In spontaneous colorectal cancer, as compared with hereditary cancers, this is referred to as the adenoma–carcinoma sequence. Up to 80% of colorectal cancers occur in people with little or no genetic risk. People with inflammatory bowel disease are at an increased risk, which increases with the duration of the disease, and accounts for 2% of cancers each year. Those with a family history in two or more first-degree relatives have a two- to threefold greater risk of disease and this group accounts for about 20% of all cases. A number of genetic syndromes are also associated with higher rates of colorectal cancer. The most common is hereditary non-polyposis colorectal cancer (HNPCC or Lynch syndrome), which accounts for 3% of people with colorectal cancer. Other syndromes include Gardner syndrome and FAP.

The most common abnormality found in colorectal cancer is mutation in the *Wnt* signalling pathway, which increases cell signalling activity. The mutations can be inherited or acquired. The most commonly mutated gene is the *APC* gene, which results in accumulation of the β-catenin protein. β-catenin activates the transcription of various proto-oncogenes that are responsible for normal cell renewal and differentiation, but when overexpressed can cause cancer. Many other mutations, other than in the *Wnt* signalling pathway, are also found in colorectal cancer. They include mutations in the *TP53* gene, which controls normal cell division and death, and in genes responsible for programmed cell death, such as the gene encoding transforming growth factor (TGF)-β and *DCC* (deleted in colorectal cancer) gene. Other genetic abnormalities include overexpression of oncogenes, including genes encoding the proteins KRAS (Kirsten rat sarcoma homologue), RAF (rapidly accelerated fibrosarcoma) and PI3K (phosphoinositide 3-kinase), which lead to increased cell proliferation, and inactivation of tumour suppressor genes, such as *PTEN* (phosphatase and tensin homologue), which normally inactivates the PI3K signalling pathway.

In addition to gene mutations, colorectal cancers frequently exhibit epigenetic alterations – cellular or physiological effects resulting from external or environmental factors that switch genes on or off. Epigenetic alterations can affect hundreds of genes and include changes in the expression of microRNAs, hypermethylation or hypomethylation of CpG islands of protein-encoding genes and alterations in histones and chromosomal architecture, all of which can influence gene expression (see ***Chapter 77***).

Clinical features

Carcinoma of the rectum can occur early in life, but the age of presentation is usually above 55 years, when the incidence rises rapidly. Often, the early symptoms are so insignificant that the patient does not seek advice for 6 months or more, and the diagnosis is often delayed in younger patients as the symptoms are attributed to benign causes. Initial rectal examination and a low threshold for investigating persistent symptoms are essential.

Summary box 79.8

Early symptoms of rectal cancer

- Bleeding per rectum
- Tenesmus
- Early morning diarrhoea

Bleeding

Bleeding is the earliest and most common symptom. Typically, the bleeding is bright red in colour and painless. It can be mixed with the motions or separate in the toilet bowel. It can be indistinguishable from haemorrhoidal bleeding, which is the most common differential diagnosis, particularly in younger patients.

Tenesmus

The patient experiences a sensation of needing to evacuate the rectum but is unable to pass a motion. This is an important early symptom and is almost invariably present in patients with tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhoea), often with the passage of flatus and a little bloodstained mucus ('bloody slime').

Alteration in bowel habit

There is frequently a change in bowel habit, with a tendency to more frequent defecation and the passage of looser stool. A patient who has to get up early in order to defecate, or one who passes blood and mucus in addition to faeces ('early morning bloody diarrhoea'), is usually found to have carcinoma of the rectum. Although a change to looser stools is more common,

Henry Thompson Lynch, 1928–2019, physician and geneticist, Omaha, NE, USA, first presented his findings of a family with a strong history of colorectal cancer without polyposis in 1964.

Eldon John Gardner, 1909–1989, geneticist, The University of Utah, Salt Lake City, UT, USA, described this syndrome in 1950.

patients with a stenosing carcinoma at the rectosigmoid junction may complain of increasing constipation.

Pain

Pain is a late symptom, but pain of a colicky character may accompany advanced tumours of the rectosigmoid, owing to a degree of obstruction. Advanced cancers invading outside the mesorectum may infiltrate the prostate or bladder anteriorly or the sacral plexus posteriorly, giving rise to severe, intractable pain.

Weight loss

Weight loss is also a late symptom and is almost always associated with metastatic disease.

Investigation

Abdominal examination

Abdominal examination is normal in early cases. Occasionally, in patients with stenosing tumours at the rectosigmoid junction, signs of subacute large bowel obstruction may be present, with abdominal distension. If large volume liver metastases are present, an enlarged liver may be palpable along with other signs, such as cachexia. Occasionally, it may be possible to elicit ascites if there is widespread peritoneal dissemination.

Rectal examination

In many cases where the neoplasm is situated within 7–8 cm of the anal verge it can be felt on digital rectal examination as an elevated, irregular and hard endoluminal mass. When the centre ulcerates, a shallow depression will be felt with raised and everted edges. An attempt should be made to determine whether the neoplasm is mobile, tethered or fixed, and to estimate the distance of the lower margin from the top of the anal sphincter complex: these factors are important in assessing resectability and methods of reconstruction following excisional surgery. In females, a vaginal examination may be useful if involvement of the posterior vaginal wall is suspected. Digital rectal examination also affords the opportunity to evaluate the anal sphincter complex, which is important in cases where resection and low anastomosis is being considered.

Rigid sigmoidoscopy

Rigid sigmoidoscopy can be performed in the outpatient clinic and is useful to identify the neoplasm and possibly obtain biopsies. However, it requires the rectum to be empty of faeces and may require a prior rectal enema, which may not be practical in the outpatient setting. As colonoscopy is almost always required to visualise the whole colorectum, it is often easier and safer to obtain biopsies at this time.

Colonoscopy

A colonoscopy is required in most patients to exclude a synchronous tumour, be it an adenoma or carcinoma. If a proximal adenoma is found, it can be conveniently snared and removed via the colonoscope. If a synchronous carcinoma is present, the operative strategy is likely to change. If a full colonoscopy is not possible, for example when there is a stenosing cancer, a CT colonography or barium enema can be performed.

Differential diagnosis

Many colorectal lesions can give rise to diagnostic difficulty. For example, it may be difficult to distinguish an inflammatory stricture or amoebic granuloma on macroscopic appearance. Similarly, endometriomas, carcinoid tumours and solitary rectal ulcers can be mistaken for adenocarcinoma. Benign adenomas can be distinguished from malignant lesions based on the appearance of their mucosal 'pit patterns', as highlighted with the 'dye spray' colonoscopy technique (see ***Chapter 9***). Biopsy and histological analysis remain the mainstay of diagnosis, accepting that there may be diagnostic limitations caused by sampling errors owing to small biopsy samples being unrepresentative of the larger lesion.

Summary box 79.9

Diagnosis and assessment of rectal cancer

All patients with suspected rectal cancer should undergo:

- Digital rectal examination
- Full colorectal visualisation, preferably by colonoscopy with biopsy or CT colonography or barium enema

All patients with proven rectal cancer require staging by:

- Imaging of the chest, abdomen and pelvis, preferably by CT
- Local pelvic imaging by magnetic resonance imaging (MRI) and/or endoluminal ultrasonography

Types of carcinoma spread

Local spread

Local spread occurs circumferentially rather than in a longitudinal direction. After the muscular coat has been penetrated, the growth spreads into the surrounding mesorectum, but is initially limited by the mesorectal fascia. If penetration occurs anteriorly, the prostate, seminal vesicles or bladder become involved in the male; in the female, the vagina or the uterus is invaded. In either sex, if the penetration is lateral, a ureter may become involved, while posterior penetration may reach the sacrum and the sacral plexus. Downward spread for more than a few centimetres is rare.

Lymphatic spread

Lymphatic spread from a carcinoma of the rectum above the peritoneal reflection occurs almost exclusively in an upward direction. Below that level, the lymphatic spread is still upwards, but when the neoplasm lies within the field of the middle rectal artery, primary lateral spread to the pelvic wall lymphatics occurs in around 20% of cases. Downward spread is exceptional, with drainage along the subcutaneous lymphatics to the groins being confined, for practical purposes, to the lymph nodes draining the perianal rosette and the epithelial lining of the distal 1–2 cm of the anal canal.

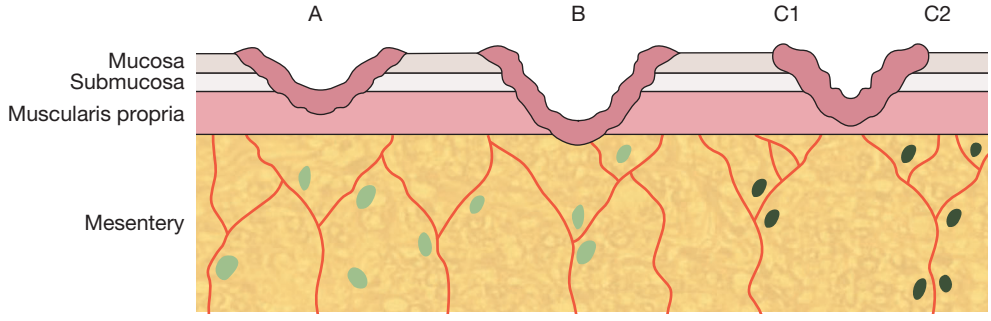

Figure 79.16 Dukes' classification of colorectal cancer. A, the cancer is confined to the bowel wall. B, the cancer penetrates the muscularis propria. C, involvement of the draining lymph nodes. Stage C was later modified: C1, pararectal nodes involved; C2, apical nodes involved.

Metastasis at a higher level than the main trunk of the superior rectal artery occurs late in the disease. A radical operation should ensure that the high-lying lymph nodes are removed by ligating the inferior mesenteric artery at its origin from the aorta. Atypical and widespread lymphatic permeation can occur with highly undifferentiated neoplasms.

Venous spread

The principal sites for blood-borne metastases are liver (34%), lungs (22%) and adrenals (11%). The remaining 33% are divided among the many other locations where secondary carcinomatous deposits tend to lodge, including the brain.

Peritoneal dissemination

This may follow penetration of the peritoneal coat by a high-lying rectal carcinoma.

Stages of progression

Dukes classified carcinoma of the rectum into three stages (***Figure 79.16***).

Dukes' staging

- A: The growth is limited to the rectal wall (15%). The prognosis is excellent (>90% 5-year survival).
- B: The growth extends to the extrarectal tissues, but without metastasis to the regional lymph nodes (35%). The prognosis is reasonable (70% 5-year survival).
- C: There are secondary deposits in the regional lymph nodes (50%). These are subdivided into C1, in which the local pararectal lymph nodes alone are involved, and C2, in which the nodes accompanying the supplying blood vessels to their origin from the aorta are involved. This does not take into account cases that have metastasised beyond the regional lymph nodes or by way of the venous system. The prognosis is poor (40% 5-year survival).

A stage D is often included, which was not described by Dukes. This stage signifies the presence of widespread metastases, usually hepatic. Other staging systems have been developed (e.g. Astler–Coller, TNM) to improve prognostic accuracy, with the tumour–node–metastasis (TNM) classification now recognised internationally as the optimum staging classification (***Table 79.2***).

TABLE 79.2 TNM staging of rectal cancer.

Tx:	Primary tumour cannot be assessed
T0:	No evidence of primary tumour
Tis:	Carcinoma *in situ*, intraepithelial or invasion of lamina propria
T1:	Tumour invading submucosa
T2:	Tumour invading the muscularis propria
T3:	Tumour penetrating the muscularis propria into perirectal fat (mesorectum)
T4a:	Tumour penetrating visceral peritoneum
T4b:	Tumour directly invading or adhering to other organs or structures
Nx:	Regional lymph nodes cannot be assessed
N0:	No lymph node metastasis and no TD
N1:	1–3 lymph node metastases
	N1a: 1 lymph node metastasis
	N1b: 2 or 3 lymph node metastases
	N1c: Submucosal, mesangial or peritoneum-covered paracolorectal TDs in the absence of regional lymph node metastases
N2:	≥ 4 lymph node metastases
	N2a: 4–6 regional lymph node metastases
	N2b: ≥ 7 lymph node metastases
M1:	There are distant metastases
	M1a: Metastases are limited to 1 organ or site (e.g. liver, lung, ovary and extraregional lymph node metastases)
	M1b: Metastases to more than 1 organ or site
	M1c: Peritoneal metastases with or without metastases to other organs

TD, tumour deposits.

Cuthbert Esquire Dukes, 1890–1977, pathologist, St Mark's Hospital, London, UK. The original Dukes' classification in 1932 gave three stages, A–C.
Vernon B Astler, surgeon, University of Michigan Medical School, Ann Arbor, MI, USA.
Frederick A Coller, 1887–1964, pathologist, University of Michigan Medical School, Ann Arbor, MI, USA.

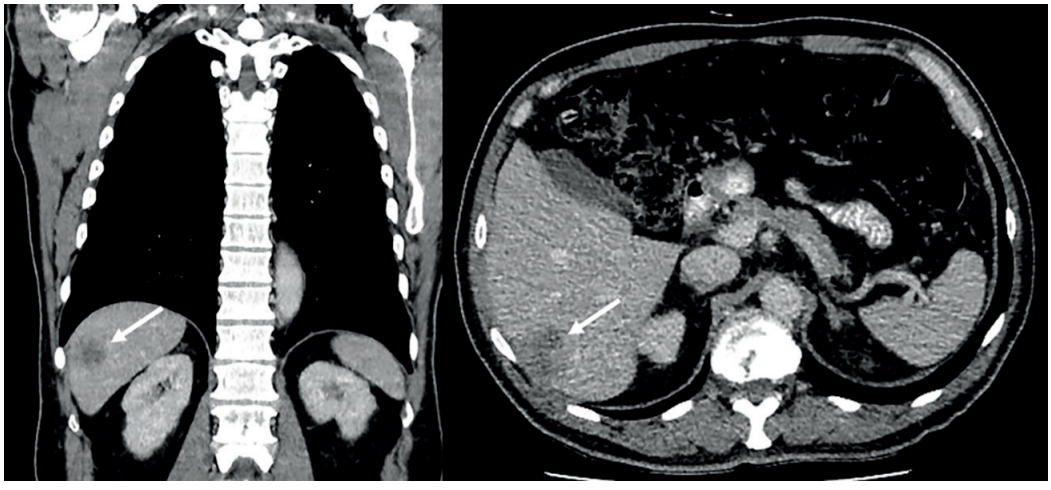

Figure 79.17 Coronal and axial images from surveillance computed tomography showing a solitary 2.5-cm metastasis in segment 6 of the liver (arrow) in a patient with rectal cancer.

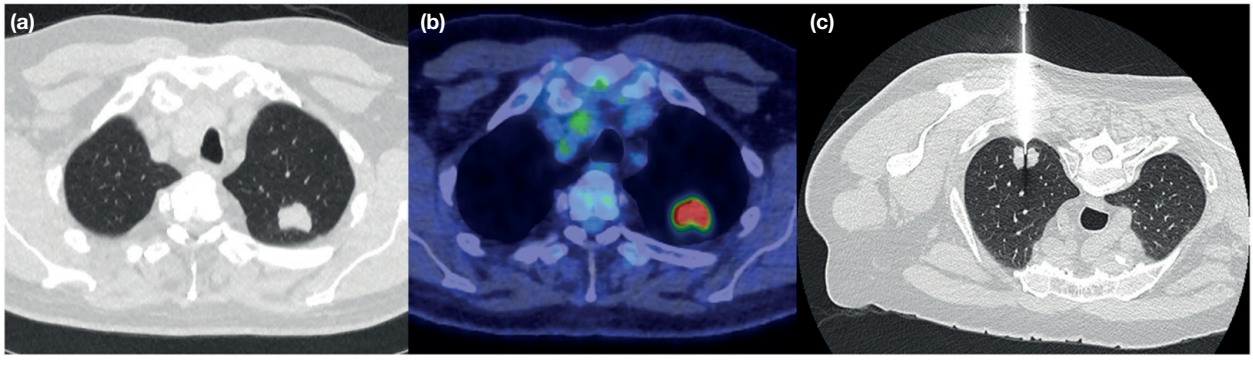

Figure 79.18 (a) Initial screening computed tomography (CT) showing a 1.5-cm diameter solid lesion in the right lung, with **(b)** positron emission tomography–CT indicating increased metabolic uptake and **(c)** later CT-guided biopsy that confirmed adenocarcinoma from a lower gastrointestinal origin (courtesy of Dr Damian Tolan, St James's Hospital, Leeds, UK).

Radiological staging

All patients with a diagnosis of rectal cancer should undergo staging CT of the thorax, abdomen and pelvis (TAP) to stage both local and metastatic disease (***Figure 79.17***). Positron emission tomography (PET) scanning can be helpful in identifying metastases if imaging is otherwise equivocal or to identify multiple metastatic foci (***Figure 79.18***).

MRI is the best modality to assess soft-tissue extent of the tumour, the degree of infiltration of the mesorectum and mesorectal lymph node involvement and to ascertain whether the mesorectal fascia is potentially involved (***Figure 79.19***). These determinations are of great importance in guiding both surgical and oncological management.

Histological grading

In the great majority of cases, carcinoma of the rectum is an adenocarcinoma, derived from malignant transformation of the columnar rectal epithelium. The more the tumour cells retain normal shape and arrangement (well differentiated), the less aggressive the behaviour. Conversely, the more cells of an undifferentiated type, the more aggressive the behaviour. Other poor prognostic features include vascular and perineural invasion, the presence of an infiltrating (rather than pushing) margin and tumour budding. In a small number of cases, the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Signet ring carcinomas grow rapidly, metastasise early and have a poor prognosis.

Summary box 79.10

Pathology and staging of rectal cancer

- Tumours are adenocarcinomas and are well, moderately or poorly differentiated
- They spread by local, lymphatic, venous and transperitoneal routes
- Circumferential local spread is the most important and dictates management
- Lymphatic spread follows the blood supply of the rectum in a cephalad direction via the superior rectal vessels to the para-aortic nodes, but in low rectal cancer it can also involve the lateral pelvic lymph nodes
- The TNM classification is the internationally recognised staging system

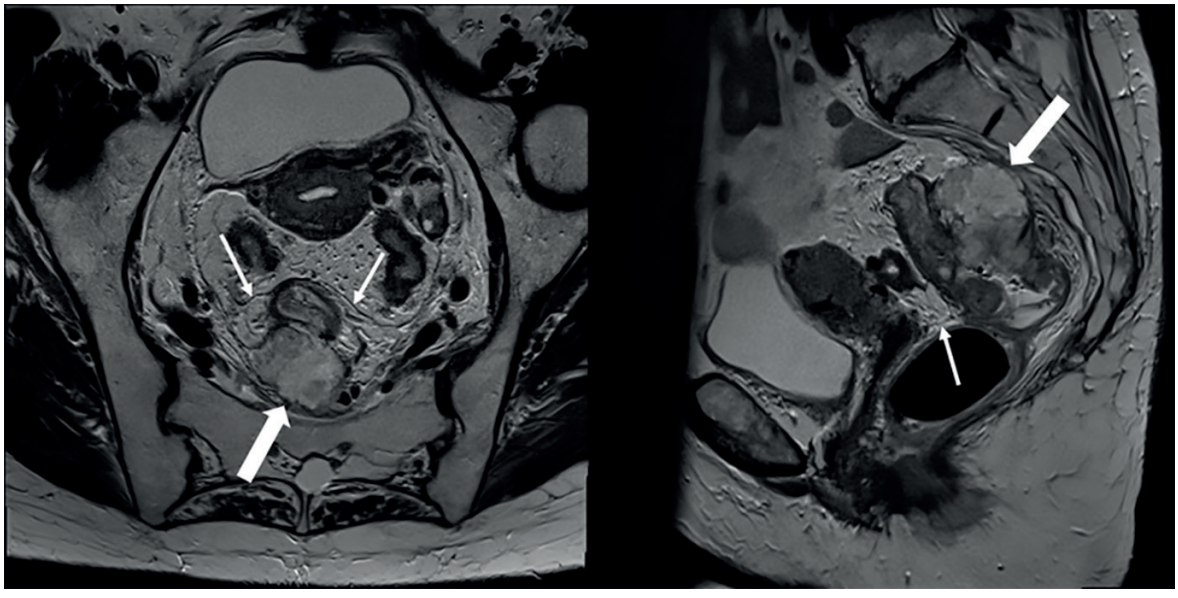

Figure 79.19 Axial and sagittal T2-weighted magnetic resonance images showing a locally advanced high-signal T3 mucinous rectal cancer with involvement of the posterior circumferential resection margin (thick arrows) anterior to the second sacral segment. Note the position of the peritoneal reflection and the peritoneum in relation to the tumour (thin arrows) (courtesy of Dr Damian Tolan, St James's Hospital, Leeds, UK).

Treatment

Surgical excision of the tumour is the conventional treatment, provided this can be achieved with clear oncological margins and acceptable risk of morbidity and mortality. However, the management of rectal cancer has become increasingly complex because of the various surgical techniques available and the range of neoadjuvant and adjuvant options. Before treatment can be planned, it is necessary to assess both the fitness of the patient and the extent of spread of the tumour. The management needs to be discussed within a multidisciplinary team (MDT) setting involving surgeons, radiologists, oncologists, pathologists and specialty nurses. It is particularly important that the recommendation be documented and discussed with the patient. The ultimate treatment decision is made jointly with the patient, taking their wishes and expectations fully into account.

Principles of surgical treatment

Radical excision of the rectum, together with the mesorectum and associated lymph nodes, should be the aim in most cases. In the presence of widespread metastases, other means of palliation should be considered, such as endoluminal stenting or external beam radiotherapy, although there may still be a role for palliative resection. The presence of liver metastases does not necessarily rule out the feasibility of cure: the results of surgery for liver metastases have greatly improved, with long-term survival being achieved in over a third of patients (see ***Chapter 69***).

When a tumour appears to be locally advanced (i.e. invading a neighbouring structure or threatening to breach the circumferential resection margin), the use of neoadjuvant (preoperative) radiotherapy or chemoradiotherapy is usually considered. Long-course chemoradiotherapy is given as five fractions of radiotherapy combined with chemotherapy over a 6-week period. The aim is to downstage the cancer and increase the chances of a complete resection with clear oncological margins. Alternatively, preoperative 'short-course' (5 days) radiotherapy can be used if the resection margins are not threatened but the cancer is still at high risk for local recurrence (e.g. perirectal lymph node involvement).

Approximately 20% of rectal cancers treated by neoadjuvant chemoradiotherapy show a complete clinical response with no evidence of residual cancer on clinical examination, biopsy or radiological imaging. There is an increasing trend for such patients to be offered the option of 'watch and wait' (Habr-Gama) in the hope that they may have been cured of the disease and spared the morbidity of resectional surgery. Some 30% of cases will recur on a 'watch-and-wait' policy, but most can be salvaged by surgical resection (***Figures 79.20 and 79.21***).

There is also growing enthusiasm for 'organ-preserving' surgical techniques in early T1 and even T2 cancers with good prognostic features. This usually involves full-thickness excision of the cancer using TEMS (***Figure 79.22***). Alternative 'organ-preserving' techniques involve the use of brachytherapy and contact radiotherapy, but these are currently reserved for patients unfit for radical resection or as a means of palliation.

When radical excision is possible, the aim should be to restore gastrointestinal continuity and continence by preserving the anal sphincter whenever feasible. A sphincter-saving operation (anterior resection) is usually possible for tumours whose lower margin is ≥2 cm above the anorectal junction. Although in the past removal of the rectum and anus with a

permanent colostomy (abdominoperineal excision) was often required for tumours, the introduction of the stapled anastomosis and chemoradiotherapy downstaging has enabled many more patients to be treated by a sphincter-saving procedure.

The principles of anterior resection involve radical excision of the cancer along with its complete mesorectal envelope, combined with high proximal ligation of the inferior mesenteric lymphovascular pedicle. Once the left colon and rectum have been mobilised, the distal rectum is divided at least 1 cm (and preferably more) below the distal cancer margin and the specimen removed. Rectosigmoid cancers and those in the upper third of the rectum are removed by 'high anterior resection', in which the rectum and mesorectum are taken to a margin of at least 3 cm distal to the tumour and a colorectal anastomosis is performed. For tumours in the middle and lower thirds of the rectum, complete removal of the rectum and mesorectum is required, i.e. TME (Heald). Restoration of continuity is usually performed using a stapling technique, which might involve an end-to-end, side-to-end or colopouch construction in low cancers (***Figure 79.23***). The retention of at least a part of the rectum in high anterior resection results in better postoperative function, with less risk of anterior resection syndrome, a condition characterised by defecatory urgency, incontinence and incomplete evacuation, secondary to removal of the normal rectal reservoir. In cancers situated below the peritoneal reflection it is usual practice to defunction the anastomosis with a temporary stoma because of the higher risk of anastomotic leak. Although a defunctioning stoma does not prevent anastomotic leak, it does mitigate against septic complications should a leak occur.

RJ (Bill) Heald, contemporary, surgeon, Basingstoke, UK, and Champalimaud Foundation, Lisbon, Portugal.

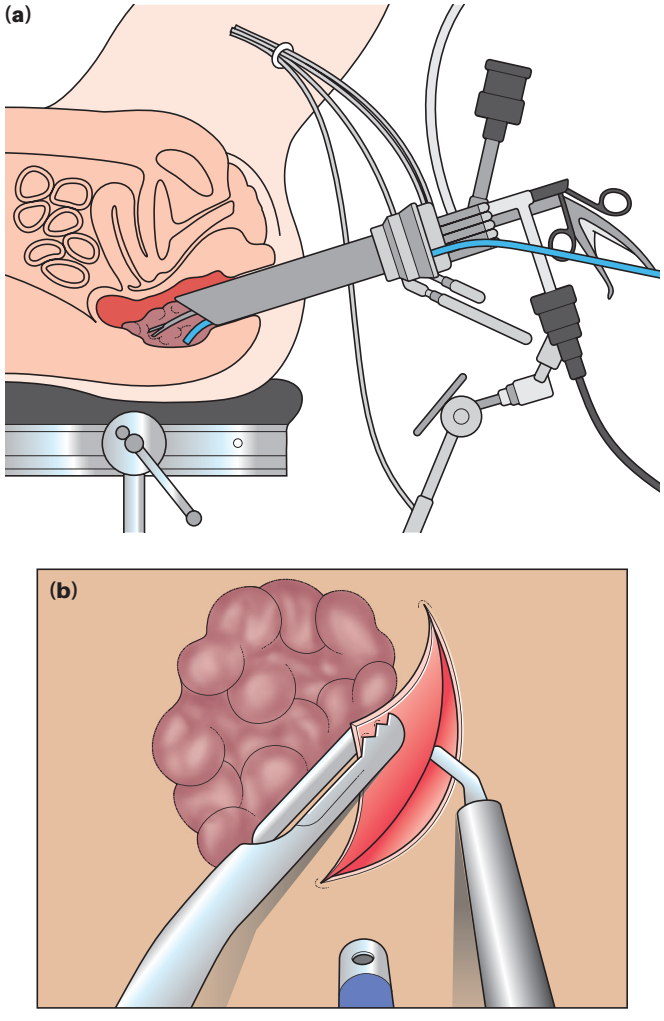

Figure 79.22 Transanal endoscopic microsurgery. **(a)** An operating sigmoidoscope is inserted through the anal canal to visualise the lesion and enable passage of a laparoscope and instruments. **(b)** A full-thickness local excision is performed. The defect is closed or, alternatively, may be left open if the peritoneum is not breached.

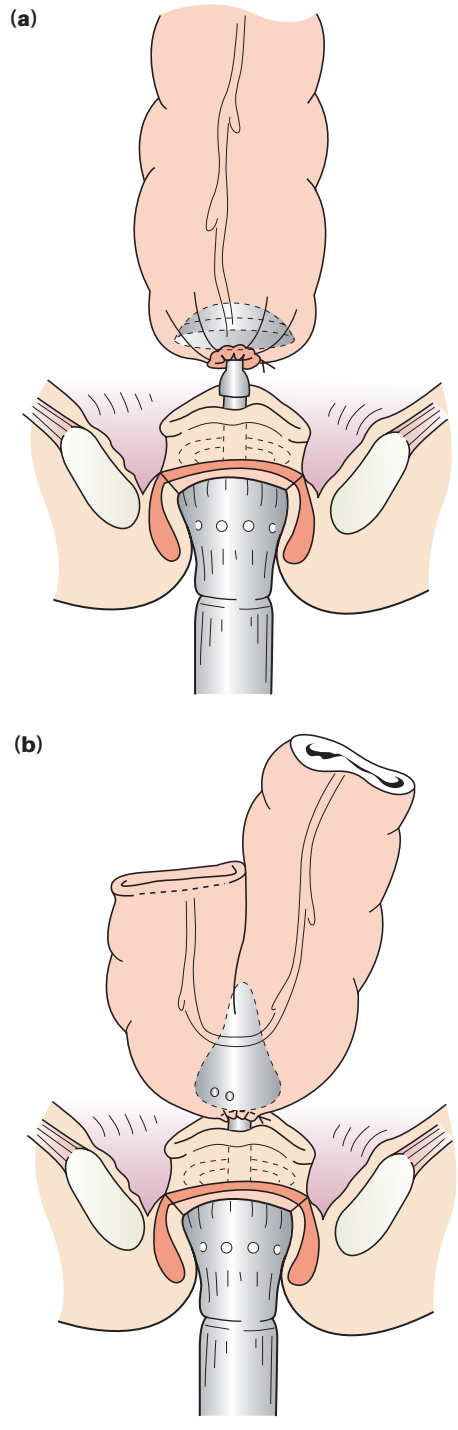

Figure 79.23 Low anterior resection by the double stapling method. The rectum has been excised and the distal anorectal stump has been transected with a transverse stapling device. A circular stapling device is used to construct either **(a)** a straight low coloanal anastomosis or **(b)** a colopouch–anal anastomosis.

Summary box 79.11

Surgery for rectal cancer

- Surgery is the mainstay of curative therapy
- The primary resection consists of rectal resection performed by TME
- Early cancers (stages T1 and selected T2) may be suitable for local excision
- Most cases can be treated by anterior resection, with a colorectal or coloanal anastomosis being achieved with a circular stapling device
- Low, extensive tumours require an abdominoperineal excision with a permanent colostomy
- Neoadjuvant chemoradiotherapy can be used to downstage the cancer and reduce local recurrence
- 'Watch and wait' non-operative management is an option for the 20% who have a complete clinical response to neoadjuvant chemoradiotherapy

Preoperative preparation

The bowel is usually prepared by mechanical cleansing using a combination of diet, purgatives and enemas to reduce intraoperative contamination and the risk of surgical site infection. While this approach has been used selectively, recent guidelines recommend preoperative bowel preparation.

Prophylactic systemic antibiotics are usually given perioperatively to reduce the risk of surgical site infection. In Europe, this usually takes the form of broad-spectrum antibiotics given intravenously at induction of anaesthesia. In the USA, antibiotic prophylaxis is more frequently administered as a course of oral antibiotics (neomycin and metronidazole) given preoperatively in addition to intravenous antibiotics at the induction of anaesthesia. There is evidence to suggest that this may reduce the risk of septic complications, including anastomotic leak.

All patients should be seen by a stoma care nurse preoperatively and be sited for a temporary or permanent ileostomy and/or colostomy. They must also be counselled as to the complications of the procedure, and particularly about the risks of pelvic autonomic nerve damage causing bladder and sexual disturbance, especially impotence in males.

Summary box 79.12

Preoperative preparation

- Counselling and siting of stomas
- Correction of anaemia and electrolyte disturbance
- Type and screen for blood transfusion
- Bowel preparation
- Deep vein thrombosis prophylaxis
- Prophylactic antibiotics

Local operations

Early rectal cancers (T1 and good prognosis T2) may be amenable to local transanal excision, preserving much of the rectal reservoir and therefore near normal function. Histological analysis of the specimen is then used to assess the adequacy of excision with respect to the probability of positive lymph nodes being left behind. This may range from 10% in T1 cancers to 20% in T2 cancers and clinical judgement, along with in-depth conversation with the patient, is required to determine whether local excision has achieved a sufficient chance of oncological cure or whether a further radical resection is required.

Local excision is usually performed with one of the commercially available transanal laparoscopic systems or with equipment modified from transanal total mesorectal excision (taTME) procedures (see ***Transanal total mesorectal excision***). A full-thickness excision of the lesion is performed and the defect closed with sutures or else left open. There is a limit to the height of lesion that can be resected, with more proximal lesions in the upper rectum being difficult.

Anterior resection

There has been a move to extend sphincter-saving operations to treat most tumours of the middle and lower thirds of the rectum, thus reducing the abdominoperineal excision rate and the need for permanent colostomy. There is also an increasing trend to use laparoscopic techniques for anterior resection, with patient benefits including less pain, quicker recovery from surgery and improved cosmesis. The evidence suggests that laparoscopic anterior resection is as safe as open surgery in terms of short- and long-term complications and oncological outcomes. More recently, robotic assistance has been employed with the da Vinci robotic surgical system (Intuitive Surgical Inc., Sunnyvale, CA, USA) (***Figure 79.24***). Although this adds significant cost to the procedure, there may be some benefit in terms of a reduced need to convert to open surgery, and

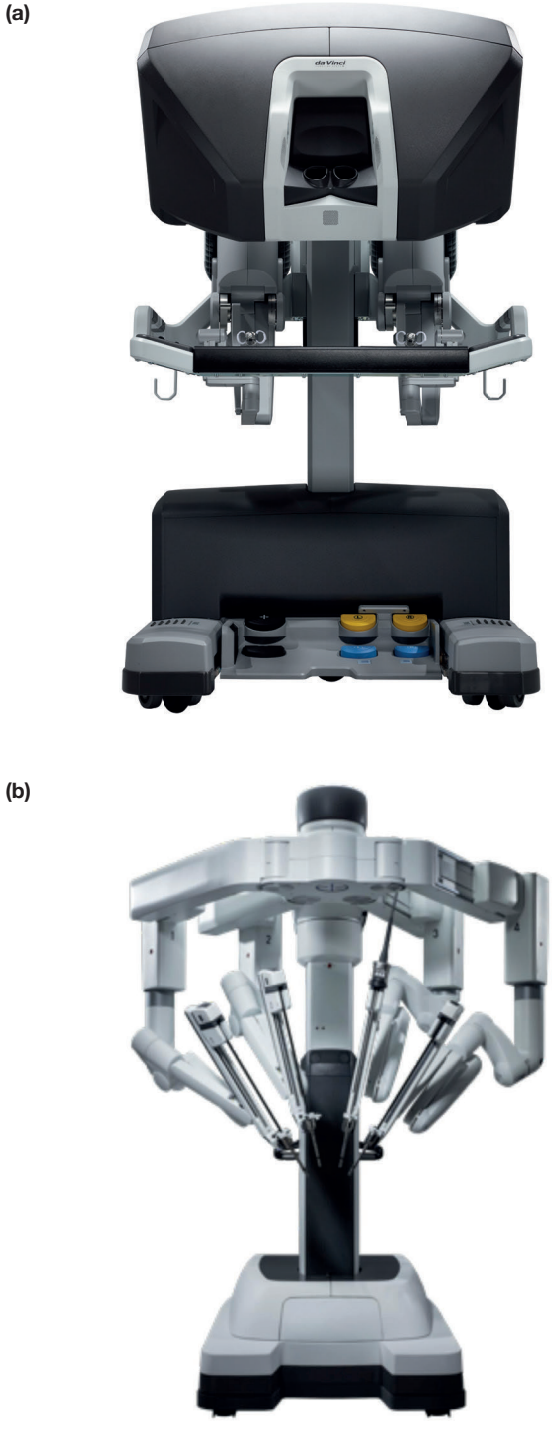

Figure 79.24 da Vinci Xi Robotic Surgical System: **(a)** surgeon console; **(b)** patient cart. (Reproduced with kind permission from Intuitive Surgical Inc. https://www.intuitive.com/en-us/products-and-services/da-vinci/systems/.)

therefore more patients benefiting from a minimally invasive approach. The operation performed is the same whether the procedure is undertaken by open, laparoscopic or robotic surgery, with the difference being in the extent of abdominal access trauma (laparotomy wound versus 'keyhole' incisions).

In open surgery, a midline abdominal incision is made and full laparotomy performed to detect synchronous pathologies, including evidence of intra-abdominal cancer spread. The sigmoid and descending colon are freed by dividing the peritoneal reflection on the left side and then mobilising them to the midline on their mesentery, protecting the left ureter and testicular/ovarian vessels. The splenic flexure is mobilised to gain sufficient left colonic length to allow tension-free colorectal anastomosis. Rectal dissection is performed in the embryological planes (TME) with preservation of the autonomic nerves, which course over the pelvic brim (sympathetic nerves) and exit from the pelvic plexuses (parasympathetic nerves) to supply the pelvic floor and the urogenital organs (***Figure 79.25***). Once rectal dissection has reached the anorectal junction (low anterior resection), or at least 3 cm below the cancer (high anterior resection), the rectum is divided, usually with the aid of a stapling device.

The mesocolon is divided at the site of the proposed division of the colon and the trunk of the inferior mesenteric artery is ligated and divided at its origin from the aorta (high tie). Resection of the specimen is completed by division of the bowel at the point to be used for the proximal anastomosis.

Restoration of bowel continuity is usually achieved by means of a stapled anastomosis. The simplest way of achieving this is by using a 'double stapling' technique, whereby a circular stapling device (***Figure 79.23***) is passed transanally to anastomose the stapled ends of the proximal colon and rectal stump. Alternatively, a 'single stapled' anastomosis may be performed in which purse-string sutures are applied to the proximal colon and rectal stump and anastomosed using a single firing of a circular stapling device inserted transanally. In cases where the anastomosis is very low (coloanal anastomosis) it may be necessary to perform a hand-sewn anastomosis.

Laparoscopic and robotic anterior resection follow the above general principles, but with abdominal access through the use of four or five abdominal ports and carbon dioxide pneumoperitoneum. The dissection usually follows a medial-to-lateral approach, i.e. dissection and high ligation of the vascular pedicle followed by lateral mobilisation of the colon, then rectal resection. A small laparotomy wound is still required to extract the specimen, unless transanal specimen extraction is possible, and restoration of bowel continuity is performed by the usual stapling techniques.

Transanal total mesorectal excision

taTME builds on the principles of laparoscopic surgery, with an airtight anal device used to provide transanal insufflation and access for laparoscopic instruments. The operation proceeds by placing a purse-string suture below the distal level of the tumour and incising the bowel wall to enter the mesorectal plane. Dissection then proceeds using a 'bottom-up' approach to accomplish TME. It is usual for this procedure to be undertaken as a combined operation, with synchronous 'top-down' laparoscopic resection by an abdominal operator who mobilises the left colon, takes down the splenic flexure and does some of the upper rectal dissection.

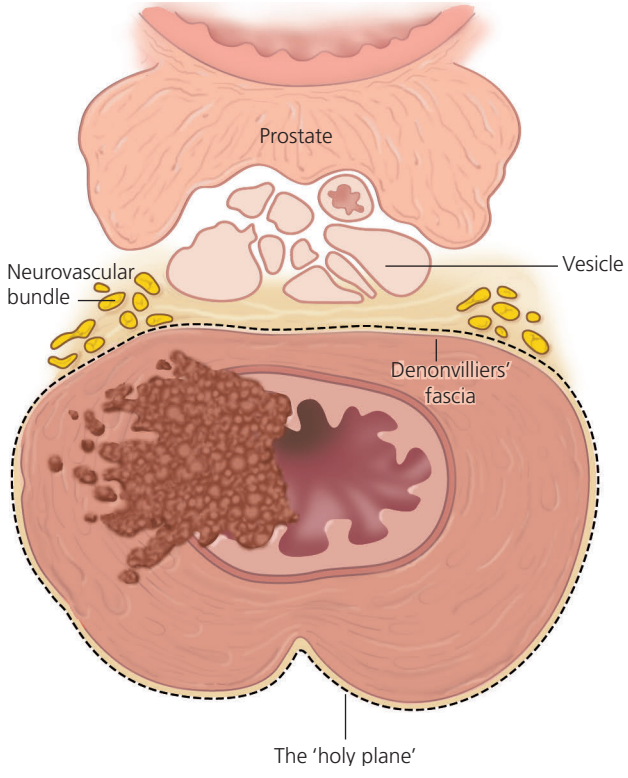

Figure 79.25 Plane of dissection for total mesorectal excision in a male with midrectal cancer. (Reproduced with permission from O'Connell PR, Madoff RD, Solomon MJ (eds). *Operative surgery of the colon, rectum and anus*, 6th edn. Boca Raton, FL: CRC Press, 2015.)

Initial results have demonstrated that taTME is safe, with short-term oncological outcomes, in terms of pathological quality of the resection specimen and circumferential resection margins, comparable to those of traditional laparoscopic and open techniques. However, concerns have been raised regarding the increased incidence of urethral injuries and the development of multifocal local recurrences. These concerns highlight the critical importance of adequate taTME training, proper case selection, and proctorship with maintenance of high procedural volumes in an MDT setting to help ensure optimal outcomes. Meanwhile, several multicentre randomised controlled trials such as COLOR III and TaLaR are well under way to confirm the long-term oncological safety of taTME.

Hartmann's operation

This is an option in elderly and frail patients in whom there is concern about poor anal sphincter function and postoperative incontinence or the viability of an anastomosis. Colorectal excision follows the same principles as outlined above, but the rectal stump is stapled closed and the proximal colon exteriorised as a permanent end-colostomy.

Abdominoperineal excision of the rectum

This operation is still required for some tumours of the lower third of the rectum that are unsuitable for a sphincter-saving

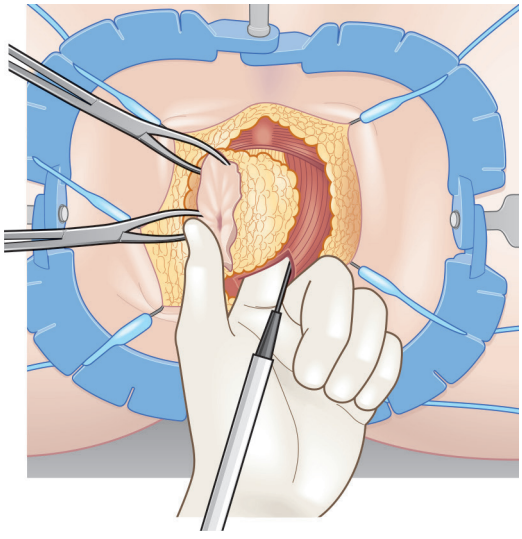

Figure 79.26 Separation and division of the pubococcygeus and puborectalis muscles in the course of the perineal phase of an abdominoperineal excision of the rectum. (Reproduced with permission from O'Connell PR, Madoff RD, Solomon MJ (eds). *Operative surgery of the colon, rectum and anus*, 6th edn. Boca Raton, FL: CRC Press, 2015.)

procedure. Traditionally, the procedure was performed by two surgeons operating simultaneously, one via the abdomen and the other via the perineum, with the patient in the Trendelenburg lithotomy position. More recently, there has been a shift to completing the abdominal procedure first (with the patient in the Lloyd-Davies position, in which the legs are in supports set lower than the lithotomy position), and then placing the patient either in a prone jack-knife or Lloyd-Davies position and completing the operation via the perineum. The aim is to produce a complete resection of the rectum and mesorectum along with cylindrical excision of the extralevator component. This achieves wide excision at the level of the pelvic floor, increasing complete resection rates and reducing local perforation and the risk of local recurrence.

The abdominal procedure is carried out laparoscopically or via a midline laparotomy and is performed in the same way as an anterior resection, except that dissection stops before the pelvic floor is reached (at the level of the seminal vesicles in men or the cervix in women) to avoid 'coning down' onto the tumour at the level of the pelvic floor. Perineal dissection is achieved through a circumanal incision, which is deepened into the ischiorectal fossae and out towards the attachment of the levator muscles to the pelvic side wall (***Figure 79.26***). The dissection is extended posteriorly by incising Waldeyer's fascia, which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Some surgeons routinely remove the coccyx to improve access and surgical margins. Anteriorly, the plane between the rectum and the prostate in the male or between the rectum and the vagina in the female is developed, with particular care to avoid the membranous urethra in the male. A catheter within it should be palpated so that it can be avoided.

The posterior wall of the vagina can be excised with the rectum if an advanced anterior tumour is present. Resection is completed when the perineal dissection reaches the abdominal dissection, with the specimen retrieved through the perineal wound. An end-colostomy is formed in the left iliac fossa and the wounds closed with drains to the pelvis.

Endoluminal stenting

An increasingly used alternative for patients with an obstructing carcinoma is placement of an endoluminal stent, which can be done endoscopically, often with fluoroscopic guidance. This can be used either as a palliative procedure or to relieve obstruction and permit elective rather than emergency surgery to be undertaken. Only rectosigmoid and upper rectal tumours are suitable for stenting because stent impingement on the anorectum in low cancers causes symptoms of tenesmus (see ***Chapter 77***).

Palliative colostomy

This is indicated only in cases giving rise to intestinal obstruction, or where the rectal cancer is not resectable. It can be performed by either an open or laparoscopic approach. In some cases, a defunctioning colostomy is required in advanced cancers to prevent obstruction during downstaging chemoradiotherapy.

Pelvic exenteration

When carcinoma of the rectum has spread to contiguous organs, a more radical operation known as pelvic exenteration can remove these structures en bloc. Thus, in the male, in whom spread is usually to the bladder or prostate, a cystectomy or prostatectomy may be required in combination with anterior resection to achieve complete oncological clearance. In the female, the uterus acts as an oncological barrier, preventing spread from the rectum to the bladder. Accordingly, a hysterectomy can be undertaken in addition to excision of the rectum.

The aim is to remove pelvic organs involved in the malignant process and may involve a partial (posterior exenteration, including rectum and posterior vagina/uterus) or complete (including rectum and urogenital organs) exenteration (***Figure 79.27***).

Total pelvic exenteration may also be necessary for local disease recurrence. It involves a large excision of the pelvic floor, leaving a sizeable perineal defect that has to be reconstructed using rectus abdominus or gluteal flaps to fill the empty pelvis. Excision of the bladder will require the formation of an ileal conduit in addition to a colostomy. Following such radical surgery, quality of life (QoL) is a crucial postoperative consideration, and therefore detailed preoperative discussion with patients regarding QoL post procedure is required.

Liver resection

Single or multiple well-localised liver metastases can now be resected with relatively low mortality and morbidity. Provided

Friedrich Trendelenburg, 1844–1924, Professor of Surgery, successively at Rostock (1875–1882), Bonn (1882–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Oswald Vaughan Lloyd-Davies, 1905–1987, surgeon, St Mark's Hospital, London, UK.

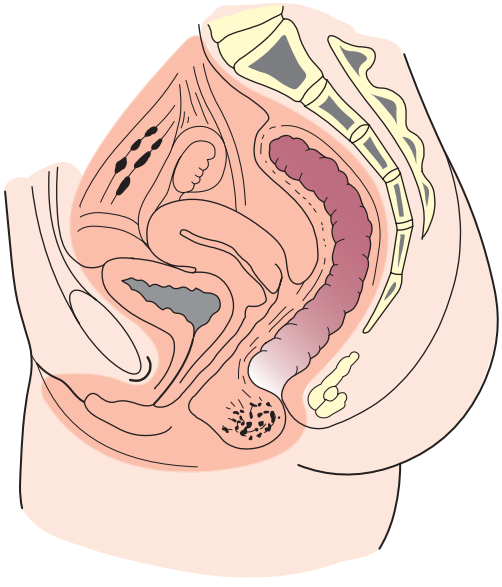

Figure 79.27 Radical pelvic exenteration, indicating the extent of the dissection and the viscera removed (shaded dark pink). (Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, rectum and colon*. London: WB Saunders, 1999.)

the patients are carefully selected, a reasonable long-term survival rate can be achieved (approximately 40%). Such surgery is usually carried out in a specialised liver unit and may be performed synchronously at the time of anterior resection or as a delayed procedure (see ***Chapter 69***).

Radiotherapy

Radiotherapy is now commonly used and may be given preoperatively (neoadjuvant) and less commonly postoperatively (adjuvant). In the neoadjuvant setting, radiotherapy is used to either 'sterilise' the operative field in cancers with suspected lymphovascular involvement, or to downstage locally advanced cancers with threatened circumferential resection margins. In the former instance, radiotherapy is often given as a 'short course' over 5 days with immediate surgery some 7–10 days later. On occasion, short-course radiotherapy can be combined with a delay before surgery (up to 12 weeks) to allow cancer regression.

When radiotherapy is used to downstage a cancer, it is often combined with chemotherapy (chemoradiotherapy) and given over a period of 6 weeks with a 6-week recovery period before surgery. Some 20% of cancers treated with chemoradiotherapy will show a complete pathological response, with a further 25–30% showing a partial response. Unfortunately, it is not yet possible to determine prior to treatment which patients will respond and therefore to tailor treatment accordingly.

Occasionally, radiotherapy is used to palliate unresectable cancers that are causing symptoms due to pain, obstruction or bleeding.

Alternative radiotherapy regimens include the Papillon technique, in which intracavity radiation is directed to the cancer in the form of 'contact radiotherapy' or else delivered by brachytherapy techniques. To date, the application of these techniques has been restricted to selected cases, usually in patients unfit for more radical surgery.

Chemotherapy

Chemotherapy is given either in combination with radiotherapy (chemoradiotherapy) to downstage a cancer prior to surgical resection or else in the postoperative setting to reduce the risk of disseminated disease. 5-Fluorouracil (5-FU)-based regimens remain the first-line therapy and are associated with a 10% improvement in disease-free survival in patients with node-positive rectal cancer. Second-line therapies include oxaliplatin and irinotecan, and biological agents such as cetuximab (see ***Chapter 12***).

Results of surgery for rectal cancer

In specialised centres, the resectability rate for rectal cancer may be as high as 95%, with an operative mortality of less than 5%. Overall, the 5-year survival rate is about 50% and has not changed appreciably over the last decade. Survival rates are influenced by TNM/Dukes' stage, with node-positive patients doing worse than those with node-negative lesions. However, with the introduction of national bowel cancer screening programmes, there is a shift to an earlier stage of disease presentation and consequently improved survival.

Local recurrence

Local recurrence after rectal excision represents a complex problem. The patient may be asymptomatic with recurrence diagnosed as part of a surveillance programme, including regular measurements of blood carcinoembryonic antigen and cross-sectional radiological imaging. The presence of symptoms is often a poor prognostic feature. Persistent pelvic pain, which may radiate down the legs, is indicative of nerve root involvement. Bladder symptoms may occur or there may be fistulating disease onto the perineum. Most local recurrences are situated extrarectally and are therefore not readily diagnosed on endoscopy examination and biopsy. CT and MRI scan are the best means for detecting local recurrence, but PET-CT is increasingly being used to differentiate metabolically active cancer recurrence from metabolically inactive scar tissue. Local recurrence rates vary between 2% and 25% and are higher after abdominoperineal excision than after sphincter-saving resection. High-quality primary surgery with preservation of the mesorectal 'package' and a clear circumferential resection margin are the most important factors in preventing local recurrence.

Overall, 80% of local recurrences develop within 2 years following surgery, are very difficult to treat and should be referred to a centre specialising in exenterative surgery. If the patient is radiotherapy naive then preoperative chemoradiotherapy may be of help. Surgical exenteration offers the only hope of cure.

Jean Papillon, d. 1993, radiation oncologist, Centre Léon Bérard, Lyon, France.

PART 11 | Abdominal

CHAPTER
80 The anus and anal canal

Learning objectives

To understand:

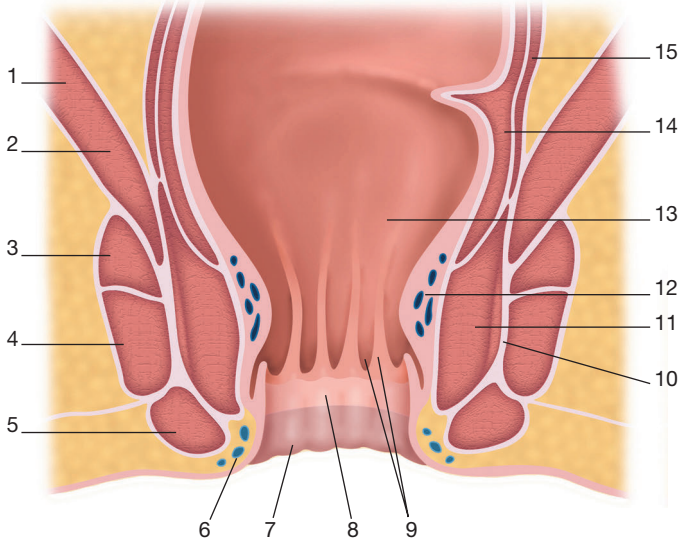
- The anatomy and physiology of the anus and anal canal with special reference to clinical presentation, investigation and differential diagnosis
- Anal disease is common and treatment is often conservative
- Aggressive or inappropriate surgery may render the patient disabled

ANATOMY AND PHYSIOLOGY OF THE ANAL CANAL

Surgical anatomy

The anal canal starts at the level where the rectum passes through the pelvic diaphragm, where the rectal ampulla suddenly narrows, and ends at the anal verge. The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge called the anorectal ring (***Figure 80.1***).

Anal canal anatomy



The anus is 3–4 cm long in adults, being longer in the adult male than in the female. Posterior is the anococcygeal ligament, which separates it from the tip of the coccyx, while anteriorly it is separated by the perineal body from the membranous urethra and penile bulb or the lower vagina. Laterally are the ischiorectal fossae. The anal canal is lined by mucosa and the sphincter muscles constitute the muscular wall. The anorectal ring is formed by fusion of the puborectalis muscle and the deep external anal sphincter. It can be clearly felt on a digital rectal examination, particularly posteriorly and laterally.

The puborectalis muscle

The puborectalis muscle maintains the angle between the anal canal and rectum (the anorectal angle) and is an important component in the continence mechanism (***Figure 80.2***). The muscle derives its nerve supply from the sacral somatic nerves. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling.

The external anal sphincter

The external sphincter forms the bulk of the anal sphincter complex and, although traditionally it has been subdivided

1	Levator ani muscle (iliococcygeal muscle)
2	Levator ani muscle (puborectal muscle)
3–5	External anal sphincter (deep, superficial, subcutaneous)
6	Inferior haemorrhoidal plexus
7	Perianal skin
8	Anoderm
9	Anal columns and crypts
10	Conjoined longitudinal muscle (corrugator ani muscle)
11	Internal anal sphincter
12	Superior haemorrhoidal plexus
13	Anorectal junction
14	Circular rectal muscle layer
15	Longitudinal rectal muscle

Figure 80.1 Anatomy of the anal canal. (Adapted from Anatomy of the colon, rectum, anus, and pelvic floor. In Herold A, Lehur PA, Matzel KE, O'Connell PR (eds). *Coloproctology*. Heidelberg: Springer-Verlag, 2008.)

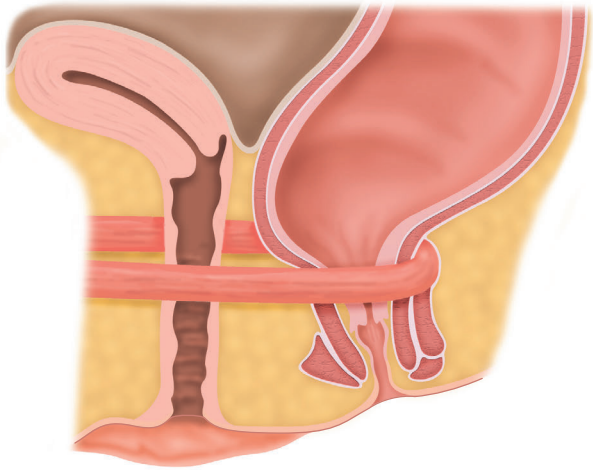


Figure 80.2 The puborectalis muscle. Note how it maintains the rectoanal angle.

into deep, superficial and subcutaneous portions, it is a single muscle (Goligher), which is variably divided by lateral extensions from the longitudinal muscle layer. Some of the fibres are attached to the coccyx posteriorly, whereas anteriorly they fuse with the perineal muscles. Being a somatic voluntary muscle, the external sphincter is red in colour. It is innervated by the pudendal nerve.

The internal sphincter

The internal sphincter is the thickened (2–5 mm) distal continuation of the circular muscle layer of the rectum. This involuntary muscle commences where the rectum passes through the pelvic diaphragm and ends above the anal orifice, its lower border palpable at the intersphincteric groove, below which lie the most medial fibres of the subcutaneous external sphincter, and separated from it by the anal intermuscular septum. When exposed during life, it is pearly-white in colour and its circumferentially placed fibres can be seen clearly. Although innervated by the autonomic nervous system, it receives intrinsic non-adrenergic and non-cholinergic fibres, stimulation of which causes release of the neurotransmitter nitric oxide, which induces internal sphincter relaxation.

The longitudinal muscle

The longitudinal muscle is a direct continuation of the smooth muscle of the outer muscle coat of the rectum, augmented in its upper part by striated muscle fibres originating from the medial components of the pelvic floor. The muscle passes caudally between the external and internal sphincters before splitting into multiple terminal septa that surround the muscle bundles of the subcutaneous portion of the external sphincter, to insert into the skin of the lowermost part of the anal canal and adjacent perianal skin. The most medial of these septa, passing around the inferior border of the internal sphincter, have been termed the 'anal intermuscular septum'. Distally the septum gives off fibres that pass medially across the internal sphincter to reach the submucosal space and laterally across the external sphincter and ischiorectal space to reach the fascia of the pelvic side walls. As well as providing support for the anal canal the septa created provide potential pathways for the spread of infection.

During defecation, contraction of the longitudinal muscle widens the anal lumen, flattens the anal cushions, shortens the anal canal and everts the anal margin; subsequent relaxation allows the anal cushions to distend and thus contribute to an airtight seal.

The intersphincteric plane

Between the external sphincter muscle laterally and the longitudinal muscle medially exists a potential space, the intersphincteric plane. This is important as it contains intersphincteric anal glands (see ***The epithelium and subepithelial structures***) and is also a route for the spread of infection, which occurs along the extensions from the longitudinal muscle layer. This plane can be surgically explored to gain access to sphincter muscles.

The epithelium and subepithelial structures

The pink columnar epithelium lining the rectum extends through the anorectal ring into the upper anal canal. Passing downwards the columnar mucosa becomes a cuboidal 'transitional zone' characterised by 8–12 vertical columns separated by anal sinuses that form folds at their lower ends, the anal valves or crypts (of Morgagni). The row of alternating columns and crypts gives a serrated appearance known as the **dentate line**, which is considered to be the embryological junction between the endodermal and ectodermal parts of the anal canal (the proctodaeum) (***Figure 80.1***). Below the dentate line the anoderm is lined by non-keratinised stratified squamous epithelium that is devoid of glands and hair but richly innervated by somatic sensory nerve endings (Wedel).

Between the epithelial layer and the internal sphincter lies the submucosa, consisting of vascular, muscular and connective tissue supportive elements. From the longitudinal muscle, medial extensions cross the internal anal sphincter and form part of the supporting meshwork of the submucosa, blending with the true submucosal smooth muscle layer supporting the mucosa itself, termed the 'mucosal suspensory ligament'. This separates the superior (portal) and inferior (systemic) haemorrhoidal plexuses. Here the mucosa is more firmly tethered to underlying tissues than above. It is important to appreciate that the meshwork of supporting tissues (muscle fibres and connective tissue) within the subepithelial space is intimately linked to deeper structures within the anal sphincter complex, including the internal sphincter, longitudinal muscle layer and external anal sphincter. With age, the smooth muscle component of this mesh is gradually replaced with fibroelastic connective tissue, which in turn becomes fragmented.

John Cedric Goligher, 1912–1998, Professor of Surgery, University of Leeds, Leeds, UK.
Giovani Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy, regarded as the founder of morbid anatomy.
Thilo Wedel, contemporary, anatomist, University of Kiel, Germany.

Blood supply

The subepithelial space contains venous dilatations supported by the fibroelastic connective tissue and smooth muscle scaffolding. Debate has centred on the nature of the vascular component of haemorrhoids. Thomson demonstrated that the divisions of the superior rectal artery were not constant and that the anal submucosa also receives a blood supply from the middle and inferior rectal arteries. In addition, there is free communication between tributaries of the superior, middle and inferior rectal veins, as well as direct arteriovenous communications with the submucosal venous dilatations. These communications have been shown both histologically and radiologically, and the oxygen tension of the blood contained within the venous dilatations is more arterial than venous. This explains the bright red colour of haemorrhoidal bleeding rather than the darker venous blood that might be expected.

Venous drainage

The anal veins are distributed in a similar fashion to the arterial supply. The upper half of the anal canal is drained by the superior rectal veins, tributaries of the inferior mesenteric vein and thus the portomesenteric venous system, and the middle rectal veins, which drain into the internal iliac veins. The inferior rectal veins drain the lower half of the anal canal and the subcutaneous perianal plexus of veins; they eventually join the internal iliac vein on each side.

Lymphatic drainage

Lymph from the upper half of the anal canal flows upwards to drain into the mesorectal lymph nodes and from there goes to the para-aortic nodes via the inferior mesenteric chain. Lymph from the lower half of the anal canal drains on each side, first into the superficial and then into the deep inguinal group of lymph glands.

Summary box 80.1

Anatomy and physiology of the anal canal

- The internal sphincter is composed of circular, non-striated involuntary muscle supplied by autonomic nerves
- The external sphincter is composed of striated voluntary muscle supplied by the pudendal nerve
- Extensions from the longitudinal muscle layer support the sphincter complex
- The space between sphincters is known as the intersphincteric plane
- The superior part of the external sphincter fuses with the puborectalis muscle, which is essential for maintaining the anorectal angle, necessary for continence
- The lower part of the anal canal is lined by sensitive squamous epithelium
- Blood supply to the anal canal is via superior, middle and inferior rectal vessels
- Lymphatic drainage of the lower half of the anal canal goes to inguinal lymph nodes

EXAMINATION OF THE ANUS

Careful clinical examination will be diagnostic in the vast majority of patients complaining of anal symptoms, but it requires a relaxed patient who is informed of what the examination will entail, a private environment, a chaperone (for the security of both parties) and good light. Most commonly, the patient is examined in the left lateral (Sims) position with the buttocks overlying the edge of the examination couch and with the axis of the torso crossing, rather than parallel with, the edge of the couch. Alternatively, in younger patients, the prone jack-knife or knee–elbow positions may be used (***Figure 80.3***). Some units with access to a gynaecology couch may place the patient supine with legs in stirrups. The examining couch should be of sufficient height to allow easy inspection and access for any necessary manoeuvres. Personal protective equipment should be worn.

Inspection

The buttocks are gently parted to allow inspection of the anus and perineum: the presence of any skin lesions and whether they are confined to the perineum or evident elsewhere on general examination, e.g. psoriasis, lichen planus, or on genital examination, e.g. warts, candidiasis, lichen sclerosus, the vesicles of herpes simplex virus (HSV); evidence of anal leakage; whether the anus is closed or patulous; and the position of the anus and perineum at rest and on bearing down (the latter may reveal prolapse of haemorrhoids or even the rectum). Pain on parting the buttocks, perhaps together with the presence of a sentinel tag, may indicate the presence of an underlying fissure, but may also prompt the need for endoluminal examination under anaesthesia to exclude more suspicious pathology, for example squamous cell carcinoma (SCC) of the anal canal.

Digital examination with the index finger

With an adequately lubricated index finger, the soft tissues around the anus are palpated for induration, tenderness and subcutaneous lesions. The index finger is then introduced gently into the anal canal along its posterior aspect. At the apex of the canal, the sling of puborectalis is felt posteriorly; supralevator induration feels bony hard and is more easily appreciated if unilateral. The posterior surface of the prostate gland with its median sulcus can be palpated anteriorly in male patients; in female patients, the uterine cervix can be palpated. The presence of any distal intrarectal, intra-anal or extraluminal mass is recorded. Sphincter length, resting tone and voluntary squeeze are assessed. On withdrawal, the examining finger

William Hamish Fearon Thomson, contemporary, surgeon, Gloucestershire Royal Hospital, Gloucester, UK.
James Marion Sims, 1813–1883, gynaecological surgeon, State Hospital for Women, New York, NY, USA, introduced this position to give access to the anterior vaginal wall during operations for the closure of vesicovaginal fistulae.

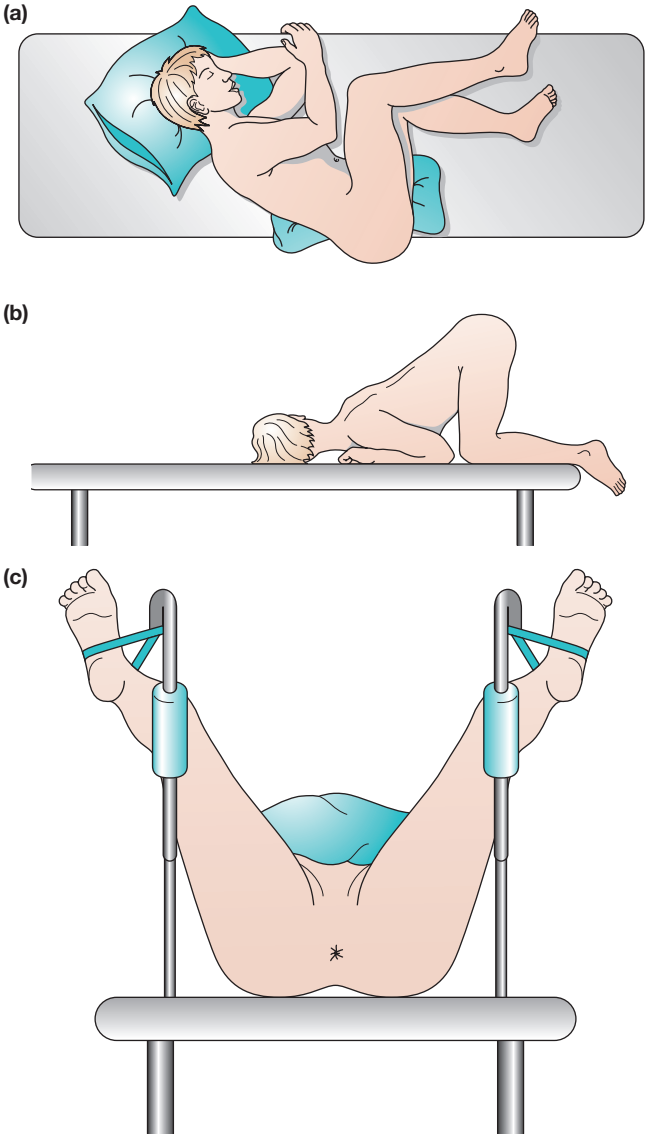

Figure 80.3 (a) The left lateral, **(b)** knee–elbow and **(c)** lithotomy positions for examination. (Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.)

is inspected for the presence of mucus, blood or pus and to identify stool colour.

Proctoscopy

Proctoscopy, performed with the patient in the same position, allows a detailed inspection of the distal rectum and anal canal (***Figure 80.4***). Minor procedures can also be carried out through this instrument, e.g. treatment of haemorrhoids by injection or banding (see ***Haemorrhoids***) and biopsy. Asking the patient to bear down on slow withdrawal of the proctoscope may reveal a descending intussusception.

Sigmoidoscopy

Although sigmoidoscopy is strictly an examination of the rectum, it should always be performed as rectal pathology is frequently associated with an anal lesion (e.g. anal fistula); not infrequently, rectal pathology is found independent of the anal lesion.

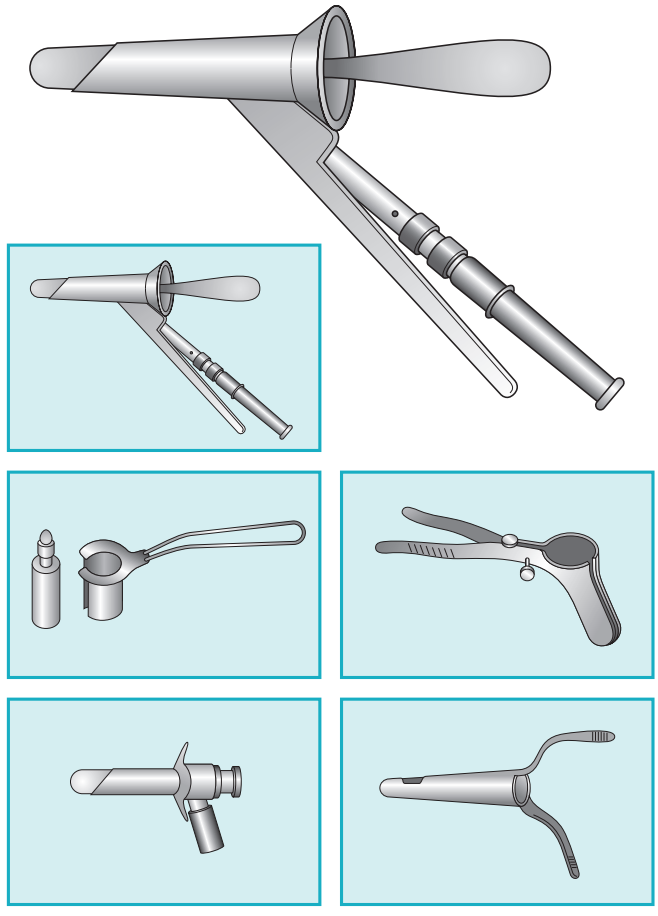

Figure 80.4 Various types of proctoscope. (Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.)

Summary box 80.2

Examination of the anus

- A rectal examination is essential for any patient with anorectal and/or bowel symptoms – 'If you don't put your finger in, you might put your foot in it'
- A proctosigmoidoscopy (rigid or flexible) is essential in any patient with bowel symptoms

PHYSIOLOGICAL ASPECTS OF THE ANAL SPHINCTERS AND PELVIC FLOOR

Anal continence and defecation are highly complex processes that necessitate the structural and functional integrity of the cerebral, autonomic and enteric nervous systems, the gastrointestinal tract (especially the rectum) and the pelvic floor and anal sphincter complex, any of which may be compromised and lead to disturbances of function of varying severity.

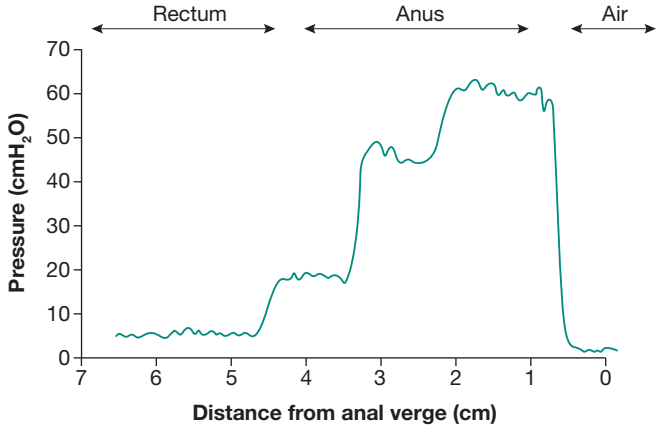

Figure 80.5 A typical normal 'pull-through' manometric study of the anal canal (3.5 cm long; maximal resting anal canal pressure approximately 60 cmH_2O).

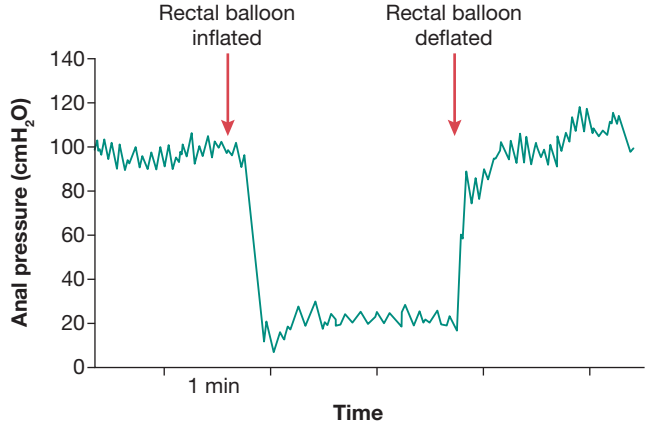

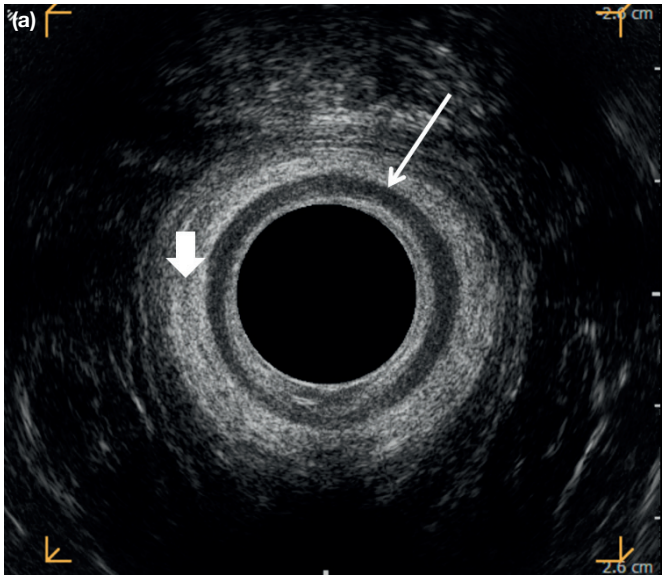

Figure 80.6 Anal manometry tracing demonstrating a normal rectoanal inhibitory reflex when the rectal balloon is inflated with 50 mL of air.

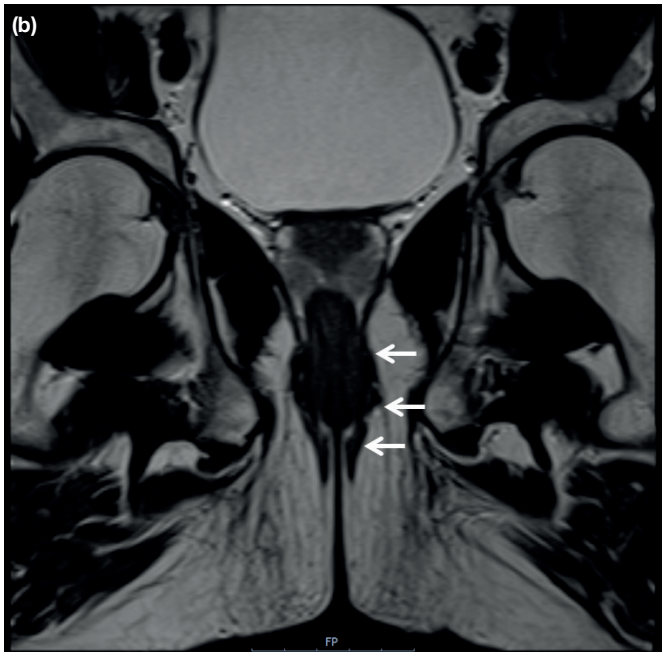

Figure 80.7 (a) Axial view of endoanal ultrasonography through the mid-anal canal of a female patient. Normal intact fibres of the internal (thin arrow) and external (thick arrow) anal sphincter complex. **(b)** Coronal T2-weighted magnetic resonance imaging through the anal canal of a male patient showing the three distinct zones of the low-signal external anal sphincter complex (arrows) (courtesy of Dr Alison Corr, Consultant Radiologist, St Mark's Hospital, London, UK).

The sphincter mechanism provides the ultimate barrier to leakage and its integrity can be assessed fairly simply and objectively in the physiology laboratory. Perineal position and degree of descent on straining (markers of pelvic floor and pudendal nerve function) can be quantified, and functional anal canal length, resting tone (reflective predominantly of internal sphincter activity) and squeeze increment (reflective of external sphincter function) can be measured by a variety of simple manometric techniques (***Figure 80.5***). Distension of the rectum produces reflex relaxation of the internal sphincter, which allows rectal contents to come into contact with the anal transition zone mucosa. This allows discrimination of solid, liquid and gas contents. The rate of recovery of sphincter tone after relaxation differs between the proximal and distal anal canal (***Figure 80.6***). This is an important continence mechanism.

The structural integrity of the sphincters can be visualised with endoluminal ultrasonography (***Figure 80.7a***), which usually consists of high-resolution three-dimensional images constructed from standard two-dimensional images. Magnetic resonance imaging (MRI) provides excellent tissue differentiation, although spatial resolution of the anal sphincters using a body coil is reduced (***Figure 80.7b***).

The dynamics of defecation can be assessed radiologically by evacuation proctography, in which radio-opaque pseudostool is inserted into the rectum and the patient asked to rest, squeeze and then bear down to evacuate the rectal contents under real-time imaging (***Figure 80.8 and*** ***80.1***). The procedure may also be performed with oral contrast to outline the small bowel and in females following insertion of a

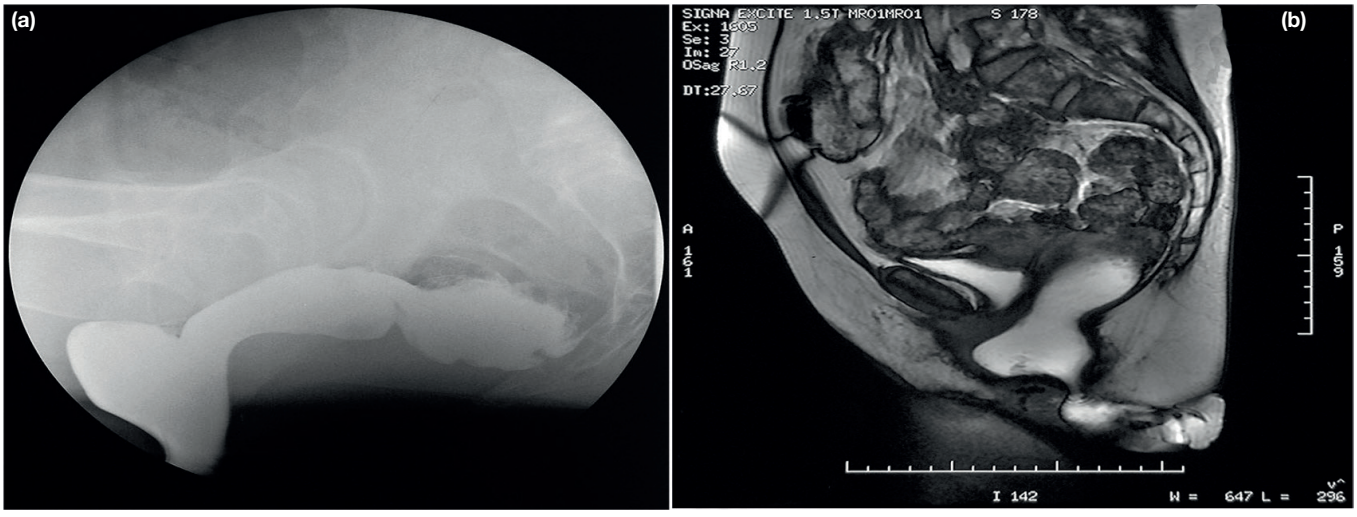

Figure 80.8 Visualisation of the rectum is achieved with barium-impregnated 'synthetic stool' using conventional defecating proctography **(a)** or magnetic resonance proctography **(b)**. A large rectocele is apparent.

radio-opaque vaginal tampon that will allow anatomical changes during defecation (e.g. rectocele, enterocele) to be identified. Dynamic magnetic resonance (MR) proctography provides more details of other pelvic organs; however, evacuation in the supine position may be less physiological than the sitting position that can be achieved within an open magnet (***Figure 80.8***). Interobserver agreement for MR proctography is better than for barium defecography; however, imaging must be interpreted in the context of the patient's symptoms and used to guide rational rather than empirical treatment strategies.

CONGENITAL ABNORMALITIES

Early in embryonic life there is a common chamber – the cloaca – into which the hind gut and the allantois open. This endoderm-lined chamber is separated from the surface ectoderm of the embryo by the cloacal membrane. The cloaca becomes divided into two parts – dorsal (rectum) and ventral (urogenital sinus) – by the downgrowth of a septum. The dorsal part of the cloacal membrane, known as the anal membrane, is thus composed of an outer layer of ectoderm and an inner layer of endoderm. Resorption of this anal membrane by the eighth week of embryonic life creates the anal canal.

Imperforate anus

Imperforate anus (strictly, it should be anal 'agenesis' or 'atresia') has historically been divided into two main groups – high and low – depending on the level of termination of the rectum in relation to the pelvic floor. Treatment and prognosis are influenced by any associated abnormalities of the sacrum and genitourinary systems (see ***Chapter 18***).

Postanal dermoid

The space in front of the lower part of the sacrum and coccyx may be occupied by a soft, cystic swelling – a postanal dermoid cyst. Hidden in the hollow of the sacrum it is unlikely to be discovered unless a sinus communicating with the exterior is present or it develops as a result of inflammation. Such a cyst usually remains asymptomatic until adult life, when it is prone to becoming infected. Exceptionally, because of its size, it gives rise to difficulty in defecation. The cyst is easily palpable on rectal examination.

Differential diagnosis

An anterior sacral meningocele must be excluded, particularly in the presence of bony abnormality of the sacrum. This enlarges when the child cries and is frequently associated with paralysis of the lower limbs and incontinence. When a discharging sinus is present, a postanal dermoid will probably be mistaken for a pilonidal sinus or even an anal fistula. Pressure over the sacrococcygeal region with a finger in the rectum may cause a flow of sebaceous material, and injection of contrast medium followed by radiography reveals a bottle-necked cyst in front of the coccyx.

Treatment

Treatment involves complete excision of the cyst and, if present, the sinus. In the case of large cysts, it is necessary to remove the coccyx to gain access. The coccyx should also be removed en bloc in any child with a presacral dermoid because of the risk of sacrococcygeal teratoma. Care must be taken to exclude the Currarino triad, an autosomal dominant hereditary condition characterised by sacral malformation, anorectal malformation (often stenosis) and a presacral mass consisting of a dermoid cyst/teratoma and/or anterior meningocele.

Guido Carlo Currarino, 1920–2015, radiologist, Southwestern Medical School and Children's Medical Center, Dallas, TX, USA.

Postanal dimple (synonym: fovea coccygea)

A dimple in the skin beneath the tip of the coccyx, sometimes amounting to a short blind pit, is noticed from time to time in the course of a clinical examination and is of no consequence.

Pilonidal sinus

The term pilonidal sinus describes a condition found in the natal cleft overlying the coccyx, consisting of one or more, usually non-infected, midline openings, which communicate with a fibrous track lined by granulation tissue and containing hair lying loosely within the lumen.

Aetiology and pathology

Although acquired theories of development are better accepted than the more historical congenital theories, exact mechanisms of development are speculative. Evidence that supports the theory of the origin of pilonidal sinuses as acquired can be summarised as follows:

- Interdigital pilonidal sinus is an occupational disease of hairdressers.
- The age of the appearance of a pilonidal sinus is older than expected of a congenital lesion.
- Hair follicles are rarely present in the walls of the sinus.
- The pointed hair ends are directed towards the blind end of the sinus.
- The disease mostly affects hirsute men.
- Recurrence is common, even though adequate excision of the track is carried out.

It is thought that the combination of buttock friction and shearing forces in that area allows shed hair or broken hairs that have collected there to drill through the midline skin, or that infection in relation to a hair follicle allows hair to enter the skin by the suction created by movement of the buttocks, so creating a subcutaneous, chronically infected, midline track. From this primary sinus, secondary tracks may spread laterally, which may emerge at the skin as granulation tissue-lined, discharging openings. Usually, but not invariably (when diagnosis may be confused with anal fistula or hidradenitis suppurativa [HA]), the sinus runs cephalad. Carcinoma arising in chronic pilonidal disease is exceedingly rare.

Clinical features

The condition is seen much more frequently in men than in women, usually after puberty and before the fourth decade of life and is characteristically seen in dark-haired individuals rather than those with softer blond hair. Patients complain of intermittent pain, swelling and discharge at the base of the spine but little in the way of constitutional symptoms. There is often a history of repeated abscesses that have burst spontaneously, or that have been incised, usually away from the midline. The primary sinus may have one or many openings, all of which are strictly in the midline between the level of the sacrococcygeal joint and the tip of the coccyx. If no primary pits are seen or if the sinus either drains lateral to the sacrum or appears caudal to the primary pits, other diagnoses should be considered. These might include HA, complex anal fistula, osteomyelitis with draining skin sinuses or infective conditions such as tuberculosis or actinomycosis.

Conservative treatment

The natural history is to regress over time. For those with minimal symptoms, simple cleaning of the tracks and removal of all hair, with regular hair exfoliation of the area and strict hygiene, may be recommended. Local techniques to cauterise the tracks using silver nitrate or laser coagulation may be useful in less complex disease.

Treatment of an acute exacerbation (abscess)

The abscess should be drained through a small longitudinal incision made over the abscess and off the midline, with thorough curettage of granulation tissue and hair. This may result in complete resolution.

Surgical treatment of chronic pilonidal disease

There are a multitude of surgical procedures advocated to eradicate pilonidal disease, which attests to the lack of overall superiority of one surgical technique. Time spent off work, recurrence rates and surgeon preference influence the choice of technique. Options include laying open of all tracks with or without marsupialisation, excision of all tracks with or without primary closure and excision of all tracks with closure by some other means designed to avoid a midline wound (Limberg procedure, Z-plasty, Karydakis procedure (***Figure 80.9***). Bascom's procedure involves an incision lateral to the midline to gain access to the sinus cavity, which is rid of hair and granulation tissue (***Figure 80.10***), and excision and closure of the midline pits. The lateral wound is left open to heal secondarily. Failure to heal or recurrence is treated by a flap or cleft lift procedure, also described by Bascom.

Irrespective of procedure, postoperative wound care is important and centres around elimination of hair (ingrown, local or other) from the wound. Recurrence rates are less but healing times slower after open healing compared with primary closure techniques. For primary closure, recurrence rates are lower and healing time faster after off-midline compared with midline closure techniques.

INCONTINENCE

Aetiology

Continence is dependent upon the structural and functional integrity of both the neurological pathways and the gastrointestinal tract. The risk factors for incontinence are many (***Table 80.1***). Patients complaining of the involuntary loss of rectal contents require a comprehensive assessment of

Alexander A Limberg, 1894–1974, plastic surgeon, Leningrad, former Soviet Union.

the nature and severity of symptoms; past history, especially of gastrointestinal disease, neurological conditions, obstetric events and anorectal surgery; and clinical examination including sigmoidoscopy and/or colonoscopy as indicated. A combination of history and examination will usually be diagnostic, but special investigations are then usually required to clarify the exact cause, including exclusion of an underlying malignancy, and to direct management. Faecal incontinence is a symptom not a diagnosis and an underlying cause should be sought.

Faecal loading or impaction is a major contributor to incontinence in the elderly. A rectum impacted with faeces can result in 'overflow incontinence'. This is easily diagnosed on digital examination and rectally administered treatment to clear the bowel, followed by regular checking to avoid recurrence. When 'empty' on digital examination or when there is no relief from incontinence after evacuation of faeces, the three main mechanisms (sometimes acting in combination) that contribute to incontinence are: loose stool, reduced rectal volume/compliance and anatomical and/or functional injuries to the anal sphincter complex.

Sphincteric causes of incontinence may be classified as structural, in which there is disruption (or atrophy) of part of the sphincter muscles; neuropathic (previously termed idiopathic), in which the nerve supply to the sphincters is damaged, usually by chronic straining or complicated vaginal delivery (prolonged second stage); or a combination of the two. The most common causes of sphincteric disruption are obstetric damage, anal surgery (following haemorrhoidectomy, dilatation or sphincterotomy for anal fissure, and fistulotomy for anal fistula) and trauma (including anal intercourse, forced or otherwise). Incontinence may also arise following major colorectal resection with a colorectal or coloanal anastomosis owing to the reduction or loss of the rectal reservoir and disruption of intramural nerve pathways. Function can be further adversely affected by radiation. This is now known as low anterior resection syndrome (LARS) (Laurberg).

TABLE 80.1 Causes of anal incontinence.

Congenital/ childhood	• Anorectal anomalies • Spina bifida • Hirschsprung's disease • Behavioural
Acquired/ adulthood	• Diabetes mellitus • Cerebrovascular accident • Parkinson's disease • Multiple sclerosis • Spinal cord injury • Other neurological conditions: ◦ Myotonic dystrophy ◦ Shy–Drager syndrome ◦ Amyloid neuropathy • Gastrointestinal infection • Irritable bowel syndrome • Metabolic bowel disease • Inflammatory bowel disease • Megacolon/megarectum • Anal trauma • Abdominal surgery: ◦ Small bowel resection ◦ Colonic resection • Pelvic surgery: ◦ Hysterectomy ◦ Rectal excision • Pelvic malignancy • Pelvic radiotherapy • Rectal prolapse • Rectal evacuatory disorder: ◦ Mechanical, e.g. rectocele, intussusception ◦ Functional, i.e. pelvic floor dyssynergia • Anal surgery: ◦ Haemorrhoidectomy ◦ Surgery for fistula ◦ Surgery for fissure ◦ Rectal disimpaction • Obstetric events
General	• Ageing • Psychobehavioural factors • Intellectual incapacity • Drugs: ◦ Primary constipating and laxative agents

Investigations

Anorectal physiology studies provide objective assessment of the anorectal function. Manometry is a simple method for measuring internal (resting) and external (squeeze) anal sphincter tone. Endoanal ultrasonography (EAUS) provides a dynamic assessment of the thickness and structural integrity of the external and internal sphincters (***Figure 80.11***). Dynamic standard or MRI defecography is not routine in patients with incontinence; however, in select cases they can be useful when obstructive or prolapse symptoms are mixed in with incontinence symptoms.

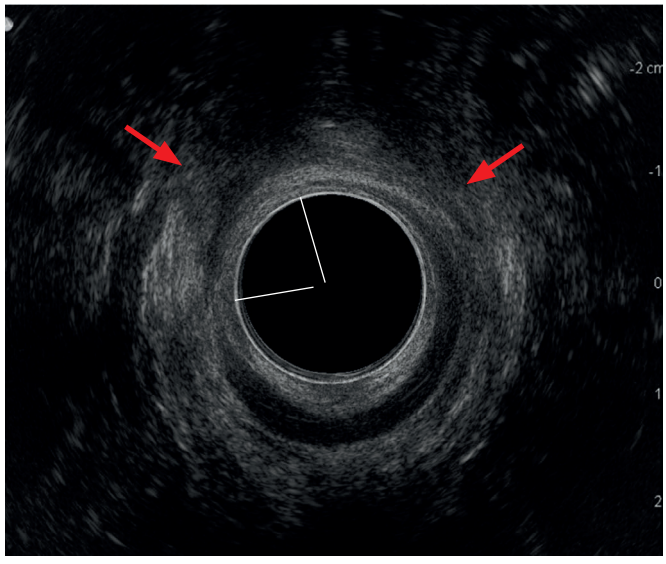

Figure 80.11 Axial view of endoanal ultrasonography through the mid-anal canal of a female patient with faecal incontinence following vaginal delivery. The study demonstrates a defect in the internal (white arrows) and external (red arrows) anal sphincter fibres in keeping with an obstetric anal sphincter injury (courtesy of Dr Alison Corr, Consultant Radiologist, St Mark's Hospital, London, UK)

Management

Most patients with incontinence can be managed conservatively with dietary advice, stool bulking or constipating agents, cleansing enemas, rectal irrigation, nurse-led bowel retraining, including specific biofeedback programmes, or anal plugs, which expand within and thus seal the anal canal. Failure of such measures and the severity of symptoms may result in selection for surgery.

Anal sphincter surgery

In situations where conservative treatment has failed, and where a discrete disruption of the sphincters exists, the ends of the divided muscle are found and reunited by an overlap repair (Parks) (***Figure 80.12***). Short-term results are good, with reports of 75–80% improvement in symptoms at first follow-up. This reduces with time to 50% or less 5–10 years after surgery. Pelvic floor repairs (postanal, preanal or total) are of historical interest only. Sphincter reconstruction (non-stimulated or stimulated) with muscle transposition has been devised to replace the anal sphincter when local repair has failed. 'Gluteoplasty' or 'graciloplasty', especially stimulated muscle transposition, has been performed; however, initial positive results were not maintained in the medium to long term. Artificial sphincters have been implanted to replace or reinforce native sphincters but devices are no longer commercially available.

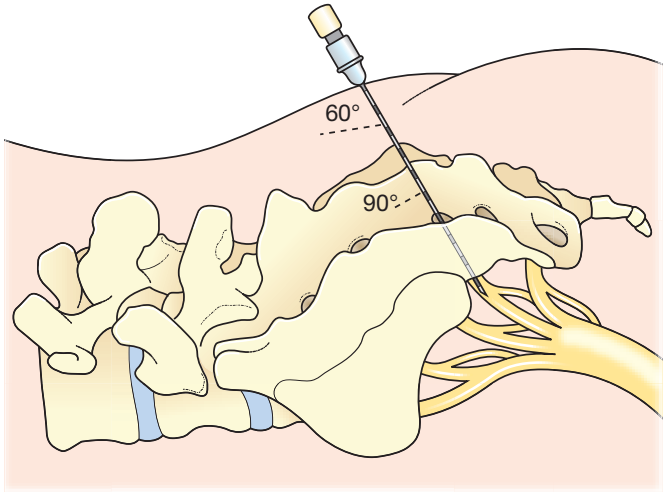

Figure 80.14 Diagram showing placement of the electrode through a sacral foramen.

Injectable biomaterials

Injectable biomaterials to add bulk to the anal canal and thereby augment faecal continence were first introduced by Shafik, who injected polytetrafluoroethylene paste into the anal submucosa. The ideal agent should be biocompatible, easy to deploy and should not migrate. Many materials have been investigated.

Recently the SphinKeeper® (Ratto) has been shown to restore sphincter function through placement of self-expanding prostheses into the intersphincteric space, adding bulk to the sphincter complex (***Figure 80.13***).

Sacral nerve stimulation (SNS) is a novel technique that uses low-voltage electrical stimulation to the S3 or S4 nerve roots to augment continence (***Figure 80.14***). It is thought to work primarily by activation of autonomic sensory pathways in patients with pelvic neuropathy, which principally occurs after childbirth. The technique consists of a *screening* phase of peripheral nerve evaluation, followed by a *therapeutic* phase of permanent neurostimulator implantation (Matzel) (***Figure 80.15***). SNS is sustainable with long-term improvement in symptoms. Postoperative complication rates are low; however, infection or loss of efficacy may require device explantation. **Percutaneous posterior tibial nerve stimulation** (PTNS) is a less expensive neuromodulation technique; however, results from prospective studies suggest only modest improvement in outcome.

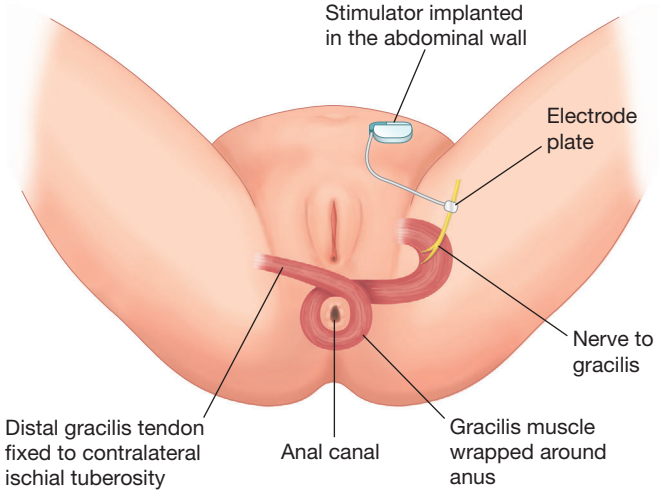

Figure 80.16 The electrically stimulated gracilis neosphincter or dynamic graciloplasty.

Operations to augment the anal sphincters

If the degree of sphincter disruption or weakness is such that restoration of function cannot be achieved by direct means, the sphincter can be augmented by using muscle transposed from nearby (gluteus maximus or gracilis) or by using an artificial sphincter. Transposition of the gracilis muscle around the anal canal is followed by electrical stimulation, with conversion from a fast-twitch to a less fatigable slow-twitch muscle by an implanted pacemaker (Williams) (***Figure 80.16***). Because of its magnitude this technique is performed only in highly selected and motivated patients, most of whom have had more conventional treatment that has failed to cure their incontinence.

Despite all currently available treatments presented and discussed above, each patient requires individualised management. The evidence unfortunately is not robust, and decision making relies on expert opinion. The surgeon is only a small part of the multidisciplinary team of specialists necessary to manage these patients. An end-stoma may be appropriate for patients with severe end-stage incontinence in whom all available treatments have failed. While a stoma is associated with significant psychosocial issues and stoma-related complications, it can allow patients to resume normal activities and improve their quality of life.

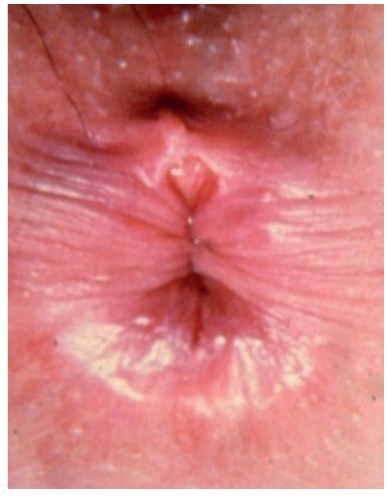

Figure 80.17 The appearance of an anal fissure. If the buttocks are gently parted, the presence of an anal fissure can usually be detected as an ulcer of variable depth with the skin tag and an anal papilla.

ANAL FISSURE

Definition

An anal fissure (synonym: fissure-*in-ano*) is a longitudinal ulcer in the anoderm of the distal anal canal (***Figure 80.17***), which extends from the anal verge proximally towards, but not beyond, the dentate line.

Aetiology

The cause of an anal fissure, and particularly the reason why the posterior midline is so frequently affected, is not completely understood. The location in the posterior midline may relate to the shearing forces acting at that site at defecation, combined with a less elastic anoderm endowed with an increased density of longitudinal muscle extensions in that region of the anal circumference. Anterior anal fissure is more common in women and may arise following vaginal delivery. Affected

Sir Norman S Williams, contemporary, Emeritus Professor of Surgery, The Royal London Hospital, London, UK.

patients frequently present with internal anal sphincter hypertonia, which, in turn, enhances the traumatic effect of the hard stool and perpetuates relative tissue ischaemia with a decrease in blood supply to the anal mucosa. After the initial tear, a vicious cycle of non-healing and repeated trauma leads to the development of chronic deep fissures. Local pain increases sphincter hypertonia, which worsens hard stool and local tissue ischaemia.

Clinical features

Although superficial, acute anal fissures are characterised by severe anal pain during defecation ('passing glass' or 'a knife cutting'), which usually resolves only to recur at the next evacuation. Frequently a trace of fresh blood is noticed on tissue paper after wiping. Chronic fissures are characterised by a hypertrophied anal papilla internally and a sentinel tag externally (both consequent on repeated healing and breakdown), between which lies an indurated anal ulcer that exposes fibres of the internal sphincter. Patients may also complain of itching secondary to irritation from the sentinel tag, discharge from the ulcer or discharge from an associated intersphincteric fistula, which has arisen through infection penetrating via the fissure base. Although most sufferers are young adults, the condition can affect any age, from infants to the elderly. A fissure that is not midline or one with atypical features should raise the suspicion of a specific aetiology. The inability to be able to conduct an adequate examination in the clinic should prompt early examination under anaesthesia, with biopsy and culture to exclude Crohn's disease, tuberculosis, sexually transmitted or human immunodeficiency virus (HIV)-related ulcers (syphilis, *Chlamydia*, chancroid, lymphogranuloma venereum, HSV, cytomegalovirus, Kaposi's sarcoma, B-cell lymphoma) and SCC.

Treatment

After confirmation of the diagnosis and exclusion of secondary causes of anal ulceration, conservative management should result in the healing of almost all acute and the majority of chronic fissures. Emphasis must be placed on normalisation of bowel habits. The addition of fibre to the diet to bulk up the stool, stool softeners and adequate water intake are simple and helpful measures. Warm baths and topical local anaesthetic agents relieve pain. Patients with normal bowel function and excessive straining at defecation might benefit from anorectal biofeedback to correct it. The mainstay of current conservative management is the topical application of pharmacological agents that relax the internal sphincter. If simple measures fail, treatment can be escalated to 'chemical sphincterotomy' using agents that induce smooth muscle (internal sphincter) relaxation. Glyceryl trinitrate (GTN) (0.2% applied two or three times per day to the anal margin) is a nitric oxide donor while diltiazem (2% applied twice daily) is a calcium channel antagonist. Botulinum toxin (10–100 units) injected into the internal sphincter in either divided or a single dose reduces anal canal pressure by blocking the release of acetylcholine at neuromuscular junctions. Temporary incontinence occurs in up to 10% of patients. The cure rate is approximately 50%, although GTN can be associated with headaches, which limits its acceptability to patients. Diltiazem and botulinum toxin have similar efficacy with fewer side effects.

Summary box 80.3

Anal fissure

- Acute or chronic ulcer in the midline of the anal canal
- Ectopic site suggests a more sinister cause

Symptoms:

- Pain on defecation
- Bright-red bleeding
- Mucus discharge
- Constipation

Operative measures

Anal sphincter dilatation has been used to reduce sphincter tone; however, this potentially disrupts the anal sphincters at multiple sites with an associated risk of incontinence such that it is rarely indicated.

Lateral anal sphincterotomy

In this operation, the internal sphincter is divided away from the fissure itself – usually either in the right or the left lateral positions. The procedure can be carried out using an open or a closed method, under local, regional or general anaesthesia, and with the patient in the lithotomy or prone jack-knife position. The distal internal sphincter is palpated with a bivalved speculum at the intersphincteric groove. In the closed method, a small longitudinal incision is made over this, and the submucosal and intersphincteric planes are carefully developed to allow precise division of the internal sphincter with a knife or scissors to the level of the apex of the fissure (***Figure 80.18***); the wound is then closed with absorbable sutures. Alternatively, either plane can be entered using a scalpel (no. 11 blade), with the blade advanced parallel to the sphincter and then rotated such that the sharp edge faces the internal sphincter, which can then be divided along its distal third. Pressure should be applied to the wound for a few minutes to prevent haematoma formation. In the open technique, the anoderm overlying the distal internal sphincter is divided longitudinally to expose the sphincter, which is divided, and the wound is closed with absorbable sutures. Although the fissure needs no specific attention, problematic papillae and external tags can be excised. The optimal amount of sphincter to be divided is a matter of debate, and additional factors have to be considered such as patient age, sex, previous vaginal delivery and operations on the anal canal. Early complications of sphincterotomy include

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA.
Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

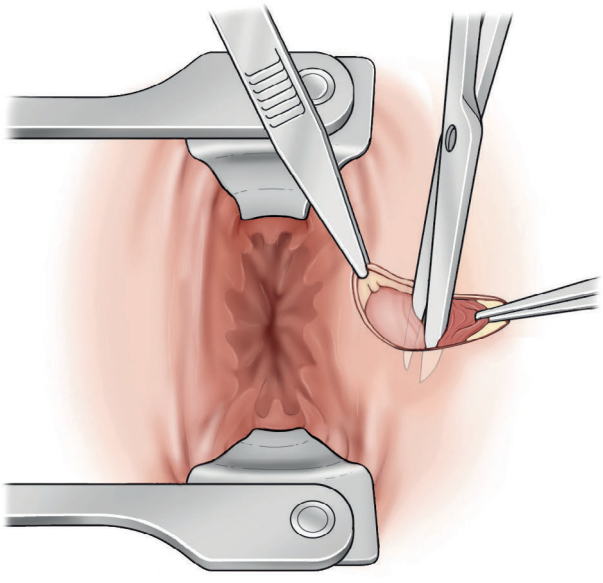

Figure 80.18 Lateral internal sphincterotomy. A dissecting scissors is used to open the intersphincteric space and divide the internal anal sphincter. (Reproduced with permission from O'Connell PR, Madoff RD, Solomon MJ (eds). *Operative surgery of the colon, rectum and anus*, 6th edn. Boca Raton, FL: CRC Press, 2015.)

haemorrhage, haematoma, bruising, perianal abscess and fistula. Healing rates are in the range of 85%, but there is also a significant risk of altered continence (9% flatus incontinence, 6% soiling, <1% solid stool incontinence).

Fissurectomy

Surgical excision of a fissure involves excising of the fibrotic edge, curettage of the base and excision of the sentinel tag and/or anal papilla. Fissurectomy is an alternative to lateral internal sphincterotomy and is used if there are contraindications to lateral internal sphincterotomy. It is frequently combined with an advancement flap anoplasty.

Anal advancement flap

An anal advancement flap to cover the anal fissure should be considered in those with an increased risk of altered continence following lateral internal sphincterotomy, especially in postpartum women and those with normal or low resting anal pressures. After fissurectomy an inverted house-shaped flap of perianal skin is carefully mobilised on its blood supply and advanced without tension to cover the fissure; it is then sutured with interrupted absorbable sutures (***Figure 80.19***). The patient is maintained on stool softeners and bulking agents postoperatively. Minor breakdown of one anastomotic edge does not herald ultimate failure.

Summary box 80.4

Treatment of an anal fissure

- Conservative initially, consisting of stool-bulking agents and softeners, and chemical agents in the form of ointments that are designed to relax the anal sphincter and improve blood flow
- Surgery if above fails, consisting of lateral internal sphincterotomy or anal advancement flap

Hypertrophied anal papilla

Anal papillae occur at the dentate line and are remnants of the ectodermal membrane that separated the hindgut from the proctodaeum. As these papillae are present in 60% of patients examined proctologically, they should be regarded as normal structures. Anal papillae can become elongated in the presence of an anal fissure. Occasionally, an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defecation is sometimes encountered in infancy. Haemorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become nipped by contraction of the sphincter mechanism after defecation. Occasionally, a red oedematous papilla is encountered, with local pain and a purulent discharge from the associated crypt. This condition of 'cryptitis' may be cured by laying open the mouth of the infected anal gland and excising the papilla. Troublesome papillae may be simply excised.

Proctalgia fugax

This problem is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurring at night, lasting minutes and disappearing spontaneously. It seems to occur more commonly in patients suffering from anxiety or undue stress. The pain may be intense but gradually subsides. It may be caused by cramp in the pubococcygeus muscle. A salbutamol inhaler can be used to treat acute attacks while amitriptyline may reduce the frequency. A more chronic form of the disease has been termed the 'levator syndrome' and can be associated with

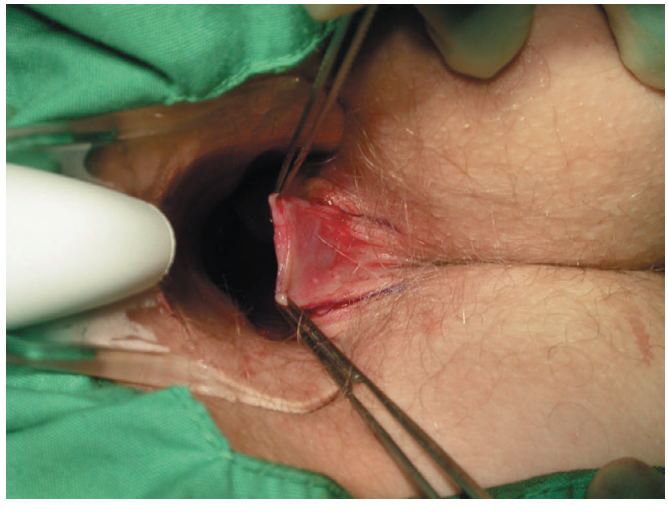

Figure 80.19 Mobilised skin flap prior to suturing intra-anally over the debrided and freshened posterior fissure base.

Figure 80.20 'Mixed' haemorrhoids; third-degree internal haemorrhoids become visible when the patient strains. This can be reproduced by withdrawal of a small swab inserted into the anal canal.

severe evacuatory dysfunction (see ***Chapter 73***). Biofeedback techniques have been used to help such patients.

HAEMORRHOIDS

Haemorrhoids are symptomatic enlargements of the internal haemorrhoidal venous plexus (Greek: *haima* = blood, *rhoos* = flowing; synonym: piles, Latin: *pila* = a ball). Internal haemorrhoids characteristically lie in the 3, 7 and 11 o'clock positions (with the patient in the lithotomy position). Secondary haemorrhoids may develop between the primary positions. External haemorrhoids relate to venous channels of the inferior haemorrhoidal plexus deep in the skin surrounding the anal verge and are frequently confused with anal skin tags that are not true haemorrhoids.

The internal haemorrhoidal plexus constitutes the submucosal component of the anal cushions that are important in sealing the anal canal. Man's upright posture, the absence of valves in the portal venous system and raised abdominal pressure due to pregnancy or particularly through straining during defecation contribute to venous plexus engorgement and development of varicosities. Shearing forces lead to mucosal trauma (bleeding) and caudal displacement of the anal cushions (prolapse). This in turn leads to impaired venous drainage, progressive venous engorgement, local stasis and transudation of fluid (pruritus). With time, fragmentation of the supporting structures (a normal consequence of ageing but perhaps accelerated in those with haemorrhoids) leads to loss of elasticity of the cushions such that they no longer retract following defecation.

Clinical features

Bleeding is the earliest symptom. The nature of the bleeding is characteristically separate from the motion and is seen either on the paper on wiping or as a fresh splash in the pan. The bleeding is rarely sufficient to cause anaemia and other causes should be excluded. The bleeding is usually painless, although pruritus (skin irritation) is common due to mucus discharge. Pain should alert to the possibility of another diagnosis (e.g. anal fissure). Internal haemorrhoids associated with bleeding alone are called **first-degree** haemorrhoids. Patients may complain of lumps ('piles') that appear at the anal orifice during defecation and that return spontaneously afterwards (**second-degree** haemorrhoids), that have to be replaced manually (**third-degree** haemorrhoids) (***Figure 80.20***) or that lie permanently outside (**fourth-degree** haemorrhoids). By this stage there is often a significant cutaneous component to the haemorrhoidal prolapse, termed '**mixed**' haemorrhoids, which may be best considered as external extensions of internal haemorrhoids that arise through repeated congestion and oedema.

Summary box 80.5

Haemorrhoids: clinical features

- Haemorrhoids ('piles') are symptomatic enlargements of anal cushions
- More common when intra-abdominal pressure is raised, e.g. constipation and pregnancy
- Classically occur in the 3, 7 and 11 o'clock positions with the patient in the lithotomy position
- Symptoms: bright-red, painless bleeding, pruritus, mucus discharge, prolapse

Summary box 80.6

Four degrees of haemorrhoids

- First degree – bleed only, no prolapse
- Second degree – prolapse but reduce spontaneously
- Third degree – prolapse but have to be manually reduced
- Fourth degree – permanently prolapsed

Summary box 80.7

Complications of haemorrhoids

- Strangulation and thrombosis
- Ulceration
- Gangrene
- Portal pyaemia

Treatment of complications

Strangulation and thrombosis are relatively uncommon. The patient presents in severe discomfort with often circumferential haemorrhoidal prolapse with impending mucosal necrosis. Distinction must be made from rectal prolapse and external haemorrhoidal thrombosis. Urgent haemorrhoidectomy (see ***Operations***) may expedite symptom resolution, but great care is needed to avoid later anal stenosis. Many surgeons adopt a conservative approach, ensuring adequate pain relief, bed rest, cold saline compresses and laxatives. Resolution usually occurs in 3–4 days. Systemic antibiotics are usually given to reduce the risk of portal pyaemia.

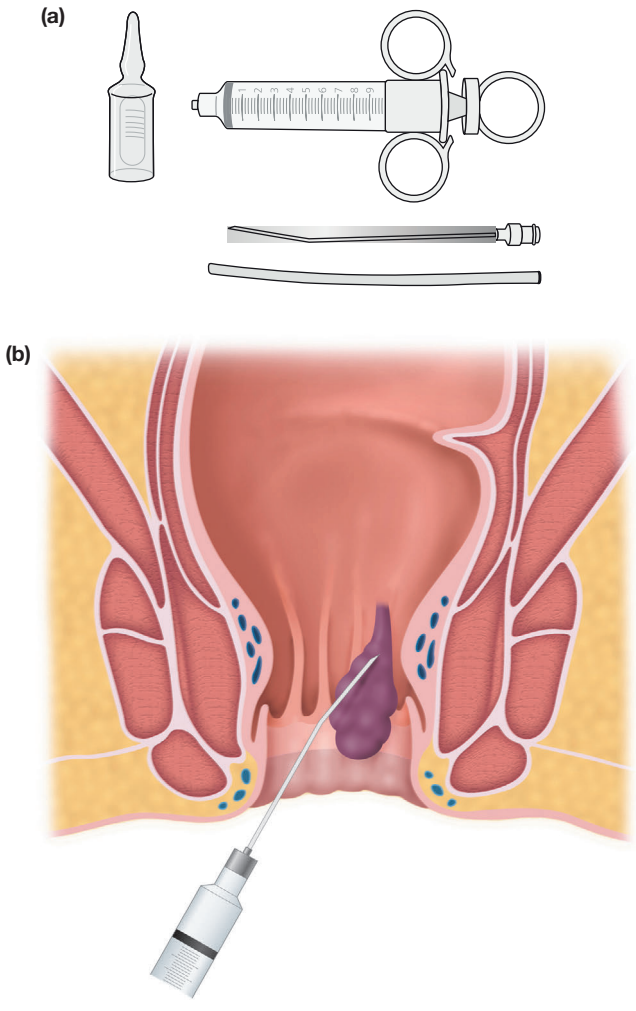

Figure 80.21 (a) Disposable kit for injection of haemorrhoids. (Reproduced with permission from O'Connell PR, Madoff RD, Solomon MJ (eds). *Operative surgery of the colon, rectum and anus*, 6th edn. Boca Raton, FL: CRC Press, 2015.) **(b)** Correct injection site at the apex of the haemorrhoidal complex.

Severe haemorrhage is usually associated with a bleeding diathesis or anticoagulation. If such causes are excluded, a local compress containing adrenaline (epinephrine) solution will usually suffice with blood transfusion if necessary. After adequate blood product replacement, examination under anaesthesia, ligation and excision of the piles may be required.

Management

Exclusion of other causes of rectal bleeding, especially colorectal malignancy, is the first priority. In the absence of a specific predisposing cause, important measures include improving bowel and defecatory habits, adopting a defecatory position to minimise straining (see ***Chapter 73***) and the addition of stool softeners and bulking agents. Various proprietary creams can be applied at night and before defecation. Suppositories of phlebotonics (plant-based flavonoid extracts) and synthetic compounds (calcium dobesilate) may reduce capillary permeability and increase lymphatic drainage.

In patients with first- or second-degree internal haemorrhoids whose symptoms are not improved by conservative measures, injection sclerotherapy with submucosal injection of 5% phenol in arachis oil or almond oil may be used (***Figure 80.21***). The aim is to cause fibrosis that obliterates the vascular channels and a scar that supports prolapsing anorectal mucosa. It is important to inject about 3–5 mL of sclerosant into the apex of the pedicle and *not* into the haemorrhoid itself using a disposable needle and syringe. The procedure is repeated for each haemorrhoid complex and the patient reassessed after 8 weeks; if necessary, the injections are repeated. Pain upon injection means that the needle is in the wrong place and should be withdrawn. Injections that are too superficial are heralded by the rapid bulging of the mucosa, which turns white; this leads to superficial ulceration but rarely serious septic sequelae. However, injections placed too deeply can have serious consequences, including prostatitis and pelvic sepsis. For this reason, haemorrhoidal injection has largely been superseded by rubber band ligation. The Barron's bander is a commonly available device used to slip tight elastic bands onto the base of the pedicle of each haemorrhoid (***Figure 80.22***). It is essential that the band is applied above the dentate line as below can cause intense pain. The bands cause ischaemic necrosis of the piles, which slough off within 10 days; this may be associated with bleeding, about which the patient must be warned. The resulting fibrosis supports the remaining anal cushions. All three primary haemorrhoids may be treated at one session, and the process may be repeated after several weeks. Other ablative techniques such as cryotherapy and infrared photocoagulation are not commonly used.

Operations

Indications

The indications for haemorrhoidectomy include:

- third- and fourth-degree haemorrhoids;
- second-degree haemorrhoids that have not been cured by non-operative treatments;
- 'mixed' haemorrhoids when the external haemorrhoid is well defined;
- bleeding causing anaemia.

If there is any doubt about the diagnosis of haemorrhoids, examination under anaesthesia and/or endoscopic visualisation are necessary. The indications are more relative than absolute, as surgery aims simply to improve symptoms and is not without risk of complication.

Technique

It is usual for the patient to have been taking stool softeners in the days before surgery and a preoperative enema to empty the rectum. The procedure is usually performed under general or regional anaesthesia with the patient in the lithotomy or prone jack-knife position. Haemorrhoidectomy can be performed using an open or a closed technique. The open technique is

James Barron, 1914–1996, surgeon, Henry Ford Hospital, Detroit, MI, USA.

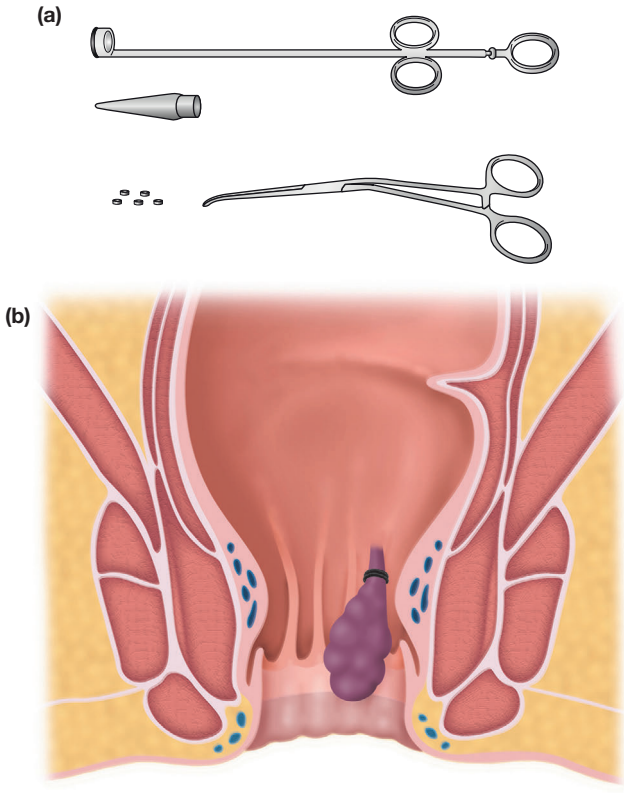

Figure 80.22 (a) Barron's banding apparatus. (Reproduced with permission from O'Connell PR, Madoff RD, Solomon MJ (eds). *Operative surgery of the colon, rectum and anus*, 6th edn. Boca Raton, FL: CRC Press, 2015.) **(b)** The appearance of a typical 'banded' haemorrhoid.

most commonly used in the UK and is known as the Milligan–Morgan operation – named after the surgeons who described it. The closed technique (Ferguson) is the popular technique in the USA. Both involve ligation and excision of the haemorrhoid, but in the open technique the anal mucosa and skin are left open to heal by secondary intention, and in the closed technique the wound is sutured.

- **Open technique**. The anoderm and subcutaneous tissues between the haemorrhoids may be injected with dilute adrenaline (1:300 000 dilution) to reduce bleeding and aid preservation of the skin bridges left following excision. Artery forceps are applied to the skin-covered external components of the haemorrhoids and traction exerted to reveal the internal components, which are also grasped by artery forceps. With scissors or cutting diathermy, a V-shaped cut is made through the skin (***Figure 80.23a***). Traction by both operator and assistant, combined with careful dissection, will expose the lower border of the internal sphincter. The dissection proceeds up the anal canal, with the sides of the mucosal dissection converging towards the pile apex and with the internal sphincter visible and separate from the dissected pile (***Figure 80.23b***). A transfixion ligature of strong Vicryl is applied to the pedicle at this level (***Figure 80.23c***), the pile is excised well distal to the ligature and, after ensuring haemostasis, the ligature is cut long. Each haemorrhoid is dealt with in this manner, taking care to leave mucocutaneous bridges. If there are significant secondary haemorrhoids under these bridges they can be excised out by submucosal dissection (Parks). Careful haemostasis is important. A soft absorbable anal dressing is inserted.
- **Closed technique**. The haemorrhoid is excised, together with the overlying mucosa, as illustrated in ***Figure 80.24***. The pedicle is transfixed with a 3/0 polyglactin suture and the mucosal defect is closed with a continuous suture, using the same stitch. The remaining haemorrhoids are excised and ligated in a similar fashion, ensuring that there are adequate mucosal and skin bridges between each area of excision to avoid a subsequent stenosis.
- **Stapled technique**. Stapled haemorrhoidopexy, also known as PPH (procedure for prolapse and haemorrhoids) (Longo), utilises a bespoke circular stapling device to excise a cylinder of mucosa and submucosa (together with the vessels within) above the dentate line while simultaneously stapling the mucosal ends together (***Figure 80.25***). Great care

must be taken to ensure the staple line is above the dentate line and that the posterior vaginal wall is not accidently included. The procedure is less painful than conventional haemorrhoidectomy and is associated with quicker recovery. However, recurrence rates are higher than following conventional haemorrhoidectomy and external haemorrhoids may persist. Moreover, stapled haemorrhoidopexy has the potential for serious morbidity (staple line dehiscence, infection, rectovaginal fistula) and distressing new symptoms such as tenesmus (related to mucosal stimulation by the staples) may require reoperation and staple removal. Counselling and shared decision making is important such that the patient can weigh the short-term benefits against higher recurrence rates.

- **Transanal haemorrhoidal ligation (HAL)**. Transanal Doppler-guided ligation of those vessels feeding the haemorrhoidal masses with or without suture 'mucopexy' can be used to treat second- and third-degree haemorrhoids. The HubBLe trial, which compared HAL with rubber band ligation, found that the recurrence rate following HAL was significantly lower, but HAL was less cost-effective. The complication rate and postoperative pain scores are better after HAL than with conventional surgery.

Summary box 80.8

Treatment of haemorrhoids

- Symptomatic – advice about defecatory habits, stool softeners and bulking agents
- Injection of sclerosant
- Rubber banding
- HAL/stapled haemorrhoidopexy
- Haemorrhoidectomy

Postoperative care

In many countries, haemorrhoidectomy is performed on a day-case basis. The patient is instructed to take two warm baths each day and is given a bulk laxative to take twice daily, together with appropriate analgesia. A 5-day course of oral metronidazole may reduce pain. Dry dressings are applied as necessary, a sterile sanitary towel usually being ideal. The patient is seen again 3–4 weeks after discharge and a rectal examination is performed. If there is evidence of stenosis, the patient is encouraged to use an anal dilator.

Postoperative complications

Postoperative complications may be early or late.

Early complications include:

- **Pain**. Opiate analgesia, local anaesthetic agents, GTN and calcium channel blockers, together with botulinum toxin are useful postoperative adjuncts for postoperative pain.

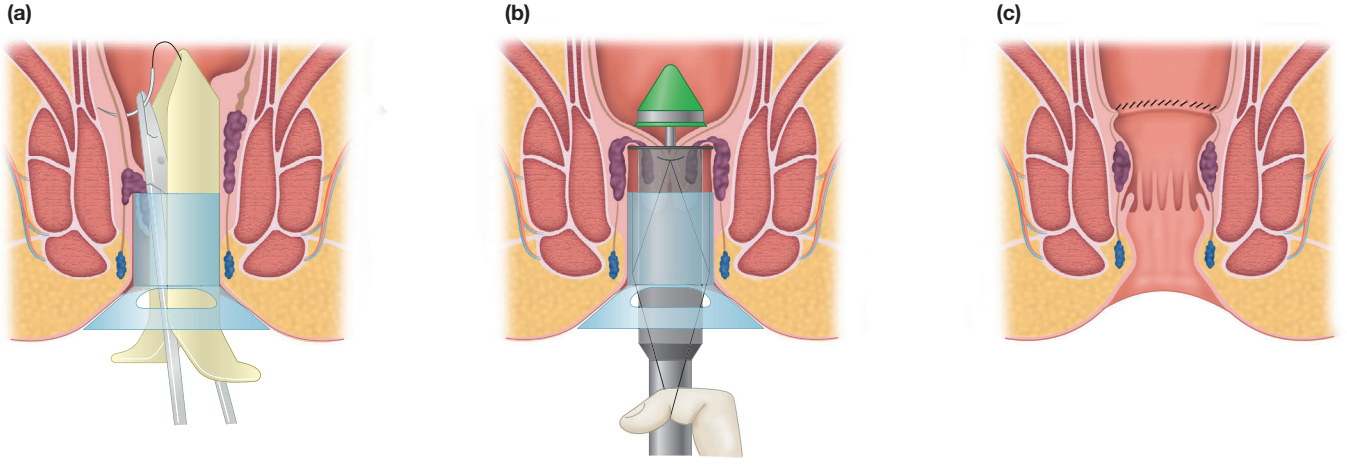

Figure 80.25 Stapled haemorrhoidectomy: **(a)** the purse-string suture is placed several centimetres above the dentate line; **(b)** the anvil of the fully opened stapling gun is inserted endoanally so that it is above the purse-string suture, which is then tied around the shaft of the gun. The gun is closed and fired; **(c)** after firing, a 3- to 4-cm strip of mucosa and submucosa containing the haemorrhoids is excised and the mucosal edges are simultaneously stapled together.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

- **Retention of urine**. This occurs especially in men, and may need relief by catheterisation.
- **Reactionary haemorrhage**. This is much more common than secondary haemorrhage. The haemorrhage may be mainly or entirely concealed but will become evident on examining the rectum. If persistent following adequate analgesia, the patient must be taken to the operating theatre and the bleeding point secured by careful diathermy or under-running with a ligature on a needle, care being taken to avoid damage to the internal sphincter. Should a definite bleeding point not be found, the anal canal and rectum should be packed to ensure haemostasis and the area re-examined under anaesthesia on removal of the packs.

Late postoperative complications include:

- **Secondary haemorrhage**. This is uncommon, occurring about the seventh or eighth day after operation. If severe, the bleeding will need to be controlled under general anaesthesia.
- **Anal stricture**. This must be prevented at all costs. A rectal examination at the postoperative review will indicate whether it may be necessary to dilate the anal canal under general anaesthetic. Daily use of a dilator should give a satisfactory result.
- **Anal fissures and submucous abscesses**.
- **Incontinence**. This occurs if there has been inadvertent damage to the underlying internal sphincter.

Summary box 80.9

Complications of haemorrhoidectomy

Early	Late
• Pain	• Secondary haemorrhage
• Acute retention of urine	• Anal stricture
• Reactionary haemorrhage	• Anal fissure
	• Incontinence

External haemorrhoids

A thrombosed external haemorrhoid relates anatomically to the veins of the superficial or external haemorrhoidal plexus and is commonly termed a perianal haematoma. It presents as a sudden onset, olive-shaped, painful blue subcutaneous swelling at the anal margin and is usually consequent upon straining at stool, coughing or lifting a heavy weight. The thrombosis is usually situated in a lateral region of the anal margin. If the patient presents within the first 48 hours, the clot may be evacuated under local anaesthesia. Untreated it may resolve, suppurate, fibrose and give rise to a cutaneous tag, burst and the clot extrude (***Figure 80.26***) or continue bleeding. In the majority of cases, resolution or fibrosis occurs.

Figure 80.26 A thrombosed external haemorrhoid that has spontaneously ruptured. Most of the underlying blood clot has extruded. There is also a mucosal prolapse, which is separate from the cutaneous lesion.

PRURITUS ANI

This is intractable itching around the anus, a common and embarrassing condition. Usually, the skin is reddened and hyperkeratotic and it may become cracked and moist. The causes are numerous but most commonly relate to poor or excessive hygiene, moist discharge secondary to other anorectal conditions, parasitic causes, especially threadworms (*Enterobius vermicularis*), and dermatological conditions (allergy, psoriasis, lichen planus). Care must be taken not to miss neoplastic changes such as anal SCC, malignant melanoma, Bowen's disease and extramammary Paget's disease.

Treatment

Symptomatic treatment begins with dietary measures to ensure a soft, formed stool. For hygiene, cotton wool or moist tissue should be substituted for toilet paper. Soap is avoided and replaced by water alone, and the area pat-dried rather than rubbed. These measures, combined with wearing cotton underwear and the application of calamine lotion or zinc oxide barrier cream, are sufficient in many cases. In patients with dermatitis topical application of 0.5% or 1% hydrocortisone cream is beneficial.

Summary box 80.10

Pruritus ani

- Common
- Numerous causes, including skin diseases, parasites (threadworm), anal discharge, allergies, diabetes
- Treat the cause if possible
- Symptomatic treatment is the mainstay

John Templeton Bowen, 1857–1941, Professor of Dermatology, Harvard University Medical School, Boston, MA, USA, described this intradermal precancerous skin lesion in 1912.

Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK, described this disease in 1874.

A, Intersphincteric; B, ischiorectal; C, superficial perianal; D, supralevator; E, submucosal.

ANORECTAL ABSCESSES

Aetiology

Acute sepsis in the region of the anus is common, more in men than women, although perianal infections with skin-type organisms (and thus unrelated to fistula) are evenly distributed. The cryptoglandular theory of intersphincteric anal gland infection (Parks) holds that pus, which travels along the path of least resistance, may spread caudally to present as a perianal abscess, laterally across the external sphincter to form an ischiorectal abscess or, rarely, superiorly above the anorectal junction to form a supralevator intermuscular or pararectal abscess (depending on its relation to the longitudinal muscle) (***Figure 80.27***), as well as circumferentially in any of the three planes: intersphincteric/intermuscular, ischiorectal or pararectal supralevator (***Figure 80.28***). Sepsis unrelated to anal gland infection may occur at other sites, including submucosal abscess (following haemorrhoidal sclerotherapy, which usually resolves spontaneously), mucocutaneous or marginal abscess (infected haematoma), ischiorectal abscess (foreign body, trauma, deep skin-related infection) and pelvirectal supralevator sepsis originating from pelvic disease. Underlying rectal disease, such as neoplasm and particularly Crohn's disease, may be the cause. Immunosuppressed patients or those with diabetes or acquired immunodeficiency syndrome (AIDS) may present with perianal or pelvirectal sepsis that may run an aggressive course.

Presentation

A perianal abscess, confined by the terminal extensions of the longitudinal muscle, is usually associated with a short (2–3 day) history of increasingly severe, well-localised pain and a palpable tender lump at the anal margin. Examination reveals an indurated hot, tender perianal swelling. Patients with infection in the larger fatty-filled ischiorectal space, in which tissue tension is much lower, usually present later, with less well-localised symptoms but more constitutional upset and fever. On examination, the affected buttock is diffusely swollen with widespread induration and deep tenderness. If sepsis is higher, deep rectal pain, fever and sometimes disturbed micturition may be the only features, with nothing evident on external examination but tender supralevator induration palpable on digital examination above the anorectal junction.

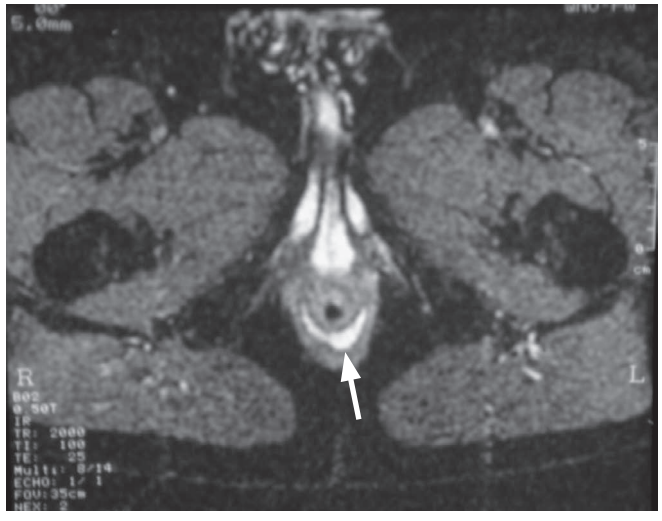

Figure 80.28 Axial magnetic resonance imaging scan (short tau inversion recovery [STIR] sequence) showing posterior horseshoe spread of sepsis within the intersphincteric space (arrow).

Differential diagnosis

The only conditions with which an anorectal abscess is likely to be confused are abscesses connected with a pilonidal sinus, Bartholin's gland or Cowper's gland.

Caspar Bartholin (Secundus), 1655–1709, Professor of Medicine, Anatomy and Physics, Copenhagen, Denmark, described these glands in 1677.
William Cowper, 1666–1709, surgeon, London, UK, described these glands in 1697.

Management

Management of acute anorectal sepsis is primarily surgical, including careful examination under anaesthesia, sigmoidoscopy and proctoscopy, and adequate drainage of the pus. For perianal and ischiorectal sepsis (with an incidence of 60% and 30%, respectively), drainage is through the perineal skin. Traditionally this has been through a cruciate incision over the most fluctuant point, with excision of the skin edges to deroof the abscess; however, although drainage must be ensured, skin preservation is important and wide excision of otherwise healthy tissue should be avoided. A gentle search may be made for an underlying fistula if the surgeon is experienced; if obvious, a loose draining seton may be passed. Injudicious probing in the acute stage is, however, potentially dangerous and may lead to a much more difficult situation. Unless by highly experienced hands, immediate fistulotomy should not be performed. Despite lack of evidence, the practice of packing the abscess cavity is commonplace.

The management of supralevator sepsis is dependent upon its origin. Sepsis originating in pelvic disease necessitates appropriate management of the underlying cause (appendiceal, gynaecological, diverticular, Crohn's disease, malignancy), although intrarectal drainage may be appropriate to avoid creation of an extrasphincteric fistula.

Summary box 80.11

Anorectal abscess

- Presents as a painful, throbbing swelling in the anal region with associated pyrexia
- Classified according to anatomical site
- Treatment is drainage of pus and appropriate systemic antibiotics
- Consider underlying diagnosis: fistula-*in-ano*, Crohn's disease, diabetes, immunosuppression

FISTULA-*IN-ANO*

Aetiology

A fistula-*in-ano*, or anal fistula, is a chronic abnormal communication extending from the anorectal lumen (the internal opening) to an external opening on the skin of the perineum or buttock (or rarely, in women, to the vagina). The majority are idiopathic or cryptoglandular and are lined by granulation tissue. Anal fistulae may be found in association with Crohn's disease, tuberculosis, lymphogranuloma venereum, actinomycosis, rectal duplication, foreign body and malignancy (which may also very rarely arise within a longstanding fistula).

Presentation

Patients usually complain of intermittent purulent discharge (which may be bloody) and discomfort, which increases until temporary relief occurs when the pus discharges. There is often a history of anorectal sepsis. The passage of flatus or faeces through the external opening is suggestive of a rectal rather than an anal internal opening.

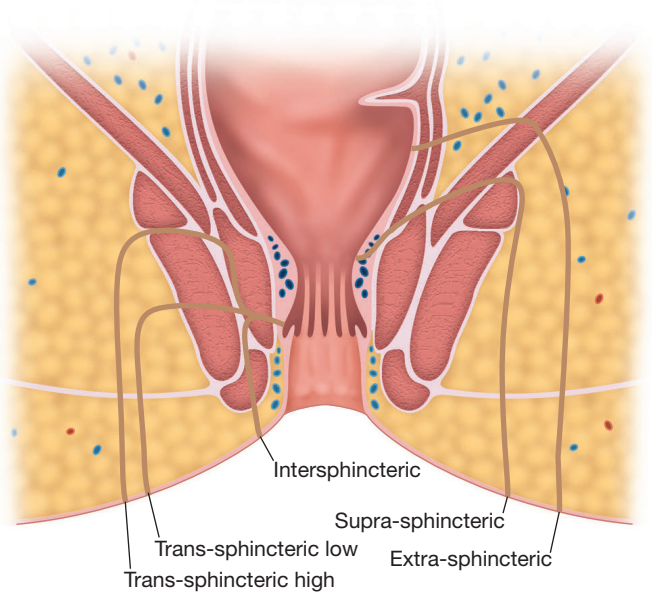

Figure 80.29 Coronal section of pelvis showing Parks' classification of anal fistula tracts.

Classification

The most widely used classification of anal fistulae (Parks') is based on anal gland sepsis in the intersphincteric space (the internal opening is at the dentate line); this results in a primary track whose relation to the external sphincter defines the type of fistula, which influences management (***Figure 80.29***).

The vast majority of fistulae are intersphincteric or trans-sphincteric. The American Gastroenterology Association classification (***Table 80.2***), which condenses the Parks' classification into simple and complex fistula, is helpful in the decision to operate on clinical findings, investigate further or refer for specialist opinion.

TABLE 80.2 American Gastroenterology Association classification of anal fistula.

Simple fistula
• Low (superficial or low inter- or low trans-sphincteric tract)
• Single external opening
Complex fistula
• High (high inter- or trans-sphincteric tract)
• Extra- or suprasphincteric tract
• Presence of abscess or collection
• Ano-vaginal fistula
• Anal stricture

Intersphincteric fistulae (45%) do not cross the external sphincter (bar, for the purist, the most medial subcutaneous fibres running below the distal border of the internal sphincter); most commonly they run directly from the internal to the external openings across the distal internal sphincter but may extend proximally in the intersphincteric plane to end blindly

with or without an abscess or enter the upper anal canal or distal rectum at a second internal opening.

Trans-sphincteric fistulae (40%) have a primary track that crosses both internal and external sphincters (the latter at a variable level) and that then passes through the ischiorectal fossa to reach the skin of the buttock. The primary track may have secondary tracks arising from it, which often reach the roof of the ischiorectal fossa; they may rarely pass through the levator muscle to reach the pelvis. Circumferential (horseshoe) spread of sepsis may occur in the intersphincteric and pararectal planes, as well as in the ischiorectal plane.

Suprasphincteric fistulae (10%) run up to a level above the puborectalis and then curl downwards through the levators and ischioanal fossa to reach the skin. They are often caused by excessive probing of an abscess cavity or fistula tract during examination under anaesthesia. They are difficult to distinguish from high-level trans-sphincteric tracks; however, the management strategies are similar. Extrasphincteric fistulae (5%) run without specific relation to the sphincters and usually result from pelvic disease or trauma.

Clinical assessment

A full medical (including obstetric, gastrointestinal, anal surgical and continence) history and proctosigmoidoscopy are necessary to gain information about sphincter strength and to exclude associated conditions. The key points to determine by clinical assessment of the fistula involve the following essential points:

- the site of the internal opening;
- the site of the external opening(s);
- the course of the primary track;
- the presence of secondary extensions; and
- the presence of other conditions complicating the fistula.

Palpable induration between the external opening and the anal margin suggests a relatively superficial track, whereas supralevator induration suggests a primary track above the levators or high in the roof of the ischiorectal fossa, or a high secondary extension. Intersphincteric fistulae usually have an external opening close to the anal verge. Goodsall's rule (***Figure 80.30***), used to indicate the likely position of the internal opening according to the position of the external opening(s), is helpful; however, the majority of internal openings are midline in both the anterior and posterior planes. The site of the internal opening may be felt as a point of induration or seen as an enlarged papilla. Dilute hydrogen peroxide, instilled via the external opening, can demonstrate the site of the internal opening (***Figure 80.31***); gentle use of probes (***Figure 80.32***) and a finger in the anorectum usually delineates primary and secondary tracks and their relations to the sphincters. Any concerns about fistula topography at clinical examination or examination under anaesthesia (more common after previous unsuccessful surgery) should prompt further investigations before surgical intervention.

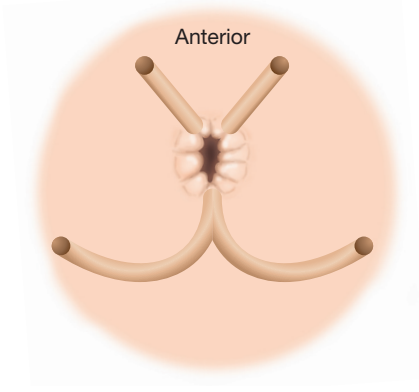

Figure 80.30 Goodsall's rule.

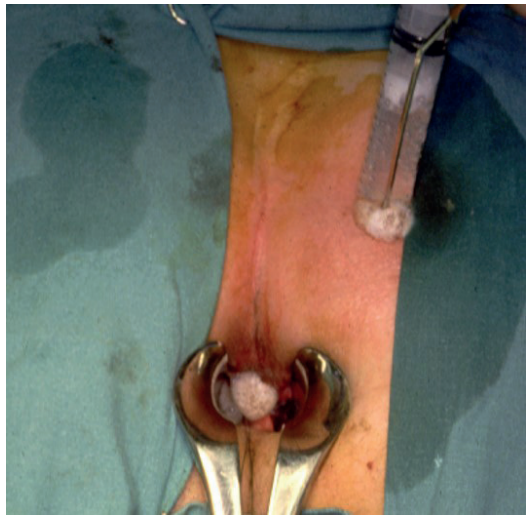

Figure 80.31 Injection of dilute hydrogen peroxide through the external fistula opening identifies the position of the internal opening at the dentate line.

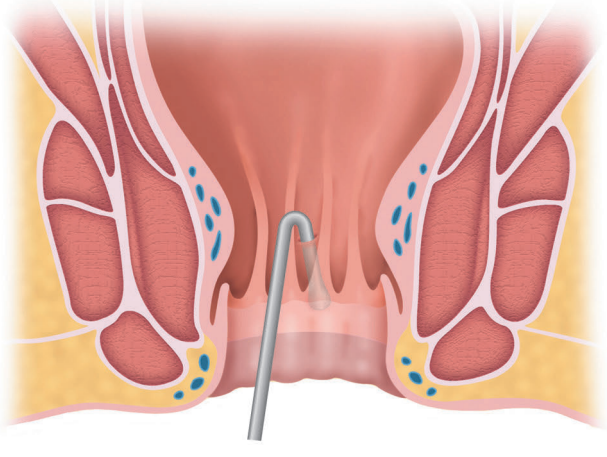

Figure 80.32 Retrograde probing of an anal canal sometimes reveals the internal orifice of the fistula.

David Henry Goodsall, 1843–1906, surgeon, St Mark's Hospital, London, UK.

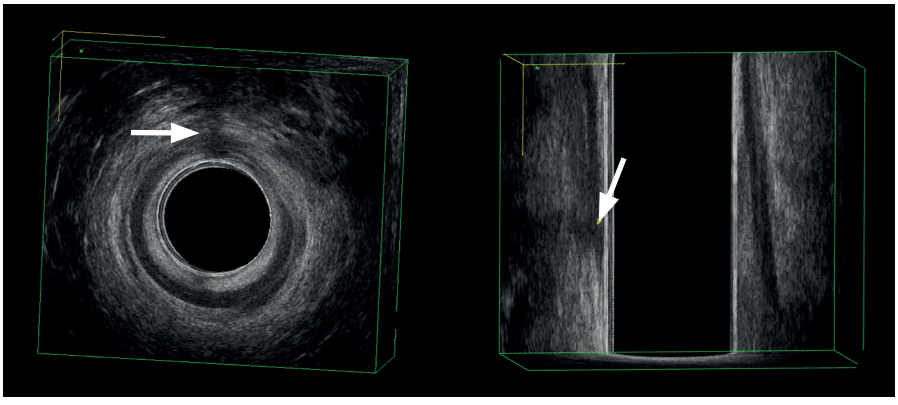

Figure 80.33 Three-dimensional endoanal ultrasonography images in the axial and sagittal plane showing an ano-vagina fistula (arrows) tracking from 12 o'clock towards the posterior vaginal wall at the lower canal level (courtesy of Dr Alison Corr, Consultant Radiologist, St Mark's Hospital, London, UK).

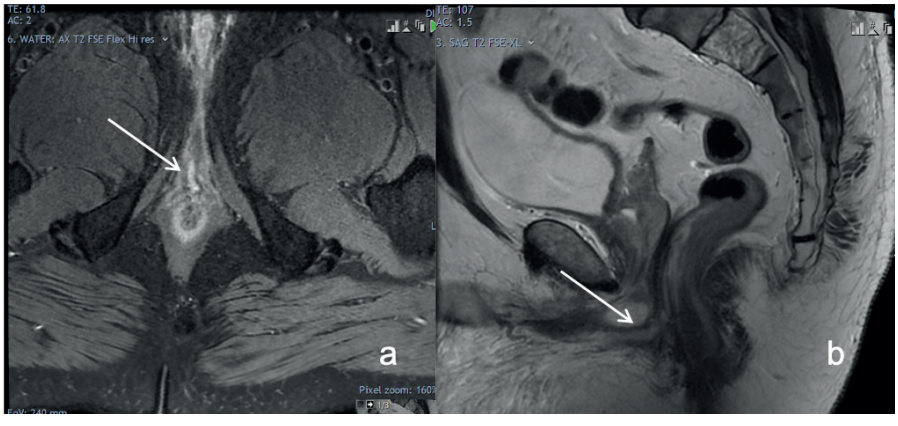

Figure 80.34 Axial T1-weighted post-contrast **(a)** and sagittal T2-weighted **(b)** magnetic resonance imaging sequences demonstrating an anterior fistula tract (arrow) traversing the perineal body to track under the base of the penis towards the scrotum (courtesy of Dr Alison Corr, Consultant Radiologist, St Mark's Hospital, London, UK).

Special investigations

A successful outcome after fistula surgery requires careful assessment of the fistula tract, sphincter integrity and function and patient expectations (especially in terms of risk to continence). Clinical examination will give some indication of functional anal sphincter length, resting tone and voluntary squeeze; these may be more objectively assessed by manometry, whereas EAUS gives useful information about sphincter integrity – the knowledge so gained may well influence surgical strategy. EAUS, especially with hydrogen peroxide instilled through the external opening, is more accurate than clinical examination and is useful to determine whether a fistula is simple or complex (***Figure 80.33***).

MRI is the 'gold standard' for fistula imaging. Short tau inversion recovery (STIR) sequencing (a fat-suppression technique) to highlight the presence of pus and granulation tissue without the need for contrast medium has been revolutionary (***Figure 80.34***). The great advantage of MRI is its ability to demonstrate secondary extensions, which may be missed at surgery and cause persistence (***Figure 80.35***). Fistulography and computed tomography (CT) are useful if an extrasphincteric fistula is suspected.

Figure 80.35 Coronal magnetic resonance imaging scan (short tau inversion recovery [STIR] sequence) demonstrating a primary track in the right ischiorectal space (short arrow) that crosses the sphincters to open into the anal canal just below the puborectalis. A blind secondary extension (long arrow) passing to the contralateral side in the roof of the left ischiorectal fossa was the cause of fistula persistence.

Principles of fistula surgery

The aim of surgery is to keep the patient continent and comfortable and whenever possible to eradicate the fistula. Fistulotomy, or laying the fistula tract open and allowing it to heal by secondary intention, has been practised for centuries and was beautifully described by John of Arderne in his *De Arte*

John of Arderne, 1307–1390, was the first English surgeon of note. He practised at Newark-on-Trent, and, from 1370, in London, UK. He described his operation for the treatment of fistulae in about 1376.

Phisicali et de Cirurgia. The use of a seton (from the Latin *seta*, meaning a bristle) to drain fistula tracts and gradually deliver the tract to the surface has a long history, most famously used by Charles Felix to treat French King Louis XIV.

Patients with minimal symptoms may be managed expectantly. Fistula eradication requires surgery, the extent of which must be balanced with the need to preserve continence. Division of any component of the sphincter mechanism carries some risk to continence. The most important determinant of function after fistulotomy is the amount of muscle left behind rather than that divided. In the presence of a normal bowel habit, continence is usually maintained as long as a minimum length of external sphincter is retained (2 cm as a rule but less in some cases).

Most fistulae are simple; however, a significant minority are complex (***Table 80.2***) and warrant specialist referral. The multitude of strategies advocated attests to these difficult situations; comparisons between techniques are difficult because of the heterogeneity of patient groups, the variability in classification, the inapplicability of certain techniques in some situations, inadequate reporting of functional outcomes, inadequate follow-up and surgeon preference over-riding entry into prospective randomised trials.

Track preparation

Tract preparation is an increasingly accepted concept in fistula surgery. It assumes that healing is prevented by epithelialisation of the track or that a secondary extension or undrained collection will induce early recurrence. Thus, a period of loose seton drainage followed by thorough debridement of the fistula track should improve healing rates. Some techniques, such as fistula plug, 'ligation of the intersphincteric fistula tract' (LIFT) (Rojanasakul) or 'fistula tract laser closure' (FiLaC™), require a particular track anatomy – such as a single straight trans-sphincteric tract – to be successful. In these cases, track preparation will facilitate healing of secondary tracks before definitive surgery.

Fistulotomy

Fistulotomy involves division of all structures lying between the external and internal openings. It is therefore applied mainly to intersphincteric fistulae and trans-sphincteric fistulae involving less than 30% of the external sphincter (but not anterior fistulae in women). After full examination under anaesthesia in the lithotomy or prone jack-knife position, during which the internal opening is identified, a grooved fistula probe is passed from the external to the internal opening (***Figure 80.36***), the amount of sphincter below and above the probe is noted and, if indicated, the track is laid open over the probe. Granulation tissue is curetted and sent for histological appraisal and the wound edges are trimmed. Secondary tracks, often identified as granulation tissue that persists despite curettage, should be laid open or drained. Marsupialisation reduces wound size and speeds up healing. Primary tracks crossing the external sphincter more deeply have been managed with good outcomes by fistulotomy and immediate reconstitution of the divided muscle – failure to eradicate all sepsis and subsequent breakdown of the repair can be problematic. Alternatively, a staged fistulotomy may be carried out in which secondary tracks are laid open and only part of the sphincter enclosed by the primary track is divided, with the remainder encircled by a loose seton. After sufficient time for healing of the wound and fibrosis, the seton-enclosed track is divided at a second stage.

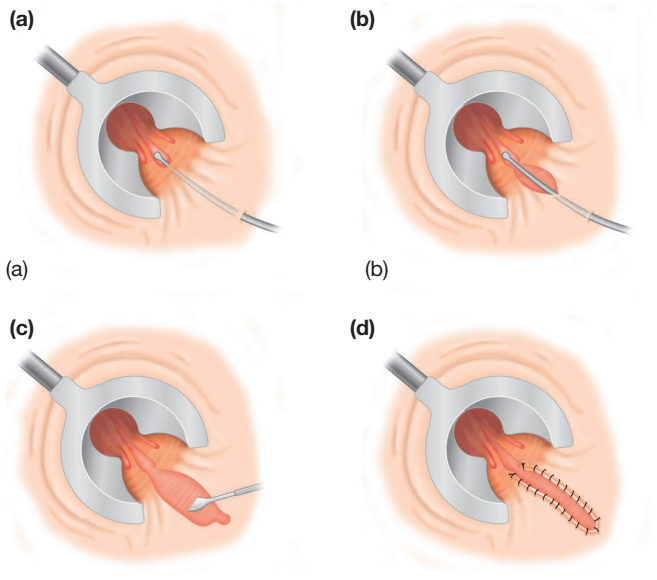

Figure 80.36 Fistulotomy. A grooved probe is passed from the external to internal openings **(a)** and the track laid open over the probe **(b)**. The track is curetted to remove granulation tissue **(c)**, the edges of the wound are trimmed and the wound may then be marsupialised **(d)**. (Redrawn with permission from Nicholls RJ, Dozois RR. *Surgery of the colon and rectum*. Edinburgh: Churchill Livingstone, 1997.)

Fistulectomy

This technique involves coring out of the fistula, usually by diathermy cautery; it allows better definition of fistula anatomy than fistulotomy, especially the level at which the track crosses the sphincters and the presence of secondary extensions. If the sphincteric component of the fistula is deemed low enough to allow safe fistulotomy, then this may proceed (at the expense of longer healing times than conventional fistulotomy). If laying open is not advisable, the sphincteric component can be managed by another method.

Setons

Setons have been used in a variety of ways in fistula surgery and it is important for surgeons to be clear about what they are trying to achieve in a particular situation. Loose setons are tied such that there is no tension upon the encircled tissue; there is no intent to cut the tissue. A variety of materials have been used but the seton should be non-absorbable, non-degenerative and comfortable. Tight or cutting setons are placed with the intention of cutting through the enclosed muscle.

Loose setons are most commonly used before 'advanced' techniques (fistulectomy, advancement flap, cutting seton)

Charles Felix de Tassy, 1635–1703, on 18 November 1686 operated on Louis XIV, inserting a seton.
Arun Rojanasakul, contemporary, Professor of Surgery, Chulalongkorn University, Bangkok, Thailand.

while sepsis resolves and secondary extensions heal as part of a staged fistulotomy. Such a staged approach is valuable in treating secondary (horseshoe) tracks in the ischiorectal fossa, where the primary track crosses the external sphincter to reach the deep postanal space (Hanley). The internal sphincter is laid open to the level of the internal opening (or higher if there is a cephalad intersphincteric extension) to eradicate the presumed source and the sepsis in the intersphincteric space. A seton is then passed along the residual track around the denuded external sphincter and tied loosely, and the wounds are dressed. The seton is left in place for 3 months and either simply removed or replaced by a cutting seton to complete the fistulotomy.

Loose setons are also used for long-term palliation to avoid septic and painful exacerbations by establishing effective drainage, most often in Crohn's disease and in those with problematic fistulae not wishing to countenance the possibility of incontinence (***Figure 80.37***).

Cutting setons aim to achieve the high fistula eradication rates associated with fistulotomy but without the degree of functional impairment endowed by division of the sphincters at a single stage. The enclosed muscle is gradually severed ('cheese wiring'), such that the divided muscles do not spring apart, and the site of the fistula track is replaced by a thin line of fibrosis. Some recommend prior internal sphincter division; others recommend incorporation of the internal sphincter within the cutting seton. A variety of seton material has been used, either elastic and 'self-cutting' or non-elastic and tightened at intervals, with the sphincter being divided at varying speeds. The same aim has been achieved by chemical cautery using an Ayurvedic method known in India as *ksharasootra*, in which a specially prepared seton thread burns through the enclosed tissue. This outpatient method has been shown to be equivalent to one-stage fistulotomy in patients with intersphincteric and distal trans-sphincteric fistulae.

Ligation of intersphincteric fistula tract

LIFT involves disconnection of the internal opening from the fistula tract at the level of the intersphincteric plane and removal of the residual infected glands without dividing any part of the sphincter complex. The tract is then ligated and divided, the internal part is removed and the external part of the track is curetted and drained (***Figure 80.38***). Hence it is a sphincter-preserving procedure, thereby maintaining continence. Systematic reviews report healing rates of 75% with little or no impairment of continence.

Advancement flaps

When the sphincter complex is not too indurated and adequate intra-anal access can be obtained, an advancement flap technique can be employed; this aims to preserve both anatomy and function. Ideally sepsis and secondary tracks have healed, leaving a direct track that can be cored. The internal opening is then closed with a broad-based, well-vascularised flap of anorectal mucosa and the internal sphincter is sutured without tension to the anoderm below the dentate line.

Figure 80.37 Complex horseshoe fistula-*in-ano* in Crohn's disease with healed ischiorectal sepsis, a loose seton in the residual tract and a draining 12 FG Malecot catheter to the deep postanal space.

Biological agents

The functional consequences of fistulotomy have led to a search for agents that seal the fistula track and allow ingrowth of healthy tissue to replace it. Intuitively, success must depend on the biomaterial itself and the environment into which it is placed. Many agents have been tried with moderate success. These include fibrin glue, cross-linked porcine dermal collagen and more recently mesenchymal stem cells. Antibiotics, particularly metronidazole and ciprofloxacin, are of value in treating fistula-associated sepsis and many have immune-modulating effects of value in Crohn's disease. Patients must be warned of potential side effects of prolonged therapy, including peripheral neuropathy (metronidazole) and tendinopathy (ciprofloxacin). Biological therapies, including the anti-tumour necrosis factor drug vedolizumab and ciclosporin, are of value as part of multimodality treatment of perianal Crohn's disease (***Chapter 75***).

Other techniques

Video-assisted anal fistula treatment (VAAFT) involves the introduction of a rigid fistuloscope into the tract through the external opening. The scope has a channel to accommodate a forceps, brush or diathermy. The scope is passed into accessible tracks to allow lavage, curettage, cautery or the introduction of setons. VAAFT represents a form of advanced track identification and preparation before a definitive technique is performed. Fistula tract laser closure (FiLaC) uses radial emitting laser to obliterate the luminal aspect of the fistula to a known depth, throughout its length. An over-the-scope clip (OTSC) involves closing the internal opening using a nitinol clip, disconnecting the external tract. Clip migration and elective removal because of pain are the main complications. The FISCLOSE trial is currently recruiting.

Summary box 80.12

Anorectal fistulae

- Are classified according to the relationship to the anal sphincters
- The majority are simple and may be safely treated by fistulotomy
- Complex fistulae require detailed anatomical assessment that may include MRI
- Staged treatment including use of setons should be considered
- LIFT, flap advancement, VAAFT, FiLaC and OTSC allow sphincter preservation
- Biological therapy is used in multimodality treatment of fistulae associated with Crohn's disease

HIDRADENITIS SUPPURATIVA

HA is a chronic suppurative condition of apocrine gland-bearing skin found in the axillae, submammary regions, nape of the neck, groin, mons pubis, inner thighs and sides of the scrotum, as well as the perineum and buttocks. It is a source of considerable physical and psychological morbidity. There is no confirmatory test or specific characteristic for diagnosis, which makes definition difficult. Acne, pilonidal sinus and chronic scalp folliculitis may coexist.

Pathology

Occlusion of gland ducts leads to bacterial proliferation, gland rupture and the spread of infection and epithelial components into the surrounding soft tissue and to adjacent glands. Secondary infection causes further local extension, skin damage and deformity, with multiple communicating subcutaneous sinus tracts. There is some evidence that the disease may be related to a relative androgen excess.

Presentation

The condition is not seen before puberty and rarely presents after the fourth decade of life. Overall, it is three times more common in women than in men, although anogenital disease is more common in men. Obesity is a common association. When affecting the perineum, lesions begin as multiple raised boils, with recurrent lesions within the same vicinity leading to sinus tract formation, bridged scarring and multiple points of discharge. Rarely, it may involve the anal canal anoderm, but it does not extend above the dentate line or involve the sphincter muscle.

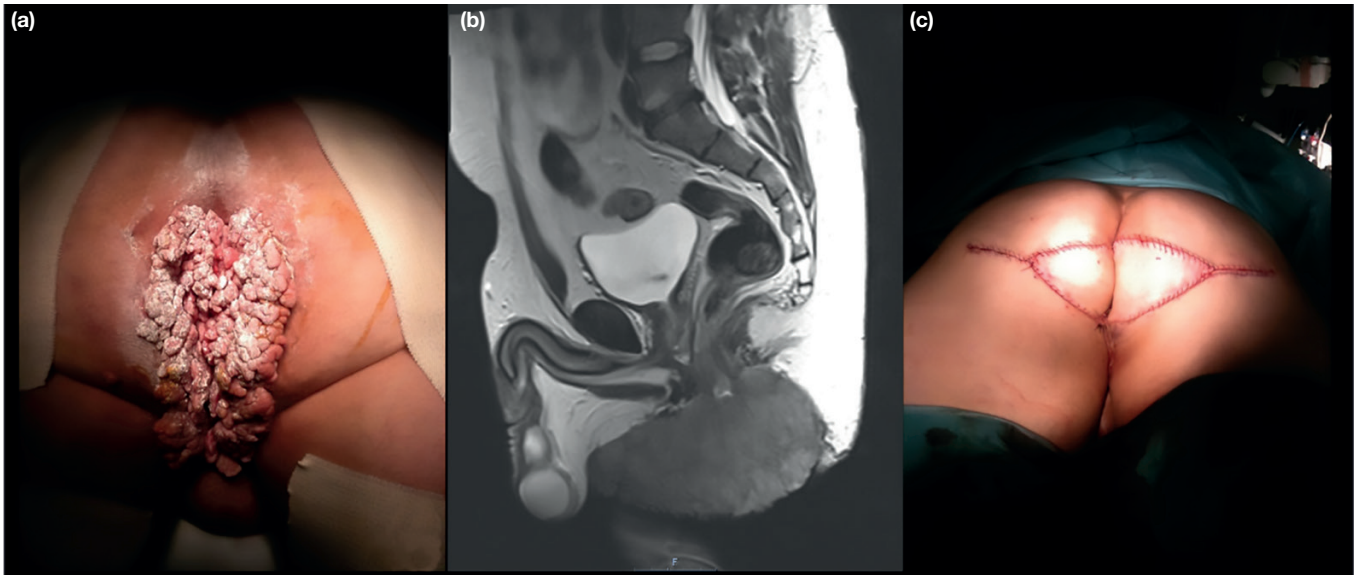

Figure 80.39 Preoperative image **(a)** of a giant condyloma acuminatum (Buschke–Löwenstein tumour) with sagittal T2-weighted magnetic resonance imaging **(b)** demonstrating the large exophytic frond-like mass protruding from the anal verge. Bilateral inferior gluteal artery perforator (I-GAP) flap reconstruction following perineal resection **(c)** (courtesy of Mr Anthony Antoniou, Consultant Colorectal Surgeon, St Mark's Hospital, London, UK).

Differential diagnosis

In the early stages, distinction from furunculosis can be difficult. Crohn's disease, cryptoglandular fistula, pilonidal sinus, tuberculosis, actinomycosis, lymphogranuloma venereum and granuloma inguinale must be considered when later stages present.

Treatment

In the early stages, general measures, including weight reduction and antiseptic soaps, may be helpful. Antibiotics may induce remission but often the disease relapses and progresses, at which point surgery is indicated. Inadequate treatment may lead to prolonged morbidity, but any surgery should be less debilitating than the condition. Surgical intervention ranges from simple incision and drainage of acute sepsis to radical excision of all apocrine gland-bearing skin. Careful laying open of all tracts, possibly as a staged procedure according to anatomical location, is an option that appeals to many patients. Radical excision requires closure by skin graft or rotation flap and, occasionally, a defunctioning colostomy to allow healing.

CONDYLOMATA ACUMINATA (ANAL WARTS)

There is increasing evidence that sexually transmitted infection with human papillomavirus (HPV) forms the aetiological basis of anal and perianal warts, anal intraepithelial neoplasia (AIN) and SCC of the anus. In areas of the world where sexual promiscuity (especially anal intercourse) is more common, and in immunocompromised individuals (HIV-infected individuals and transplant recipients), there have been dramatic increases in the incidence of these conditions over the last 30 years, most importantly of AIN and anal cancers. Similar virally induced changes have been noted in the genital tracts of women (vulval intraepithelial neoplasia [VIN], cervical intraepithelial neoplasia [CIN] and cancers). It is essential to examine all areas of the genitalia and perineum in an affected person as there is often a field change with the virus affecting any squamous epithelium in that area. There are over 170 subtypes of HPV, but certain subtypes (16, 18, 31, 33) are associated with a greater risk of progression to dysplasia and malignancy. SCC is associated with HPV (especially subtypes 16, 18, 31 or 33). Associated warts on the penis and the female genital tract are common.

Presentation

Many are asymptomatic but pruritus, discharge, bleeding and pain are usual presenting complaints. In the early stages, examination reveals separate pinkish-white warts close to the anal margin and also often on the anoderm within the distal anal canal. Later, the warts enlarge, coalesce and carpet the skin. Rarely, relentless growth results in giant condylomata (Buschke–Löwenstein tumour), which may obliterate the anal orifice (***Figure 80.39***). The diagnosis is aided by aceto-whitening on application of acetic acid but confirmed by biopsy, which will also indicate the presence or absence of dysplasia.

Treatment

Because of the field effect endowed by viral skin infection, long-term resolution can be problematic. Careful serial application of 25% podophyllin to discrete warts on the perianal skin is

Abraham Buschke, 1868–1943, Chief of Dermatology, Rudolf Virchow Hospital, Berlin, Germany.
Ludwig W Löwenstein, 1895–1959, pathologist, Berlin, Germany, later New York Post-Graduate Medical School, NY, USA, described this condition in 1925.

often used; however, it cannot be used intra-anally. Surgical excision under local, regional or general anaesthesia involves raising and separating the lesions with local infiltration of dilute adrenaline, which allows more accurate scissor or electrocautery excision to maximise the preservation of normal skin.

ANAL INTRAEPITHELIAL NEOPLASIA

AIN is a multifocal virally induced dysplasia of the perianal or intra-anal epidermis associated with HPV. Subtypes 6 and 11 are most often associated with warts and early AIN, whereas subtypes 16 and 18 account for more than 75% of anal cancers. The prevalence is <1% of the population with a rising incidence, especially in those areas where ano-receptive intercourse and HIV are prevalent. At-risk groups include patients with HIV as well as immunocompromised patients, women with a history of other genital intraepithelial neoplasia (VIN and CIN) and patients with extensive anogenital condylomata. Patients may be asymptomatic and the diagnosis is often a histological surprise, although increasing numbers in high-risk groups are picked up on anal cytology. It is classified according to the degree of dysplasia on biopsy into AIN I, AIN II and AIN III, according to the lack of keratocyte maturation and extension of the proliferative zone from the lower third (AIN I) to the full thickness of the epithelium (AIN III), in the same manner as cervical or vulval dysplasia. The natural history is uncertain but progression from AIN II to AIN III to invasive carcinoma has been observed, notably in the immunocompromised. The term Bowen's disease is no longer used.

Presentation

Around 10% of AIN lesions are diagnosed by the pathologist after excision of abnormal skin lesions. Low-grade lesions may be raised and similar to anal condylomata; however, high-grade AIN III lesions may be characterised by hyperkeratosis or by changes in the pigmentation of the epithelium, so this may appear white, red or brown with the pigmentation commonly being irregular. The lesions may be flat or raised, but ulceration is suggestive of invasive disease. It is important that any suspicious areas are biopsied and examined histologically.

Patients' symptoms include pruritus, pain, bleeding and discharge. AIN is present in 28–35% of excised anal warts. Approximately 10% of AIN III lesions will progress to anal carcinoma at 5 years. Regression of AIN III rarely occurs, but AIN I and AIN II may regress. The association between AIN III and carcinoma is strengthened by the findings of AIN III in 80% of anal cancer biopsies.

Diagnosis and management

A high index of suspicion and targeted biopsy yields the diagnosis, whereas multiple (mapping) biopsies give an indication of the extent and overall severity of the disease. AIN III should be regularly monitored clinically and, if necessary, by repeat biopsy to exclude invasive disease. Specialised centres may offer colposcopy of the anus (anoscopy), utilising 5% acetic acid with Lugol's iodine to assess *in vivo* the dysplastic areas of the anus. The affected areas show up white and can be biopsied. Focal disease may be excised and local excision is effective for lesions <30% of the circumference of the anus. More widespread disease can be dealt with surgically by wide local excision and closure of the resultant defect by flap or skin graft, with or without covering colostomy (especially if there is intra-anal disease). However, for a condition with uncertain malignant potential, this approach should be used with caution as it carries with it significant morbidity. Anal mapping uses a 3-mm corneal punch biopsy, and a total of 8–12 biopsies allows for adequate mapping of most disease. An operative map or photograph is helpful. Examination of the vulva, vagina and cervix is also needed as female patients are at risk of other anogenital intraepithelial neoplasia; it is recommended that those with AIN III have a yearly cervical smear test. The grade and extent of anal disease determines management. Localised or focal AIN is defined as <30% of the anal circumference, whereas extensive AIN involves more than 30% of the circumference. Lesions involving <30% of the anal circumference can be simply excised with the resulting wound left to granulate or closed as appropriate. AIN III lesions involving >30% of the anal margin or canal cannot be excised as the risk of severe anal stenosis is significant. The remaining areas are regularly observed at 6-monthly intervals. AIN I/II and AIN III have differing natural histories.

Topical imiquimod (5%) or oral retinoids have some effect on the progression of dysplasia and can cause regression by at least two histological grades. Other newer options may include anti-HPV treatment; vaccination may reduce the incidence in the long term.

AIN I/II has an indolent course except in immunocompetent patients, for whom 12-monthly anoscopy is recommended. Patients with AIN III and multicentric intraepithelial neoplasia should be managed by clinicians with an interest in this disease and require a multidisciplinary approach involving gynaecological specialists. Immuno-incompetent patients (including those with HIV) are considered separately in view of the higher progression rates and poorer results, with higher recurrence rates after surgery compared with immunocompetent patients. These require extended follow-up with 6-monthly anoscopy.

MALIGNANT TUMOURS

Malignant lesions of the anus and anal canal

Anal malignancy is rare and accounts for less than 2% of all large bowel cancers; however, the incidence is rising, with a direct association with HPV infection, AIN and immunosuppression. The crude incidence rate is 0.65 per 100 000 in the UK. The male-to-female ratio is approximately 1:2. The great majority are SCCs. Those arising below the dentate line are usually keratinising, whereas those above

Jean Lugol, 1786–1851, French physician, Lugol's iodine was first made in 1829.

Figure 80.40 Anus squamous cell carcinoma.

are non-keratinising squamous, variously termed basaloid, cloacogenic or transitional. There is now broad consensus that both are similar in their presentation and response to treatment and should be treated as carcinomas whether keratinising or not. Adenocarcinomas are the next most common and are thought to arise from anal glands. Other tumours include melanoma, lymphoma, sarcoma and tumours of perianal skin.

Squamous cell carcinoma

Anal SCC usually presents with pain and bleeding, thus it is often initially misdiagnosed as a benign condition, highlighting the need for a level of suspicion and adequate examination. A mass, pruritus or discharge is less common. Advanced tumours may cause faecal incontinence by invasion of the sphincters and, in women, anterior extension may result in anovaginal fistulation. On examination, anal margin tumours look like malignant ulcers, with raised indurated edges (***Figure 80.40***). There may be associated HPV lesions. Anal canal tumours are palpable as irregular indurated tender ulceration. Sphincter involvement may be evident. Involvement of perirectal and groin lymph nodes may be palpable on examination.

Investigation

An examination under anaesthetic allows detailed assessment of the tumour size, involvement of regional nodes and adjacent structures and the opportunity to obtain a biopsy for histological examination.

Management

MRI scanning of the pelvis and CT of the chest, abdomen and pelvis allows locoregional and distant staging. Positron emission tomography (PET)-CT is increasingly used and may help in equivocal inguinal node assessment.

Historically anal cancer was treated by abdominoperineal resection; however, since the late 1970s chemoradiotherapy (Nigro) has become the primary treatment. The UK Coordinating Committee on Cancer Research (UKCCCR) Anal Cancer Trial (ACT I) found that chemoradiation with radiotherapy (50.5 Gy) gave superior local control compared with radiotherapy alone while the ACT II trial found similar outcomes when chemoradiotherapy using cisplatin/5-fluorouracil (5-FU) was compared with mitomycin/5-FU. The longer infusion time required to administer cisplatin/5-FU has led to the preferred use of the mitomycin/5-FU combination. Current trials (ACT III, ACT IV and ACT V) are investigating more personalised treatment protocols, including local excision only for small tumours and a combination of excision along with varying radiotherapy regimes for other tumours.

Radical surgical excision by abdominoperineal resection is indicated in those with residual tumour, complications of treatment, incontinence or fistula after tumour resolution and recurrent disease. Despite good results with chemoradiotherapy, 20–25% of patients will have an incomplete tumour response or local disease recurrence. After thorough assessment, these patients may require radical abdominoperineal resection as a salvage procedure. Locally extensive disease may require pelvic exenterative procedures that usually entail perineal reconstruction using a myocutaneous flap.

Enlarged regional inguinal lymph nodes are common and may be secondary to inflammation rather than malignancy. Histological/cytological confirmation is mandatory. Positive nodes are treated by chemoradiotherapy. Radial groin dissection has a high morbidity.

Other anal malignancies

Adenocarcinoma within the anal canal is usually an extension of a distal rectal cancer. Rarely, adenocarcinoma may arise from anal glandular epithelium or develop within a longstanding (usually complex) anal fistula, hence the need to biopsy non-healing fistula-*in-ano*. The treatment is as for low rectal cancers (i.e. abdominoperineal excision of the rectum with or without neoadjuvant chemoradiotherapy, ***Chapter 79***). Malignant melanoma of the anus is very rare and usually presents as a bluish-black soft mass that may mimic a thrombosed external pile, although it may be amelanotic. The prognosis, irrespective of treatment, is extremely poor. Perianal Paget's disease is exceedingly rare.

Summary box 80.13

Anal cancer

- Uncommon, usually squamous cell
- Associated with HPV, HIV and immunosuppression
- Lymphatic spread is to the inguinal lymph nodes
- Treatment is by chemoradiotherapy in the first instance
- Major ablative surgery is required for salvage

Norman D Nigro, 1912–2009, surgeon, Wayne State University, Detroit, MI, USA.

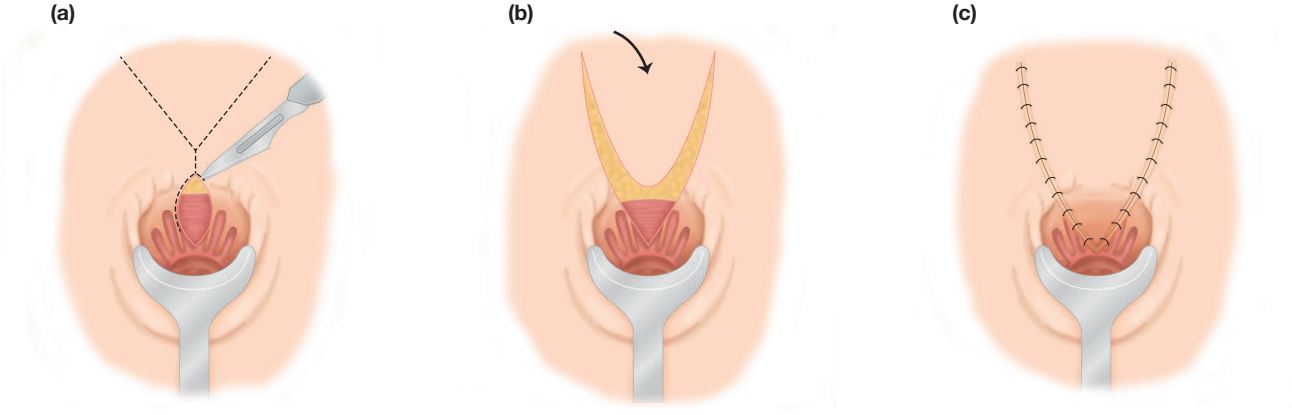

Figure 80.41 Y–V advancement flap for anal stenosis.

NON-MALIGNANT STRICTURES: ANAL STENOSIS

Anal stenosis is a rare but serious complication of anorectal surgery. Removal of excess anoderm and mucosa without adequate skin bridges during haemorrhoidectomy can lead to scarring and stricturing. Stenosis can also occur after stapled haemorrhoidopexy and coloanal anastomoses. Other causes include trauma, postradiation fibrosis, tuberculosis and fibrosing skin conditions, e.g. scleroderma. Lymphogranuloma inguinale may cause an inflammatory stricture of the rectum.

Inflammatory bowel disease

Stricture of the anorectum may complicate Crohn's disease and, in this instance, the stricture is annular. These stenoses are characterised by transmural scarring and inflammation. Occasionally, an anal stricture may occur in ulcerative colitis. Until a biopsy is obtained, a carcinoma should be suspected.

Endometriosis

Endometriosis of the rectovaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with severe pain during the first 2 days of the menstrual flow.

Clinical features

Increasing difficulty in defecation is the leading symptom. The patient finds that increasingly large doses of aperients are required and, if the stools are formed, they are 'pipe-stem' in shape. In cases of inflammatory stricture, tenesmus, bleeding and the passage of mucopus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

Rectal examination

The finger encounters a sharply defined shelf-like interruption of the lumen. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture must be taken. Often the examination will be painful and needs to be performed under general anaesthesia when biopsies and gentle, graduated dilatation may be undertaken.

Treatment

Non-operative treatment is recommended for mild stenosis. The use of stool softeners and fibre supplements helps aid the passage of stools.

Dilatation

Anal dilatation can be performed under general anaesthesia and then by the patient, using an anal dilator. For anal and many rectal strictures, dilatation at regular intervals is all that is required.

Anoplasty

For severe anal stenosis, an anoplasty is used to replace loss of anal tissue. The stricture is incised and a rotation or advancement flap of skin and subcutaneous tissue replaces the defect and enlarges the anal orifice (***Figure 80.41***). This technique is particularly useful for postoperative strictures.

Colostomy

Colostomy must be undertaken when a stricture is causing intestinal obstruction and in advanced cases of stricture complicated by fistulae-*in-ano*. In selected cases, this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, a loop ileostomy is constructed.

Rectal excision and coloanal anastomosis

Rectal excision is required when the strictures are at, or just above, the anorectal junction and are associated with a normal anal canal, but irreversible changes necessitate removal of the area. Coloanal anastomosis can restore function but is contraindicated in Crohn's disease.

Summary box 80.14

Benign anal stricture

- May be iatrogenic, e.g. after haemorrhoidectomy
- Biopsy must be taken to rule out malignancy
- Can usually be managed by regular dilatation
- Severe anal stenosis may require an anoplasty

PART 12 | Genitourinary

CHAPTER

81 Urinary symptoms and investigations

Learning objectives

To understand:
- The significance of pain relating to urinary tract pathology
- The difference between renal pain and ureteric colic
- The definitions of common lower urinary tract symptoms

To be able to:
- Select the appropriate diagnostic tests

PAIN

Pain is a common urological symptom. Pain while passing urine is called dysuria and refers to discomfort experienced during voiding – typically described as a sensation akin to passing razor blades or glass. Most commonly, dysuria is due to an infection in the lower urinary tract but can rarely be due to carcinoma *in situ* (CIS) of the bladder, especially in an older male smoker with haematuria.

Renal pain is usually caused by distension of the renal capsule and is felt as a constant, gnawing pain in the loin/renal angle. Ureteric colic (often incorrectly referred to as renal colic) is different from renal pain and is typified by the lateralised, colicky pain experienced by someone with a ureteric calculus. Ureteric colic can radiate to the groin or to the testicle/labium but does not radiate to the back of the leg. Ureteric colic can also, rarely, be caused by a blood clot or a sloughed renal papilla in the ureter. Some patients simultaneously experience both ureteric colic and renal pain.

Summary box 81.1

Pain from the urinary tract

- Renal colic is a misnomer and should be referred to as ureteric colic
- Renal pain can be distinguished from ureteric colic by careful history taking
- Renal pain and ureteric colic may be experienced simultaneously
- Ureteric colic may radiate to the groin/testicle/labium
- Ureteric colic does not radiate to the chest or the back of the leg

Infection or inflammation of the bladder can produce suprapubic pain. Suprapubic pain that is experienced when the bladder is full and is relieved by micturition is typical of interstitial cystitis, an idiopathic inflammatory disorder of the bladder typically seen in middle-aged women.

Testicular pain is a common symptom in boys and young men. Sudden, severe testicular pain should be treated as a medical emergency to rule out a diagnosis of acute testicular torsion. Hydroceles and epididymal cysts usually do not cause significant pain but can have an increasing pressure effect as they enlarge. A dragging sensation in the scrotum that gets worse towards the end of the day is characteristic of a varicocele. Testicular tumours in young men are not usually associated with significant pain. Investigation of testicular pain in the young adult male/middle-aged male is frequently negative, resulting in a highly unsatisfactory diagnostic label of 'idiopathic testicular pain' or 'chronic orchialgia'. Patients undergoing vasectomy are routinely counselled about the approximately 10% risk of testicular pain in the short term following surgery and, more importantly, the 1% chance of chronic testicular pain in the longer term.

Perineal pain is often a feature of a complex of symptoms typically seen in middle-aged men who, by a process of exclusion, are diagnosed as having acute or chronic prostatitis. With prostatitis, perineal pain may be accompanied by suprapubic pain, low back pain that radiates to the legs and penile pain as well as frequency of micturition and dysuria. In the absence of the specific features that are required to diagnose prostatitis, these patients should be considered to have chronic pelvic pain syndrome (CPPS) and not prostatitis. Perineal pain is an ominous symptom after previous treatment for a pelvic malignancy, often signifying recurrent pelvic disease.

LOWER URINARY TRACT SYMPTOMS

A normal micturition cycle consists of two phases: storage and voiding. During the storage phase, the bladder holds urine at low pressures and the urethral sphincter is closed. During voiding, the bladder contracts to expel urine and the voluntary urethral sphincter relaxes to allow its passage. In addition, the urethral lumen must be patent to allow voiding to occur. Disruption of these processes results in lower urinary tract

symptoms (LUTS). In general terms, LUTS are classified as either storage LUTS (frequency, nocturia, urgency and urinary incontinence); voiding LUTS (hesitancy, a reduced stream, straining); or postmicturition LUTS (incomplete emptying and postmicturition dribble). Storage LUTS result from failure of the bladder to act as a functioning reservoir and are commonly seen in patients with an overactive bladder or a bladder neuropathy. Voiding and postmicturition LUTS are commonly seen in men with bladder outlet obstruction (BOO) or an underactive bladder; however, a man with BOO may also have storage LUTS. BOO is also reported in women and may be caused by urethral stenosis, strictures or a hypocontractile bladder.

The term 'prostatism' is obsolete. It was used to describe a combination of LUTS in men who were presumed to have an enlarged prostate or benign prostatic hyperplasia (BPH). However, the symptoms are not specific to BPH and may occur in several other conditions, including urinary tract infections (UTIs), urethral stricture, overactive bladder, CIS of the bladder, etc. Further, not all symptoms may be present in every patient and most patients have a variable degree of different symptoms. Thus, the term LUTS is now used to describe all such symptoms. It may not always be possible to identify the aetiology of LUTS and additional investigations with urodynamics (see ***Urodynamics***) may occasionally be required.

The International Continence Society provides the internationally accepted definitions for symptoms relating to lower urinary tract function.

- **Frequency** – the patient considers that they void too often during the day.
- **Nocturia** – the individual wakes at night at least once to void.
- **Strangury** – a sensation of constantly needing to void. Typically, the patient describes having to stand/sit for long periods with the sensation that micturition is imminent.
- **Urgency** – a sudden compelling desire to pass urine that is difficult to defer.
- **Urge incontinence** – involuntary urinary leakage, often a large volume, immediately preceded by the sensation of urgency.
- **Stress incontinence** – involuntary urinary leakage that occurs when the intra-abdominal pressure rises during coughing, laughing, sneezing or exercising.
- **Nocturnal enuresis** – involuntary loss of urine during sleep.
- **Hesitancy** – when an individual has difficulty initiating micturition, resulting in a delay in the onset of voiding.
- **Reduced urinary stream** – usually reported compared with previous performance or in comparison with the performance of others.
- **Intermittency** – when urine flow stops and starts, on one or more occasions.
- **Straining** – the muscular effort used in order to initiate, maintain or improve the urinary stream.
- **Incomplete emptying** – the sensation that, at the end of micturition, bladder fullness persists.
- **Postmicturition dribble** – when involuntary loss of urine occurs immediately after the individual has finished passing urine.

Summary box 81.2

Lower urinary tract symptoms (LUTS)

- LUTS are classified as storage, voiding or post micturition
- Storage LUTS are typical of an overactive bladder
- Voiding LUTS are typical of BOO
- Some patients have storage and voiding LUTS in combination
- LUTS are sometimes investigated with urodynamics

HAEMATURIA

Haematuria occurs when there is blood in the urine. This is now classified as visible haematuria (VH) or non-visible haematuria (NVH). Enquiry should be made about the timing of the blood in relation to the urinary stream – initial (urethral pathology), throughout the stream (bladder or upper tracts) or terminal (bladder neck or prostatic pathology) – as well as the degree of haematuria and its frequency. A patient with haematuria should be investigated regardless of whether they are taking anticoagulant therapy. The concern is that the haematuria, especially if painless, may be due to an underlying neoplasm, usually a bladder or renal tumour. Causes of haematuria include trauma (**T**), infection (**I**) and neoplasm (**N**) anywhere in the urinary tract. Haematuria in association with loin pain and a palpable loin mass defines the classic triad of symptoms and signs of a renal tumour, although this triad is seen in less than 10% of these patients. In countries with endemic tuberculosis (TB) or filarial disease, haematuria is also seen in patients with these genitourinary infections. In genitourinary TB, haematuria is usually associated with dysuria and frequency due to bladder infection. In patients with filarial involvement of the retroperitoneal lymphatics, haematuria is intermittent, often lasting months or years, and is associated with 'milky' or cloudy urine, a condition called chyluria.

Haematuria requires detailed investigation in almost all cases except young women with a proven UTI. Investigations include an ultrasound scan (USS) of the kidneys–ureters–bladder (KUB) and additional contrast imaging if needed. If no aetiology can be identified on laboratory and imaging studies, cystoscopy is mandatory. Although BPH can cause haematuria in older men, this diagnosis should be considered after exclusion of all other causes. The cancer detection rate depends on the degree of haematuria, being approximately 20% in those patients with VH but very much lower in those with NVH (<5%).

Summary box 81.3

Haematuria

- Classified as VH or NVH
- A list of potential causes for haematuria can be rapidly generated by considering trauma (T), infection (I) and neoplasm (N) anywhere in the urinary tract
- Haematuria requires detailed investigation in nearly all cases

Discoloration of the urine

Many drugs and foodstuffs have been reported to produce abnormal discoloration of the urine. Most colours have been reported but the most frequently encountered clinically are red/orange and brown. Apart from haematuria, the presence of haem in the urine also produces red discoloration and generates a positive dipstick test. Red urine discoloration due to haemoglobinuria may present in haemolytic disorders such as 'march haematuria', classically seen in dehydrated soldiers after prolonged marching. Likewise, myoglobinuria due to myocyte destruction, e.g. caused by rhabdomyolysis after crush injury or compartment syndrome, can also result in red discoloration of the urine. Disordered haem production, seen in porphyria, can result in red discoloration that may change to brown or purple with exposure to sunlight. Several medications can cause red/orange discoloration of the urine, most commonly rifampicin, isoniazid or phenazopyridine. Others include chlorpromazine, thioridazine, senna and laxatives containing a phenolphthalein component. Consumption of large quantities of beetroot can result in red discoloration of the urine. This discoloration is due to the excretion of betalain (betacyanin) pigments such as betanin. The commonly used antibiotics nitrofurantoin and metronidazole can lead to brown urine. Brown urine due to high levels of circulating bilirubin is a feature of obstructive jaundice.

Uraemia

Rarely, the initial symptoms of urological disease may be those of severe renal dysfunction or uraemia. In infants and children, this may manifest as failure to thrive as well as anorexia, vomiting and altered sensorium due to encephalopathy.

LESS COMMON URINARY SYMPTOMS

Haematospermia

This refers to blood, which can be bright red or a brown colour, in semen. It is most commonly due to benign inflammatory change in the prostate or TB. A digital rectal examination (DRE) should be performed alongside a prostate-specific antigen (PSA) test. A transrectal ultrasound (TRUS) or magnetic resonance imaging (MRI) of the prostate should be considered. In most cases, haematospermia is self-limiting.

Pneumaturia

This is gas in the urine. Patients typically describe frothy urine, bubbles in the urine or a stream that intermittently stops and starts. The commonest cause is an underlying colovesical fistula, usually due to primary pathology in the rectum or sigmoid colon.

'White urine'

White urine is a complaint seen in two distinct conditions. One is in young men who may report the presence of a white substance in urine. This substance is usually semen and requires no treatment other than reassurance. The second condition is chyluria where lymphatic fluid, from channels obstructed by filarial inflammation, leaks into the renal pelvicalyceal system. This condition requires investigation for confirmation of the diagnosis.

SYMPTOMS RELATED TO THE EXTERNAL GENITALIA

Testis

A testis may be absent from the scrotum in patients with undescended or ectopic testes.

In boys <5 years, a common cause of testicular pain and swelling is torsion of a hydatid of Morgagni (appendix testis). In a young male suspected of having a testicular torsion, examination of the normal, i.e. contralateral, testis may reveal a horizontal lie or 'clapper bell testis', raising the level of clinical suspicion. If torsion is suspected, immediate testicular exploration is mandatory and, if confirmed, bilateral testicular fixation is performed. A Doppler USS may aid in the diagnosis.

Patients with Klinefelter's syndrome have bilateral small, firm testes in addition to the other signs typical of this condition.

A hydrocele is an accumulation of fluid between the testis and the tunica vaginalis; in the younger male it can be associated with a patent processus vaginalis. The hydrocele fluid is typically a yellow colour. A testis that cannot be felt in a tense hydrocele, in the age groups at risk of testicular cancer, needs to be assessed by USS.

Epididymis

Epididymal pathology is rare in prepubertal males. In sexually active males, acute epididymitis (often due to *Chlamydia*) with significant pain and swelling needs to be distinguished from acute testicular torsion. A Doppler USS may help differentiate between the two conditions: in epididymitis it shows an increased blood flow into the inflamed epididymis, whereas in torsion it shows decreased or complete lack of blood flow to the testis. If there is any doubt, scrotal exploration is undertaken.

Epididymal cysts can form similar scrotal swellings to hydroceles but can be distinguished by the fact that the testis can often be felt separately. They contain clear or white fluid. Both hydroceles and epididymal cysts transilluminate on clinical examination.

Genitourinary TB can result in bilateral nodular induration of the epididymis and nodularity of the vas deferens. It may also result in scrotal abscesses that, unlike pyogenic abscesses,

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, University of Padua, Italy.
Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.
Harry Fitch Klinefelter, 1912–1990, American rheumatologist and endocrinologist, first described Klinefelter's syndrome in 1942.

are chronic, painless and not warm to touch ('cold abscess') (*Figure 81.1*).

Figure 81.1 Cold abscess of the left scrotum. (Reproduced with permission from Kumar R. Reproductive tract tuberculosis and male infertility. *Indian J Urol* 2008; **24**: 392–5.)

Spermatic cord

Ten per cent of males have a left-sided varicocele and a smaller left testis. Masses are occasionally found associated with the spermatic cord, which on removal are found to be lipomas, mesotheliomas or sarcomas.

Prepuce (foreskin)

Phimosis occurs when the distal foreskin is tight and will not retract. Paraphimosis occurs when a poorly retractile foreskin becomes trapped in the retracted state and cannot be replaced. Significant oedema of the foreskin results, making replacement of the foreskin increasingly difficult. Depigmentation and scarring of the distal prepuce occurs in balanitis xerotica obliterans (BXO).

Penis

Peyronie's disease is an idiopathic condition in which fibrosis develops in the corpora cavernosa of the penis. The 'plaque' of Peyronie's fibrosis is usually palpable in the midline anywhere from the base of the penis to just behind the corona. It gives rise to painful angulation of the penis on erection.

Penile fracture occurs when there is trauma to the erect penis. Classically, there is an audible crack during sexual intercourse or forceful masturbation that is followed by immediate penile detumescence. The patient presents with gross bruising of the penile shaft skin.

Glans penis

In the younger male, genitourinary warts due to human papillomavirus (HPV) infection may be observed. In the older male, red raised patches on the glans penis or the inner aspect of the prepuce due to Zoon's balanitis or CIS (also known as erythroplasia of Queyrat or Bowen's disease) are distinguished only on penile biopsy.

Urethra

Hypospadias occurs when there is failure of the urethra to completely close on the ventral aspect and epispadias occurs when there is failure of closure on the dorsal surface. A urethral diverticulum in a female can be a cause for recurrent UTIs and is notable for its capacity to fill and empty at cystoscopy. A urethral caruncle is a minor prolapse of the urethral mucosa in a female and usually requires no treatment.

INVESTIGATION OF URINARY SYMPTOMS

Blood tests

Blood counts and chemistry

Initial blood tests in suspected urological pathologies include a full blood count, urea, creatinine and electrolytes. Creatinine, a surrogate marker for renal function (glomerular filtration), is an end product of muscle catabolism and may be unchanged despite a wide variation in estimated glomerular filtration rate (eGFR). eGFR is recommended as the optimal method of reporting renal function in many countries.

Patients with calculous disease routinely have serum calcium, uric acid and parathyroid hormone levels checked to rule out a metabolic predisposition to stone formation.

Serum alkaline phosphatase may be elevated in patients with bone metastases due to a urological malignancy and is commonly seen in men with disseminated prostate cancer.

Summary box 81.4

Biochemical assessment of renal function

- eGFR is increasingly reported along with urea and creatinine as it is more informative of true renal function
- With both kidneys functioning normally, an individual has approximately six times the renal function needed to remain off dialysis
- Serum creatinine will remain normal with unilateral renal pathology but a normally functioning contralateral kidney

François Gigot de la Peyronie, 1678–1747, French surgeon.
Johannes Jacobus Zoon, 1902–1958, Professor of Dermatology, University of Utrecht, The Netherlands, described Zoon's balanitis in 1952.
Louis Auguste Queyrat, 1856–1933, French dermatologist, described erythroplasia of Queyrat in 1911.
John Templeton Bowen, 1857–1940, American dermatologist, described Bowen's disease.

Tumour markers

Serum tumour markers are utilised in patients with prostate and testicular cancer. Currently no serum tumour markers exist in routine clinical practice for renal or bladder cancer.

Prostate-specific antigen

PSA is a glycoprotein produced by prostatic epithelial cells. Altered architecture of the prostate in conditions such as BPH, prostatitis and prostate cancer allows PSA to enter the bloodstream and be detected by a blood test. The commonly used PSA assays measure the total amount of PSA (tPSA). PSA levels can be influenced by certain drugs, most notably 5α-reductase inhibitors used to treat men with LUTS, but also by aspirin, statins and thiazide diuretics. The PSA test can be significantly influenced by a recent UTI and the true PSA level only returns to baseline 6 weeks after eradication of an infection.

Summary box 81.5

Prostate-specific antigen

- Is not significantly altered by DRE
- Can be significantly altered by a UTI
- After an infective episode, takes 6 weeks to return to baseline values
- Is artificially lowered, up to two times, in men taking 5α-reductase inhibitors (finasteride, dutasteride)

PSA values in a population of men form a continuum with no clear abnormal threshold. The value of PSA that triggers a biopsy is variable and is influenced by age, ethnicity, family history and findings on DRE.

The benefits of screening asymptomatic men for prostate cancer using PSA testing are controversial and a large UK-based clinical study (ProtecT trial) found that at a median of 10 years very few patients died of prostate cancer irrespective of treatment or surveillance. At present, PSA-based screening for prostate cancer is not routinely performed in the UK but men interested in having a PSA test can request this from their family practitioners. A similar practice is followed in many countries.

Risk prediction models have been developed in recent years to assist clinicians and patients in predicting prostate cancer diagnosis, stage and prognosis. A number of these risk assessment tools are available online as a decision aid for an individual man to evaluate his own risk of prostate cancer. These include the Prostate Cancer Prevention Trial (PCPT) Risk Calculator and the European Randomized Study of Screening for Prostate Cancer (ERSPC) Risk Calculator.

For men newly diagnosed with prostate cancer, PSA assists with risk (of disease progression) stratification. It is also a useful marker of response to treatment and of disease recurrence after treatment.

Prostate-specific antigen derivatives and kinetics

Since PSA may be elevated in non-malignant conditions, PSA derivatives/kinetics have been used to improve the specificity of testing. Some of the derivatives include free PSA (fPSA), complexed PSA (cPSA) and free/total PSA ratio (f/tPSA). Since BPH tissue within the prostate also contributes to tPSA, PSA density (PSAD) factors in the volume of the prostate by dividing tPSA by prostate volume. A high PSAD increases the likelihood that the elevated PSA is due to malignancy and not due to the large gland alone. PSA kinetics involve measurement of the rate of change of various forms of PSA based on the premise that a rapid increase or change may be more predictive of cancer. PSA velocity is the annual absolute increase in tPSA and a value >0.75 ng/mL per year compared with baseline has been considered suspicious. PSA doubling time is the number of months it takes for a baseline PSA to double.

Testis tumour markers

Serum tumour markers routinely used in the management of men with suspected testicular cancer are alpha-fetoprotein (αFP), beta-human chorionic gonadotropin (βHCG) and lactate dehydrogenase (LDH). These markers sometimes provide insight into the likely diagnosis, histological subtype of germ cell tumour present, success of treatment and recurrence. They also contribute to the stratification of patients with testicular cancer into prognostic categories using a classification devised by the International Germ Cell Cancer Collaborative Group.

Urine-based tests

Urinalysis

In a urine dipstick test, used to screen for significant disease, urine is dipped with a stick on which there is a series of small chemical-containing pads designed to detect, typically, glucose, bilirubin, ketones, the specific gravity, blood, pH, protein, urobilinogen, nitrites and leukocyte esterase through colour changes. A similar test may be performed using reagents in a laboratory.

Midstream specimen of urine or urine culture

A midstream specimen of urine (MSU) or urine culture is used to establish the diagnosis of a UTI and allows identification of the urinary pathogen and selection of the most appropriate antibiotic. Most MSUs will be processed in two stages, with initial urine microscopy followed by urine culture only if appropriate. Normal urine contains small numbers of white blood cells, red blood cells and epithelial cells as indicated in *Table 81.1*.

Early-morning urine

Early-morning urine (EMU) samples are sent on three consecutive days for Ziehl–Neelsen staining and culture for acid-fast bacilli if genitourinary TB is suspected. Staining results are

Franz Ziehl, 1859–1926, German bacteriologist and a professor in Lübeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1898, German pathologist and professor at the Institute of Pathology, University of Rostock, Germany.

TABLE 81.1 Cells in normal urine.

White blood cells	3–5 per high-power field
Epithelial cells	<10–15 per high-power field
Red blood cells	0–2 per high-power field

available within a day but culture results take 6 weeks. Nucleic acid amplification tests based on polymerase chain reaction (PCR), such as GeneXpert® and TruNAAT®, are frequently used for rapid detection of a small amount of bacterial DNA. An early-morning sample is preferred since it is expected that overnight shedding of bacilli will increase detection rates.

Voided urine cytology

Voided urine cytology is performed when a urothelial carcinoma is suspected. The test has the disadvantage of a high false-negative rate. Approximately 15% of low-grade transitional cell carcinomas produce positive voided urine cytology compared with approximately 50% of high-grade transitional cell tumours.

Urine for chyle

Testing urine for chyle is performed in specific situations where the suspicion for chyluria is high. This is restricted to certain endemic regions of the world. A high-fat diet is administered the night prior to collection of a morning sample of urine. The urine may visibly appear milky white (***Figures 81.2 and 81.3***).

Endoscopy

Cystoscopy

To further evaluate urinary symptoms, the entire lining of the urinary tract can be directly visualised from the urethra and bladder (using a cystoscope) to the ureter and renal pelvis (using a semirigid ureteroscope), and finally the renal calyces (using a flexible ureteroscope). Cystoscopy can be undertaken either as flexible cystoscopy (***Figure 81.4***), using local anaesthesia, or as rigid cystoscopy (***Figure 81.5***), preferably under a general anaesthetic. Telescopes with different fields of view are available (0°, 12°, 30° and 70° lenses are commonly used). In the operating theatre, most endoscopic procedures, including cystoscopy, require a urology stack consisting of a camera, monitor, light source, electrocautery and insufflator for laparoscopy procedures (***Figure 81.6***).

The male urethra is longer than the female urethra and is angulated at the level of the symphysis pubis (***Figures 81.7–81.12***). Flexible cystoscopy is thus relatively poorly tolerated in young males, in whom it may be uncomfortable. It is principally a diagnostic tool but a few minor procedures can be

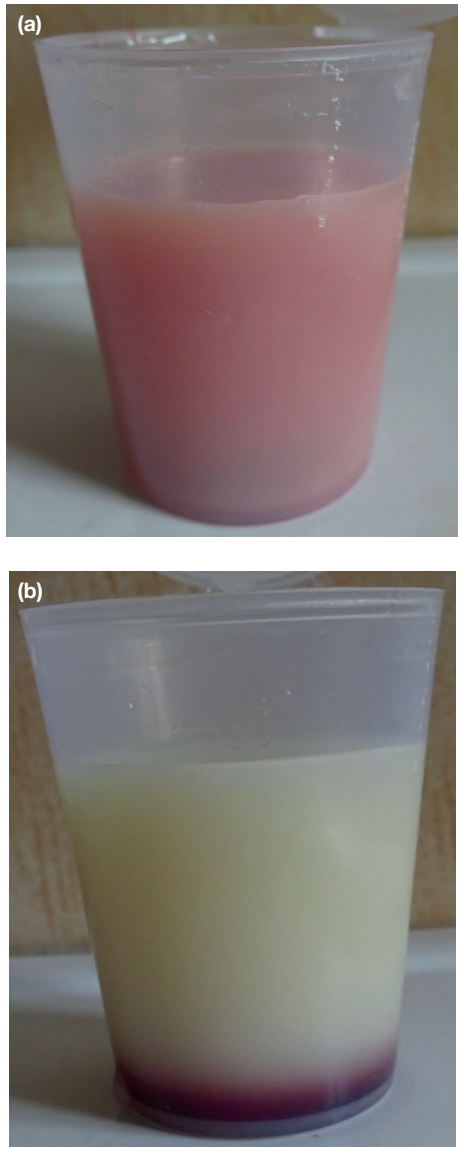

Figure 81.3 Haematochyluria with milky-red urine **(a)**; the blood settles after some time, leaving chyluria above **(b)** (courtesy of Dr TC Goel).

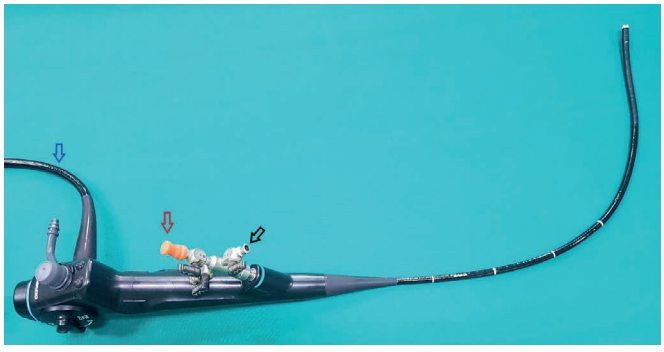

Figure 81.4 Flexible cystoscope with attachments for irrigating fluid (black arrow), instruments (red arrow), and connection to video equipment (blue arrow).

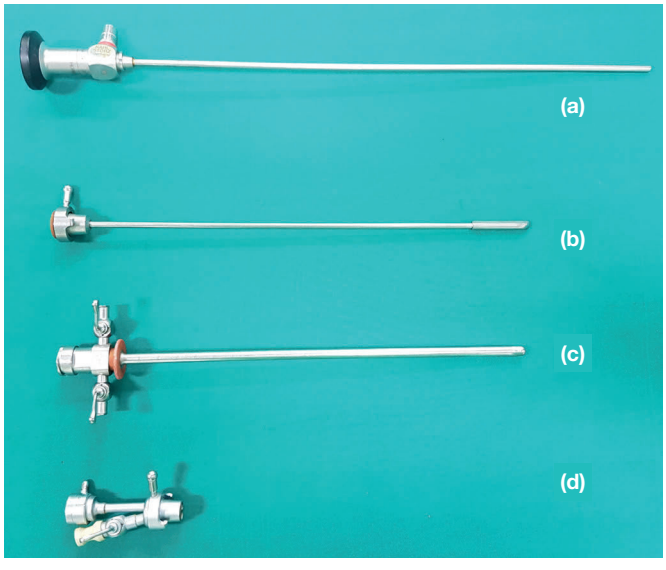

Figure 81.5 Parts of a rigid cystoscope. Telescope **(a)**, obturator **(b)**, sheath **(c)** and bridge **(d)**. The obturator is inserted into the outer sheath for blind insertion of the cystoscope sheath – usually in females. The light cable and camera are attached to the telescope, which replaces the obturator in blind insertions. In males, the bridge is attached to the sheath to provide additional length and the telescope is placed through the bridge for insertion of the cystoscope under vision.

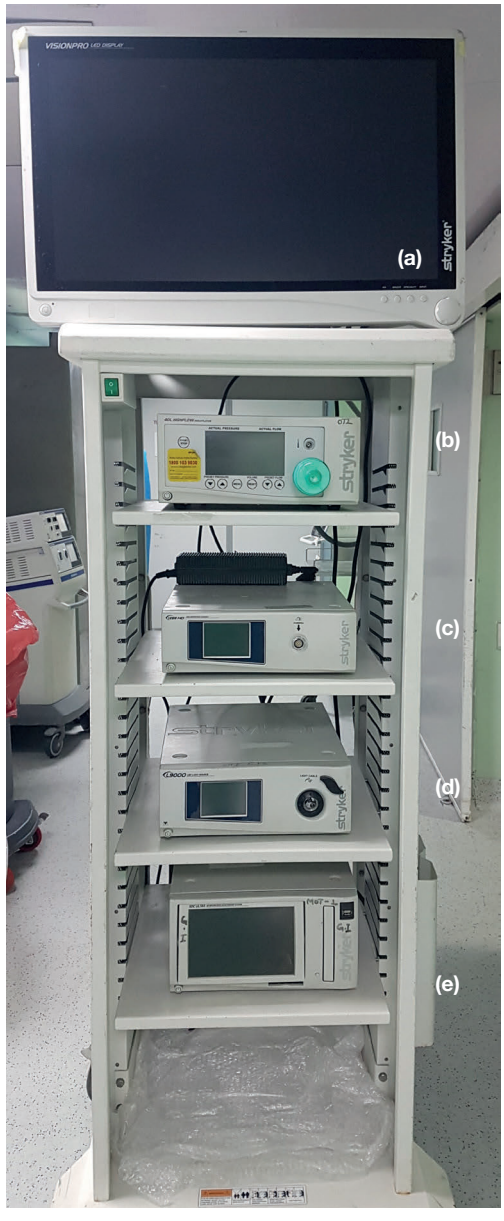

Figure 81.6 The urology stack. In this stack, from top down, are the monitor **(a)**, insufflator for carbon dioxide for laparoscopy **(b)**, camera connector **(c)**, light source **(d)** and a video recording device **(e)**.

accomplished using the flexible cystoscope, such as insertion/removal of ureteric stents, small biopsies and diathermy/laser of small bladder lesions. More can be achieved with a rigid cystoscope under general anaesthesia, especially in relation to instrumentation of the ureters.

Summary box 81.6

Cystoscopy

- Can be performed with either a rigid cystoscope under general anaesthesia or a flexible cystoscope under local anaesthesia
- Flexible cystoscopy is principally a diagnostic procedure
- Rigid cystoscopy allows more procedures to be performed

Ureteroscopy

Ureteroscopy can be performed as both a diagnostic and a therapeutic procedure. A rigid or semirigid ureteroscope can be used in the ureter as far as the renal pelvis, but to inspect or operate on the renal pelvis or renal calyces a flexible ureteroscope is, generally, needed (***Figure 81.13***). The procedure is most often performed when pathology, commonly stones, strictures or tumours, of the ureter is suspected.

Radiology

Urinary tract ultrasound scan

USS (***Figure 81.14***) can characterise pathologies of the kidney, bladder, prostate and testis very well but is not very good for

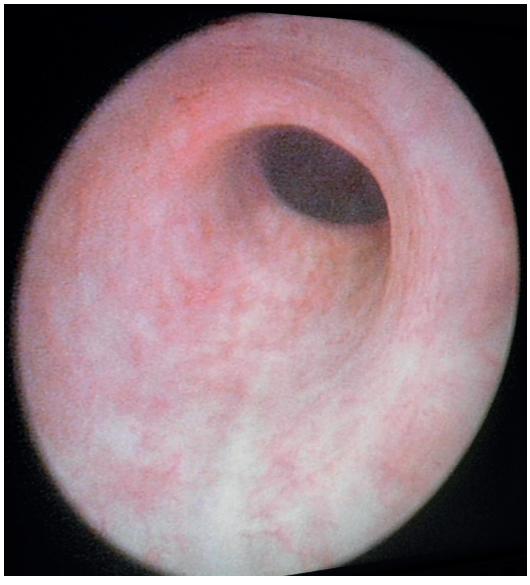

Figure 81.7 A normal urethra on urethroscopy.

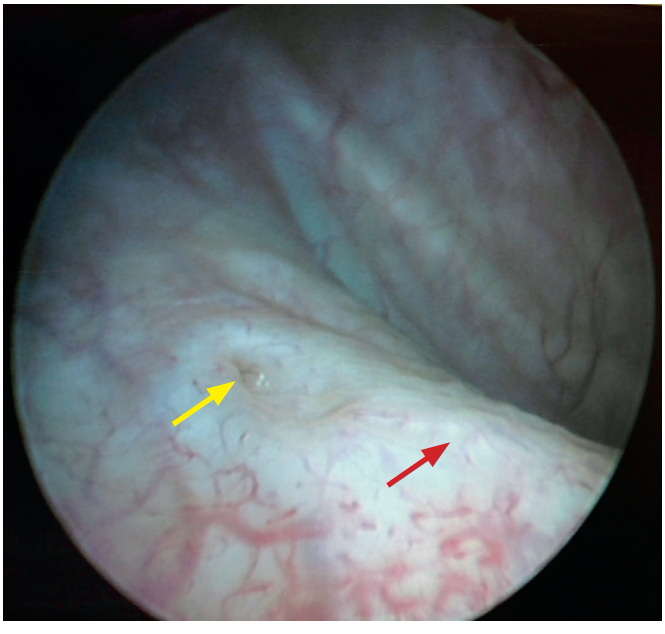

Figure 81.8 The appearance of normal bladder mucosa on cystoscopy: a normal right ureteric orifice (yellow arrow) at the end of the interureteric bar (red arrow).

assessing the ureters unless they are significantly dilated or have sizeable pathology. The lack of radiation and contrast exposure coupled with portability and availability make USS the first imaging investigation in urological diseases. It is extremely useful in the detection of hydronephrosis (even at the bedside in an emergency), renal cysts, tumours, scarring and stones. Stones classically produce an acoustic shadow, but USS is not the most sensitive imaging modality for detecting renal stones. USS is extensively used for the insertion of a percutaneous nephrostomy (PCN) to drain an obstructed renal collecting system. It is sometimes used to further characterise renal lesions detected by other modalities such as computed

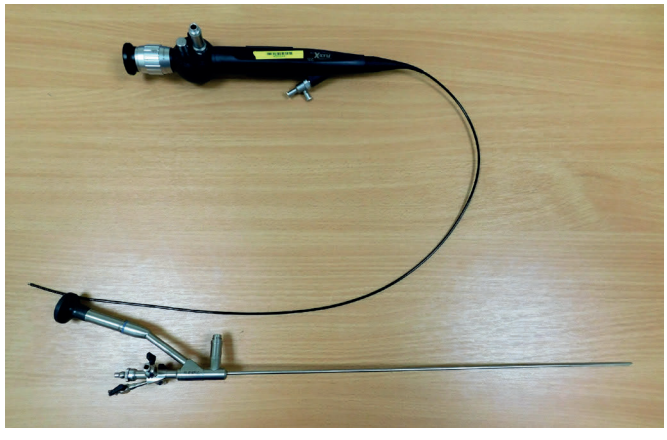

Figure 81.13 A flexible ureteroscope (top) and a semirigid ureteroscope (bottom).

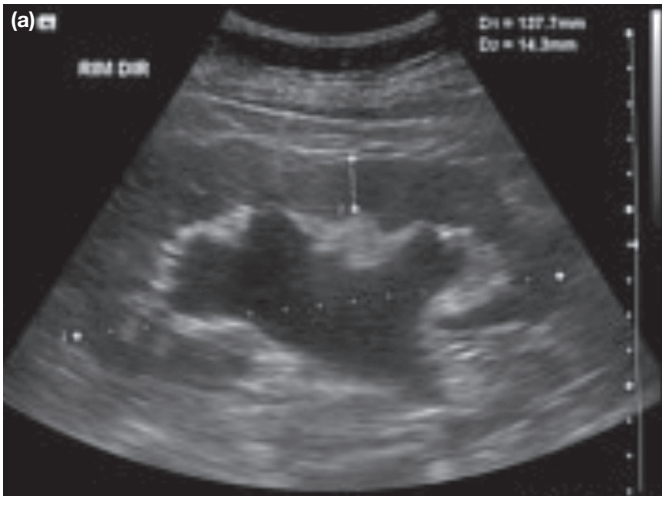
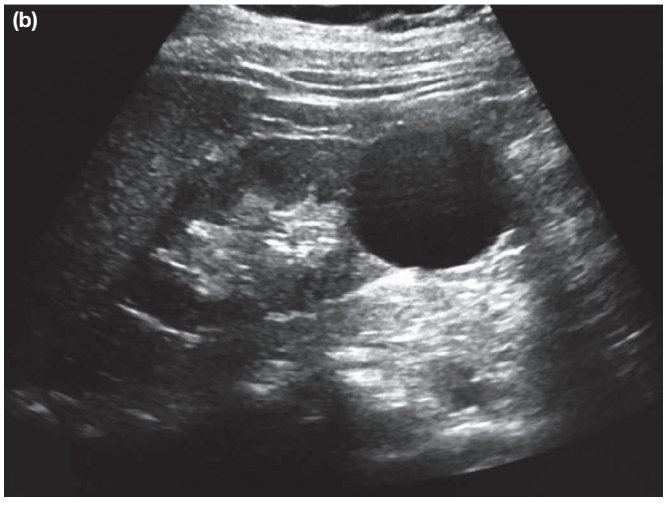
tomography (CT) or MRI, particularly for haemorrhagic cysts versus solid lesions. USS can detect bladder tumours, calculi, a thickened, trabeculated bladder wall in patients with BOO and large bladder diverticula. It can also be used to determine the residual urine after micturition.

In addition, USS is frequently employed to investigate men with scrotal swellings and has a role to play in the assessment of urethral stricture disease.

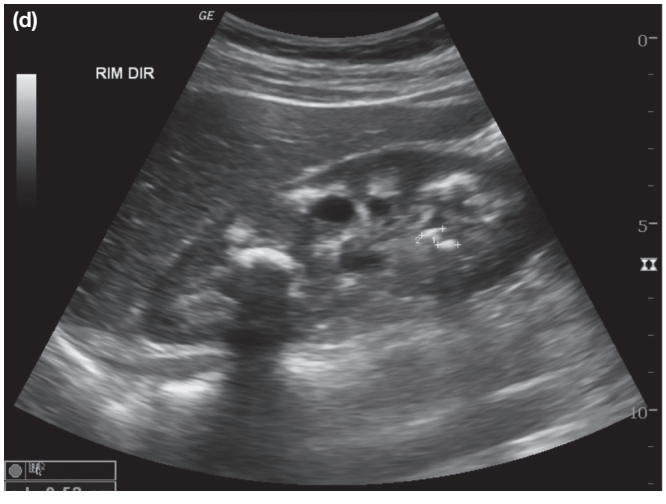


Transrectal ultrasound scan



TRUS is often performed in conjunction with biopsy of the prostate. It requires the use of a special probe (***Figure 81.15***) that provides transverse as well as sagittal views of the prostate (***Figure 81.16***). TRUS is most often used to guide a prostate biopsy in men suspected to have prostate cancer. The classic abnormality associated with prostate cancer is a hypoechoic area in the peripheral zone but this is rarely found in the absence of a palpable abnormality on DRE. Typically, 12 or more systematic biopsies are taken using a biopsy device such as that shown in ***Figure 81.17***. Additional biopsies may be taken from areas that are suspected to be malignant.

Summary box 81.7



Ultrasound scan

- Frequently used to screen patients with suspected urological pathology
- Frequently part of a haematuria clinic protocol
- An excellent method to detect hydronephrosis
- Can be performed at the bedside in critically ill patients
- Recently has been combined with contrast enhancement in certain settings, such as in the assessment of renal cysts

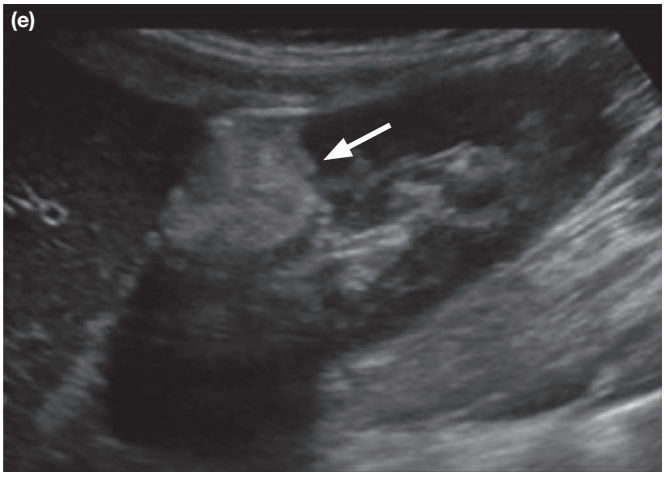


Figure 81.14 Ultrasound scan showing: **(a)** hydronephrosis (courtesy of Dr Bruno Di Muzio, Radiopaedia.org, rID: 21885); **(b)** renal cyst (courtesy of Dr Ian Bickle, Radiopaedia.org, rID: 21139); **(c)** renal tumour (courtesy of Wendy Boller); **(d)** medullary sponge kidney with renal calculi – note the stone gives rise to an acoustic window (courtesy of Dr Bruno Di Muzio, Radiopaedia.org, rID: 12141); **(e)** angiomyolipoma (arrow).

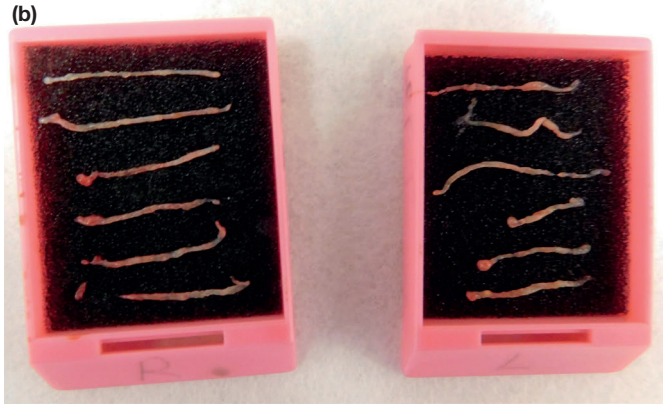

Figure 81.17 (a) A biopsy device used for prostatic biopsy. **(b)** Biopsy cores taken from the right and left prostatic lobes during transrectal ultrasound scanning.

Transperineal template biopsies of the prostate

Transperineal template biopsies of the prostate (TPTBP) are increasingly used clinically and may replace TRUS-guided prostate biopsies as a first-line test. Currently, TPTBP are used to further evaluate men with a negative TRUS-guided prostate biopsy in whom the PSA trend remains suspicious, or younger men for whom a diagnosis of low-risk prostate cancer has been made and in whom it is important to exclude more significant disease in other parts of the prostate (most notably in the anterior aspects of the gland) not easily accessible via the transrectal route. TPTBP are usually performed under local anaesthetic and have a much lower risk of sepsis than TRUS-guided biopsies.

Summary box 81.8

Prostate biopsies

- TRUS has been the traditional method of guiding prostate biopsies
- TPTBP are becoming increasingly popular
- TPTBP have a much lower sepsis risk than TRUS biopsies

Kidneys-ureters-bladder radiograph

A plain radiograph of the abdomen and pelvis that includes the regions of the body occupied by the KUB is frequently called an x-ray KUB (***Figure 81.18***). In the normal setting, soft-tissue outlines of the kidneys are commonly seen but normal ureters and bladder will not be seen. The commonest indication for a KUB radiograph is to screen patients for the presence of urinary tract calculi. Patients who have had a CT scan resulting in the diagnosis of a urinary tract calculus often have a supplementary KUB radiograph to determine if a plain radiograph can be used in the subsequent follow-up of the patient. Phleboliths (thrombosed, calcified veins in the pelvis) can easily be mistaken for distal ureteric stones. Finally, a KUB radiograph is often used to check for correct positioning of a ureteric stent.

Intravenous urography

Intravenous urography (IVU) continues to be frequently used in the evaluation and management of patients with urinary

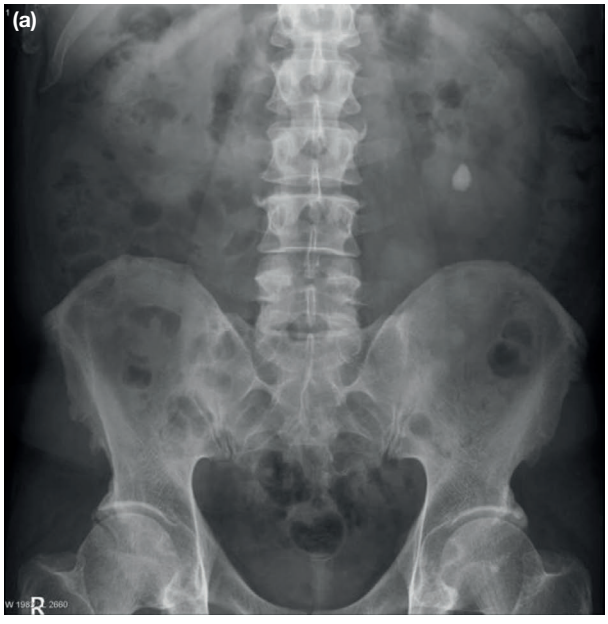

Figure 81.18 (a) Left lower pole renal stone on a plain kidneys–ureters–bladder radiograph (courtesy of Professor Frank Gaillard, Radiopaedia.org, rID: 12555). **(b)** A staghorn calculus in the left kidney (courtesy of Dr Natalie Yang, Radiopaedia.org, rID: 9733). **(c)** Right lower pole calculi and steinstrasse (multiple stone fragments from shock-wave lithotripsy to break the kidney stone), leading to the formation of a 'stone street or steinstrasse' in the distal right ureter (arrow) (courtesy of Dr Ali Abougazia, Radiopaedia.org).

stones and urinary TB in many parts of the world, even though it provides less information than a CT scan. This is primarily due to its wider availability, lower cost and lower radiation exposure (***Figure 81.19***).

Retrograde urethrogram and voiding cystourethrogram

During a retrograde urethrogram (RGU), radiocontrast material is gently instilled into the urethra to delineate its anatomy. The investigation is primarily used to identify urethral strictures in men. Radiocontrast material is instilled into the bladder, through either a urethral catheter or a suprapubic tube for a voiding cystourethrogram (VCUG). VCUGs are used to identify reflux into the ureter, usually in children, and for delineation of the proximal urethra in men with complete urethral strictures. They may also help in assessing bladder capacity in TB (***Figure 81.20***).

Computed tomography scan

A non-contrast CT scan is the imaging modality of choice in the investigation of a patient with suspected urinary tract calculi (***Figure 81.21***). This investigation is quick, often taking less than 2 minutes to perform, picks up most calculi and can be tailored to deliver low radiation doses. Other variations of the CT scan include a contrast CT, which can be tailored to acquire images in multiple phases (triple phase for renal tumours) and a urographic phase for urothelial tumours.

A contrast CT scan of the chest, abdomen and pelvis is frequently used to stage patients with renal tumours (***Figure 81.22***), muscle-invasive bladder cancer and young men with testicular cancer. CT is less frequently used in men with prostate cancer but does have a role to play when lymph node disease is being assessed prior to treatment.

Cysts are a frequent incidental finding on USS and CT scans of the kidneys. In 1986, a classification of renal cysts based on CT criteria, known as the Bosniak classification, was devised. This classification can also be applied to MRI.

Morton A Bosniak, 1929–2016, Professor of Radiology, New York University (NYU) Langone School of Medicine, New York, NY, USA.

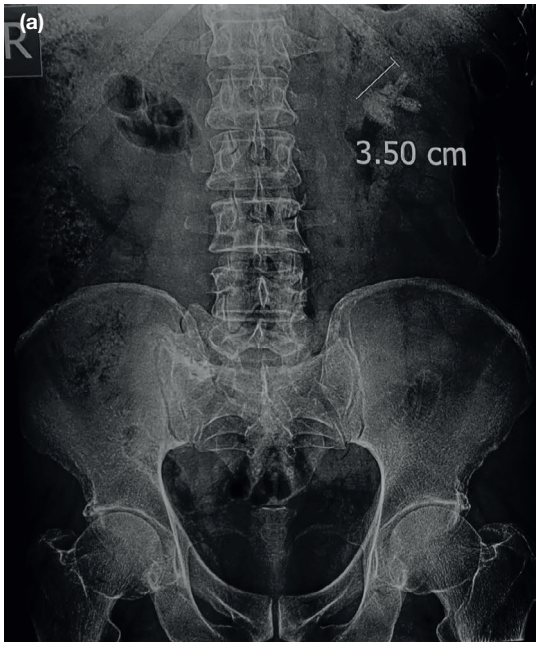

Figure 81.19 Intravenous urogram plain **(a)** and 5-minute **(b)** films, demonstrating a partial staghorn stone in the left kidney. The right kidney is normal. A 5-minute film shows contrast entering the pelvicalyceal system and helps in identifying the location of the stone.

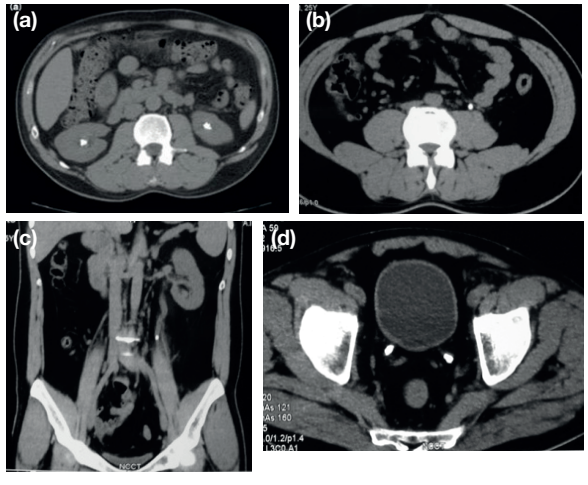

Figure 81.21 (a) A non-contrast computed tomography scan demonstrating bilateral renal calculi (courtesy of Dr Jeremy Jones, Radiopaedia.org, rID: 6211); **(b, c)** left ureteric calculus in the axial and coronal reconstructions (courtesy of Dr Raju Sharma and Dr Ankur Goyal); **(d)** bilateral lower ureteric calculi (courtesy of Dr Raju Sharma and Dr Ankur Goyal).

It is used to predict the likelihood of malignancy in the lesion. Based on this classification (***Figures 81.23 and 81.24***), the majority of cysts are category I and II and do not require treatment or follow-up imaging. Category IIF ('F' indicating the need for follow-up) cysts do require further imaging but the duration of this is uncertain. Category III cysts have a risk of malignancy of 30–100% and should undergo a biopsy to identify those patients requiring surgery. Category IV 'cysts' have an incidence of malignancy of 67–100% and surgical removal should be considered.

Magnetic resonance imaging

MRI scanning has a significant role to play, either on its own or as an adjunct to other cross-sectional imaging modalities, in the staging of a number of urological cancers, particularly prostate cancer. Modern MRI techniques utilise both anatomical and

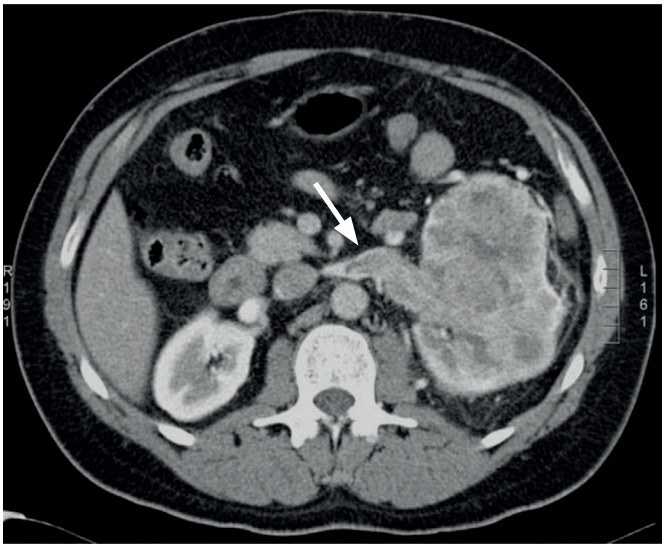

Figure 81.22 Computed tomography scan demonstrating a large left renal tumour with involvement of the left renal vein (arrow) (courtesy of Dr Laughlin Dawes, Radiopaedia.org, rID: 35937).

functional imaging and are known as multiparametric MRI (mpMRI). Anatomical imaging is based on standard MRI techniques (T1- and T2-weighted images) and functional imaging is based on diffusion-weighted imaging (DWI) (for water molecule motion assessment) and dynamic contrast-enhanced (DCE) imaging (for tissue perfusion assessment after intravenous contrast administration) (***Figure 81.25***). The multiple parameters assessed in the scan are combined in a five-point scoring system, called PI-RADS (Prostate Imaging – Reporting and Data System), to assign a likelihood (from 1, benign to 5, highly suspicious) that prostate cancer is present within the abnormality detected on mpMRI of the prostate. The lesions identified on mpMRI can be specifically targeted for biopsy using novel technologies. MRI images can be fused with real-time TRUS-USS images to guide the biopsies to these abnormal areas in a similar manner to TRUS biopsy. Such 'fusion' biopsies require specialised workstations. Similar scoring systems are being used to assess bladder cancer.

Summary box 81.9

Magnetic resonance imaging

- Used to stage many urological cancers
- mpMRI has a significant role in the assessment of men with suspected prostate cancer
- mpMRI is increasingly used prior to prostate biopsy. Prebiopsy MRI permits selection of biopsy technique (TRUS versus TPTBP)
- Prebiopsy MRI assists with targeting of biopsies

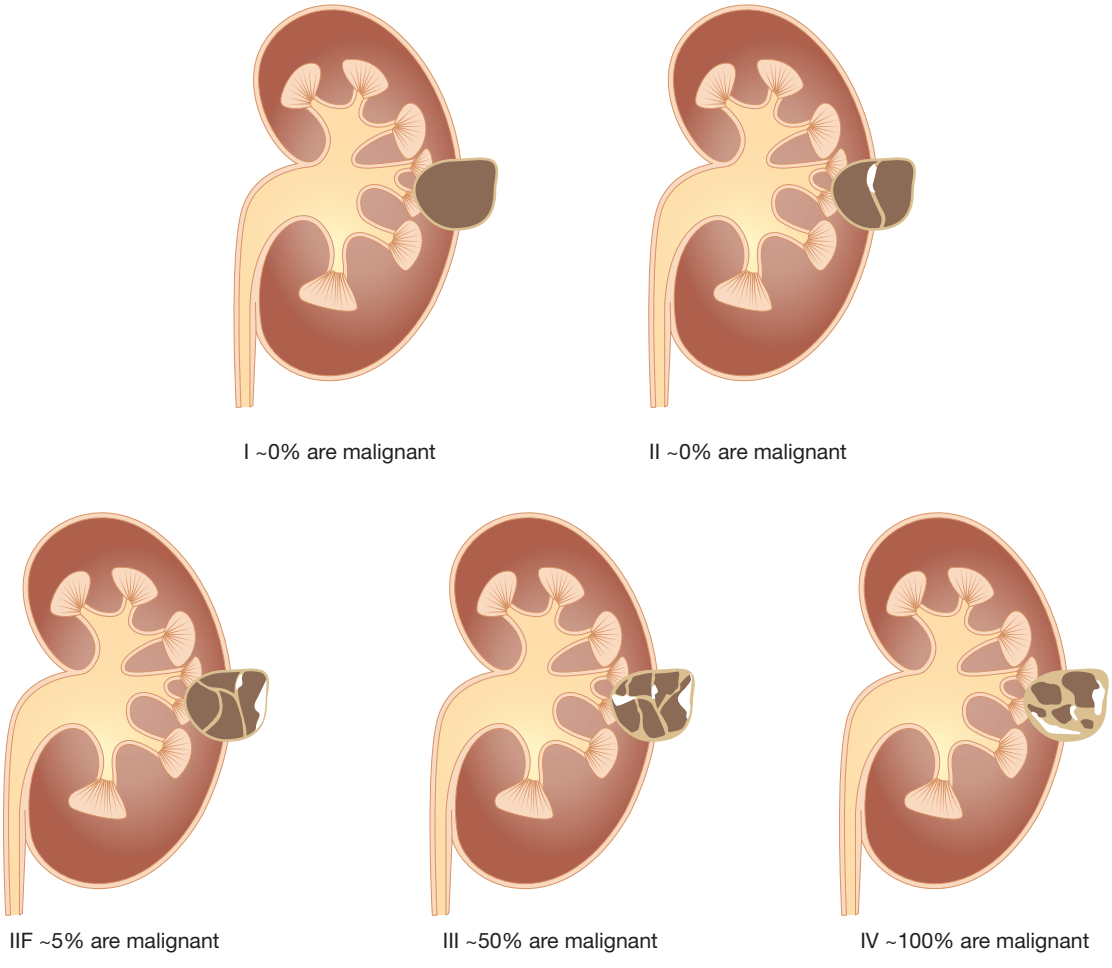

Figure 81.23 Bosniak classification of renal cysts. The classification depends on the characteristics of the cyst wall, septae, solid component and enhancement on contrast administration.

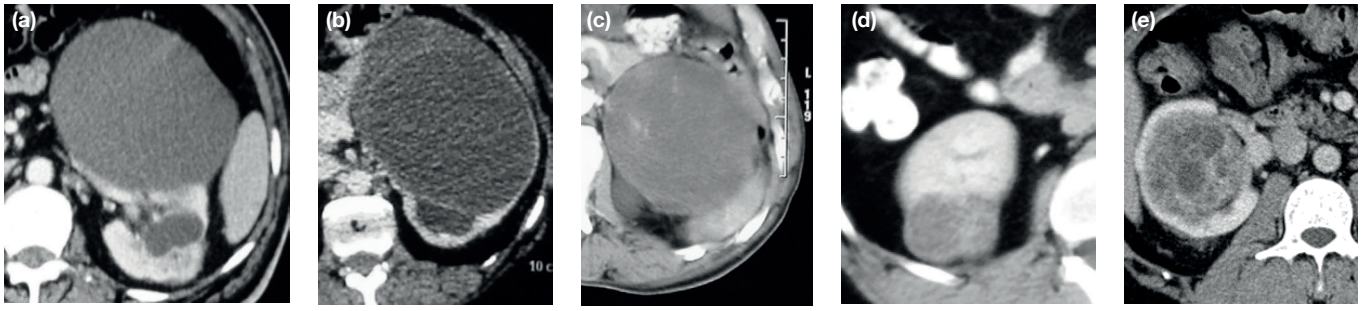

Figure 81.24 Computed tomography scans showing cysts of various categories: **(a)** Bosniak I cyst; **(b)** Bosniak II cyst; **(c)** Bosniak IIF cyst; **(d)** Bosniak III cyst; **(e)** Bosniak IV cyst (courtesy of Dr Raju Sharma and Dr Ankur Goyal).

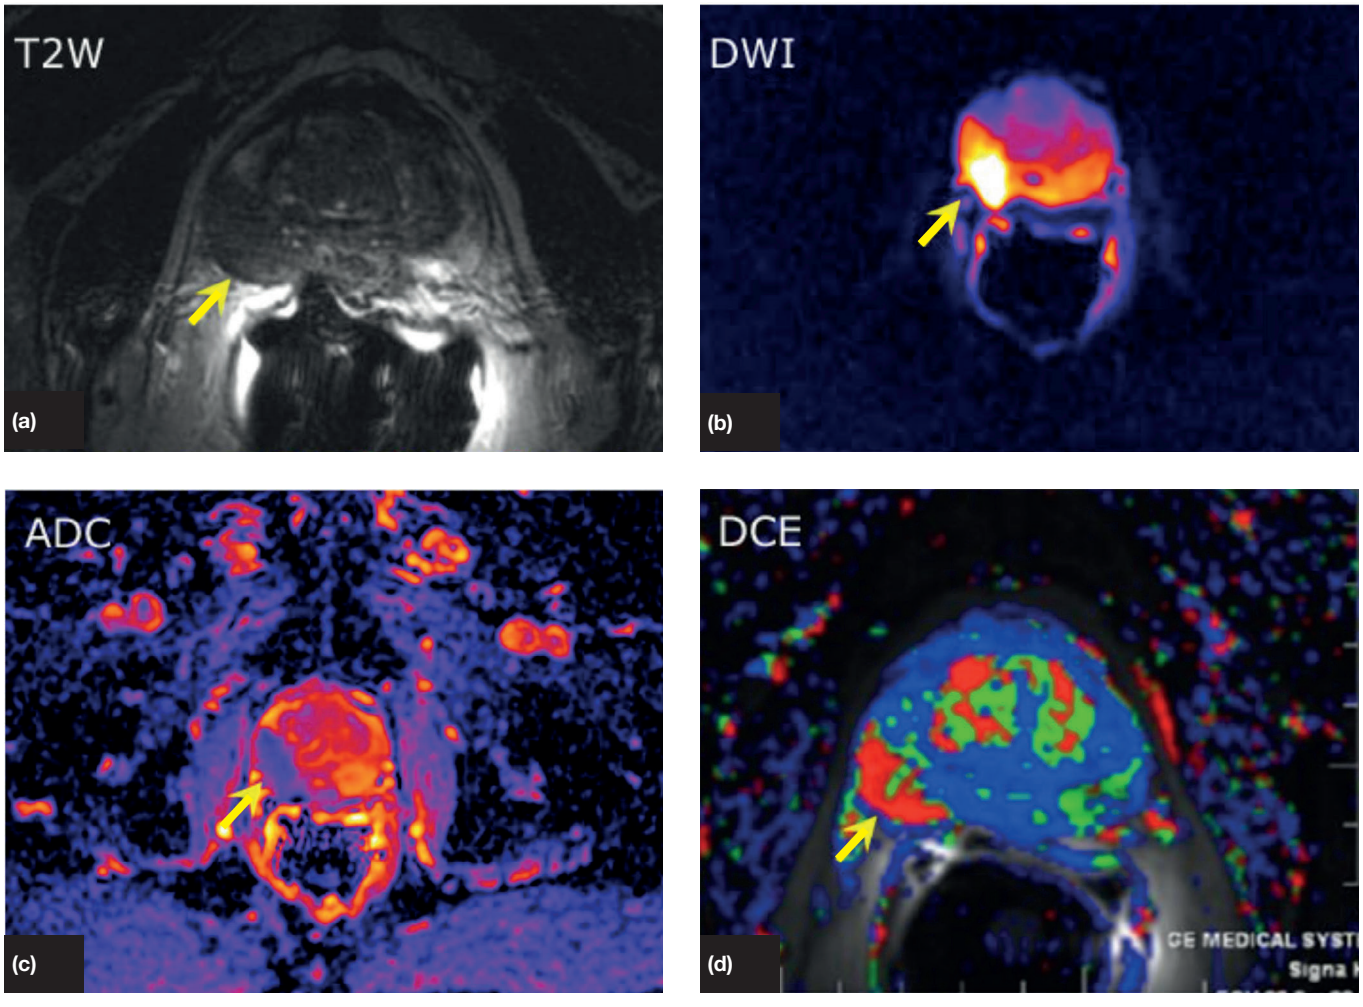

Figure 81.25 Multiparametric magnetic resonance images of a patient with prostate cancer. **(a)** T2 weighted. **(b)** Diffusion weighted (DWI). **(c)** Apparent diffusion coefficient (ADC). **(d)** Dynamic contrast enhanced (DCE). The tumour appears dark on the axial T2-weighted image (arrow); the corresponding area shows restricted diffusion on the DWI and ADC images as well as abnormal contrast enhancement on the DCE axial image (within the prostate, the red colour denotes abnormal areas that are possibly malignant) (courtesy of Janet Cochrane Miller, Radiology Rounds, Massachusetts General Hospital).

SPECT/CT and PET/CT

Single photon emission computed tomography (SPECT) and positron emission tomography (PET) are nuclear medicine imaging techniques that provide metabolic and functional information, unlike CT and MRI. They have both been combined with CT and MRI to provide detailed anatomical and metabolic information.

PET/CT looks promising as a tool for the detection of distant metastases in bladder cancer. To date, the technique has not been used extensively in patients with renal cancer. In men with testicular cancer, it is recommended in the

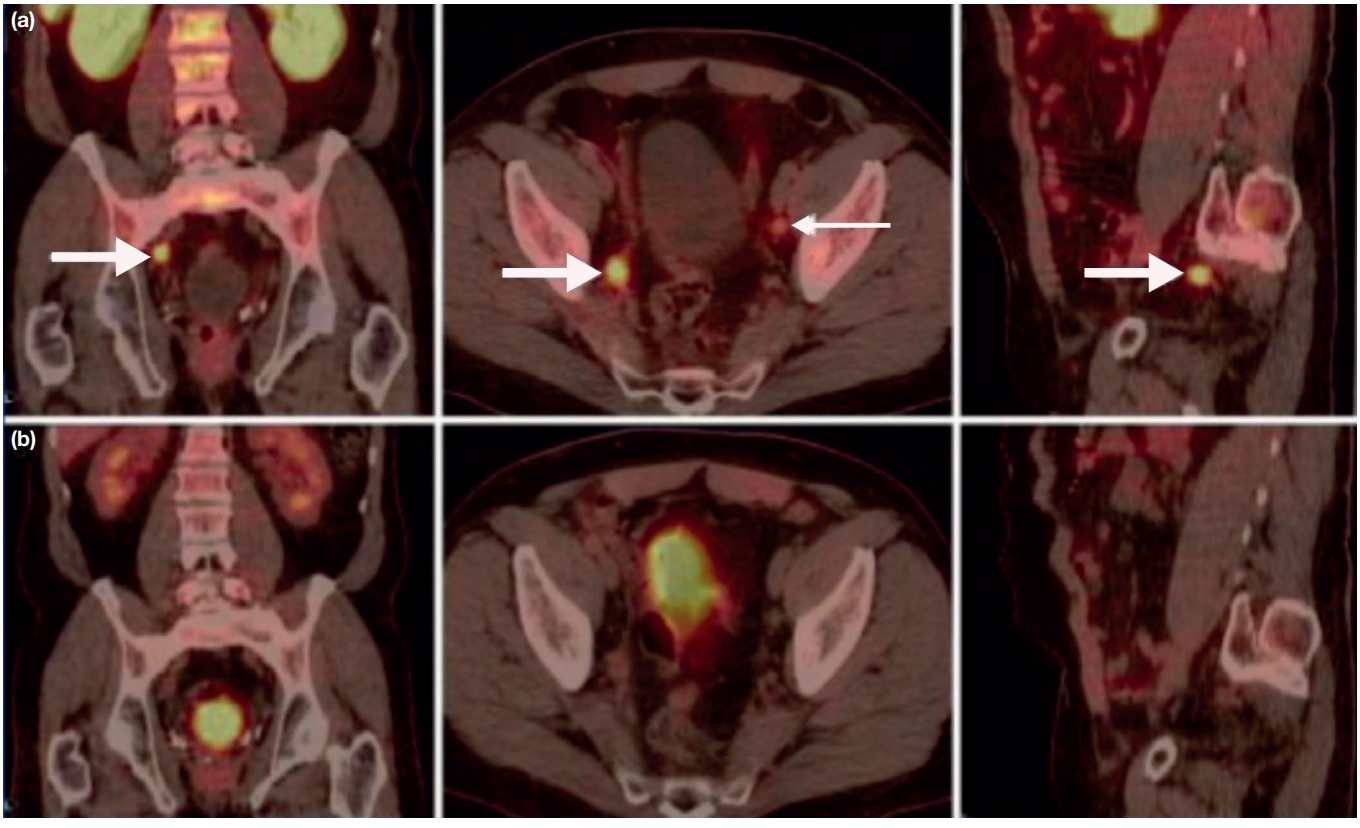

Figure 81.26 A 55-year-old patient with an increasing prostate-specific antigen level 27 months after radical prostatectomy. Coronal (left), axial (middle) and sagittal (right) fused image projections of choline positron emission tomography/computed tomography (PET/CT) scans. **(a)** Focal ^{11}C-choline uptake in the right (large arrow) and left (thin arrow) iliac regions revealed lymph node involvement. **(b)** This was not observed with 18F-fluorodeoxyglucose PET (courtesy of Hussein Farghaly).

follow-up of patients with seminoma with any residual mass. PET/CT may use a number of different radiotracers, including ^{11}C-choline, ^{18}F-choline (***Figure 81.26***), ^{18}F-fluciclovine and the newer gallium-68 (^{68}GA)-labelled antibodies targeting prostate-specific membrane antigen (PSMA) for the detection and staging of prostate cancer and its recurrence after initial definitive therapy.

Bone scan

A bone scan is most frequently used when bone metastases are suspected based on symptoms or other investigations. It is also used in the routine staging of patients with high-risk prostate cancer, although there is a <5% chance of a bone scan being positive until the PSA is >40 ng/mL.

Dimercaptosuccinic acid renogram

^{99m}Tc dimercaptosuccinic acid (DMSA) is a technetium radiopharmaceutical used in renal imaging to evaluate renal structure, especially in the paediatric population, where it is used to detect renal scarring (***Figure 81.27***).

Diethylenetriaminepenta-acetate renogram

^{99m}Tc diethylenetriaminepenta-acetate (DTPA) is another technetium radiopharmaceutical used in renal imaging. Previously it was used frequently in patients suspected of having ureteropelvic junction (UPJ) obstruction but it has largely been superseded by the mercaptoacetyltriglycine (MAG3) renogram in such cases.

Mercaptoacetyltriglycine renogram

^{99m}Tc Mercaptoacetyltriglycine (MAG3) is now the radiopharmaceutical of choice used in the assessment of patients with suspected upper urinary tract obstruction such as UPJ obstruction.

The shape of the renogram curve (following subtraction of background activity) is dependent, first, on MAG3 uptake from the circulation to the kidney and, second, on MAG3 elimination from the kidney into the bladder.

Classically, the normal MAG3 renogram curve has three phases (***Figure 81.28***):

1. The curve rises steeply upwards following intravenous tracer injection. This is indicative of the speed of tracer injection and its delivery to the kidneys (i.e. renal vascular supply).
2. A more gradual slope that represents renal handling of MAG3 (renal uptake by tubular secretion and glomerular filtration) and peaks between 2 and 5 minutes. The time taken for the curve to peak following tracer injection is referred to as T_{max}. This may be delayed in patients with renovascular insufficiency, renal failure and obstruction.
3. Commences after the peak. It is associated with the

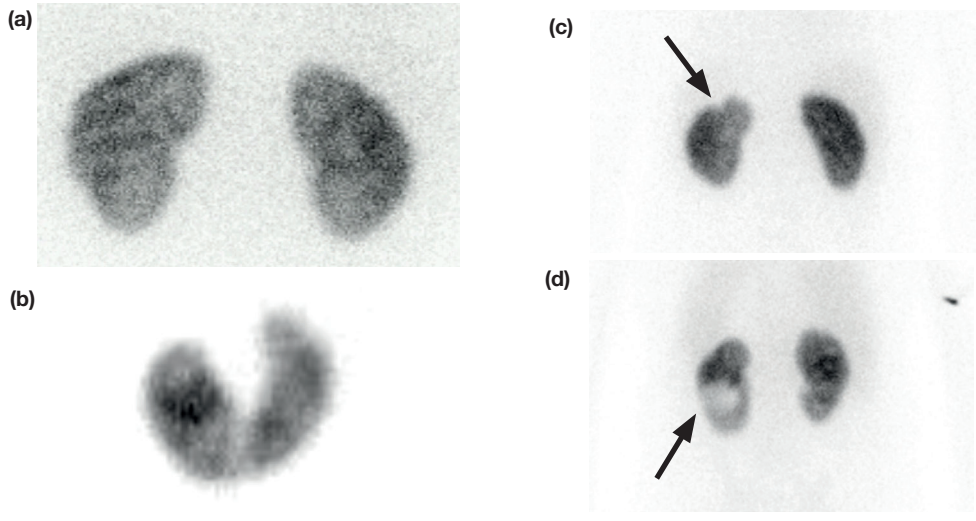

Figure 81.27 Dimercaptosuccinic acid scans. **(a)** Normal kidneys; **(b)** horseshoe kidney; **(c)** focal renal scarring (arrow); **(d)** renal tumour (arrow).

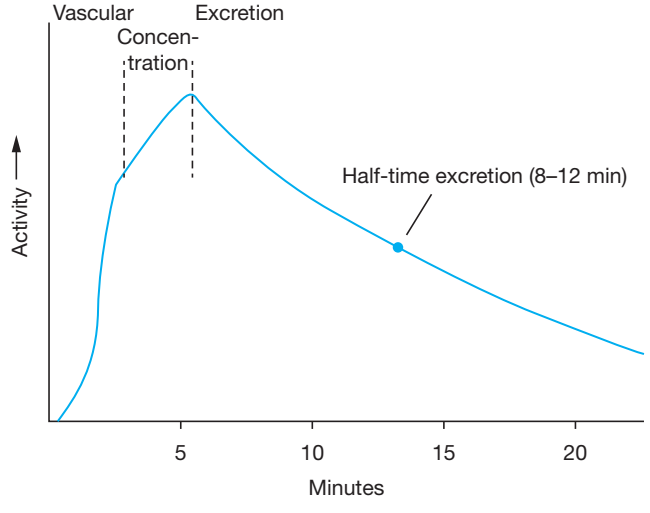

Figure 81.28 Diagrammatic representation of the three principal phases (vascular, concentration and excretion) of a mercaptoacetyltriglycine renogram curve. The time taken for the activity to become half of the peak level is called the half-time excretion and is used to determine the presence or absence of obstruction to urine outflow. Increased half-time suggests obstruction.

emergence of tracer in the bladder and represents elimination (but also delivery) of tracer from the kidney.

After 3 minutes, both elimination and uptake are in competition, but the former subsequently dominates. It is this elimination curve that is dependent on the upper tract urodynamics. Renogram curves of a number of normal and pathological conditions are shown in ***Figure 81.29***.

Bladder function assessment

Flow rate and ultrasound scan residual urine

Men with LUTS and women with recurrent UTIs or LUTS are frequently investigated with a flow rate and a USS residual urine at the first clinic appointment (***Figures 81.30–81.32***). A peak flow rate (Q_{max}) in excess of 15 mL/s suggests that significant BOO is not present, whereas a flow rate of <10 mL/s suggests that BOO is present. A very low flow rate with a very protracted pattern of voiding is suggestive of a urethral stricture. Caution is required when interpreting the significance of a single high USS residual volume; repeated tests often give a more representative picture of the degree of bladder emptying.

Urodynamics

A urodynamic evaluation provides information about bladder pressure and urine flow and has been referred to as a pressure–flow study. The test is performed to investigate patients with unexplained or complicated LUTS or incontinence. It is also commonly used in patients with a suspected bladder neuropathy. A device for urodynamic assessment is shown in ***Figure 81.33***. During urodynamics, fine catheters (or a dual-lumen catheter) are inserted through the urethra into the bladder to allow bladder filling and to record the intravesical pressure. Involuntary rises in the intravesical (detrusor) pressure during the filling phase, with or without a desire to void, are a classical sign of an overactive bladder. High intravesical pressure during voiding with a reduced flow rate is typically seen with BOO. An atonic bladder (no detrusor activity) is seen in diabetic neuropathy and in some patients following abdominoperineal excision of the rectum when damage to the pelvic nerve

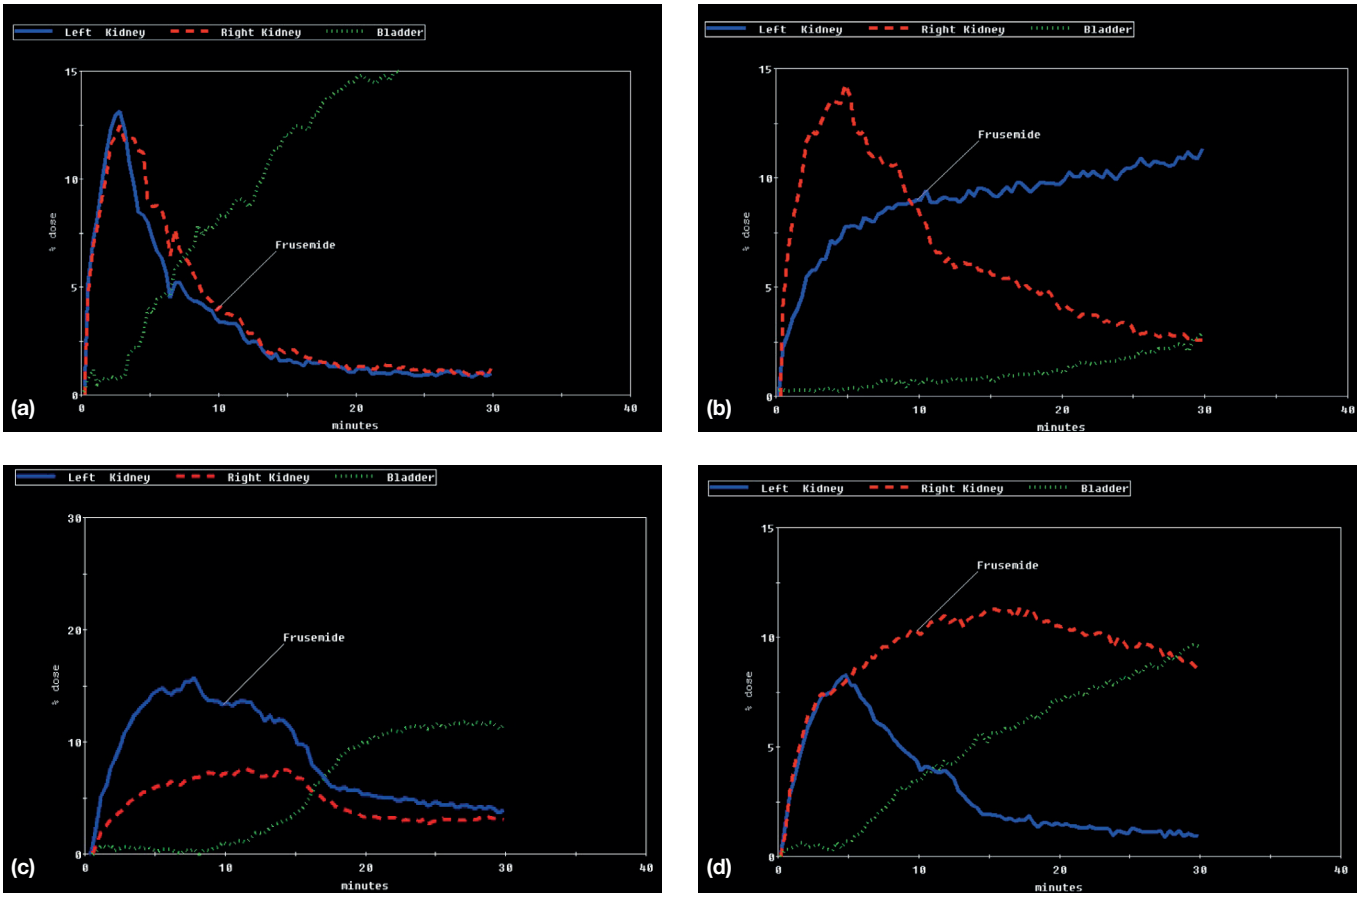

Figure 81.29 Curves from a series of mercaptoacetyltriglycine renograms (red line for right kidney; blue line for left kidney). **(a)** Normal excretion. **(b)** The left kidney graph does not go downwards, suggesting accumulation of radiotracer in the kidney – a sign of outflow obstruction. **(c)** Both the graphs show prolonged plateau phases, suggesting slow drainage from the kidneys – suggestive of bilateral dilated non-obstructed systems. **(d)** The right kidney shows a plateau phase with a delayed decline in the curve, suggesting a partially obstructed right system.

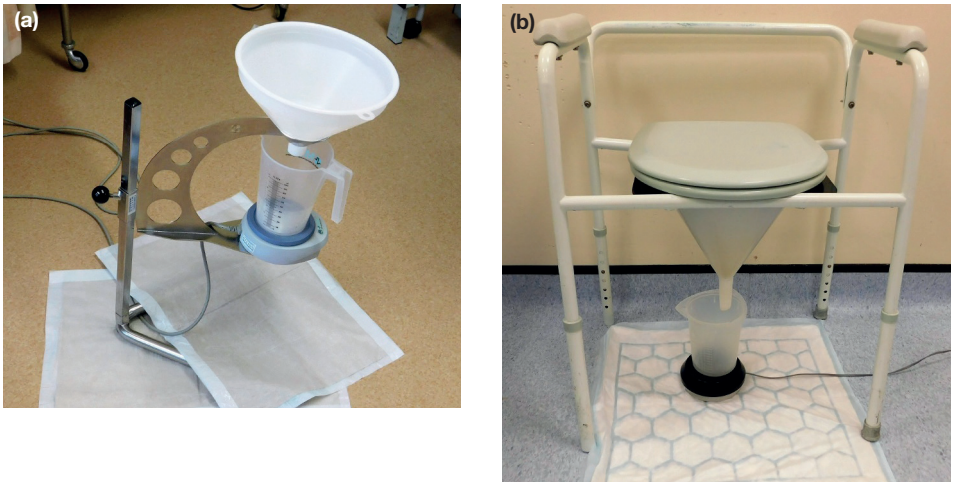

Figure 81.30 (a) A flow meter for use in males. **(b)** A flow meter for females

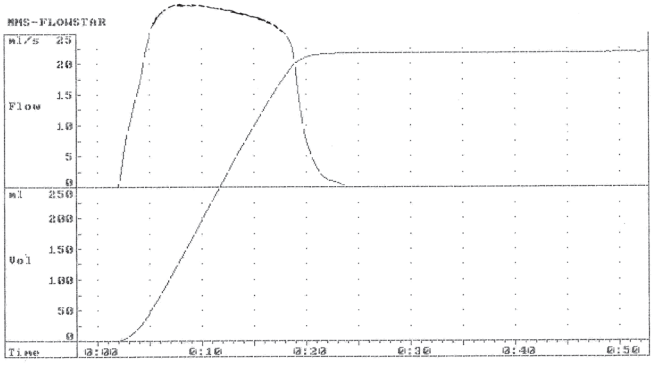

Figure 81.31 A flow study from a young healthy male patient showing a high-volume rapid void with an excellent peak flow of 32 mL/s. The upper curve shows the flow rate of urine while the lower graph shows total urine voided.

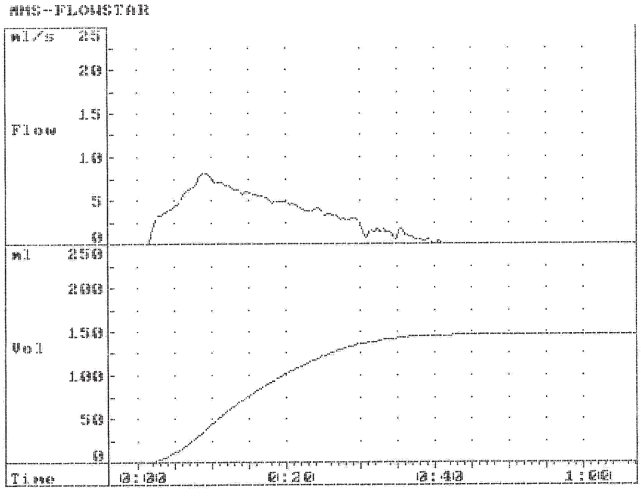

Figure 81.32 A flow study performed by a patient with bladder outlet obstruction showing a reduced peak flow of urine (8.1 mL/s).

plexus has occurred. Detrusor–sphincter dyssynergia – when coordinated contraction of the detrusor muscle in conjunction with relaxation of the external sphincter, necessary to permit normal voiding, is lost – is often seen in neurological conditions such as multiple sclerosis.

Summary box 81.10

Assessment of bladder function

- Simple tests are a flow rate and a USS residual urine estimation
- Urodynamics provides a pressure–flow profile
- Urodynamics requires fine catheters to be inserted into the bladder and usually the rectum
- A non-invasive technique in males using a penile cuff has a limited clinical role

Figure 81.33 A modern urodynamic machine.

PART 12 | Genitourinary

CHAPTER
82 The kidney and ureter

Learning objectives

To know:

- Congenital anomalies of the kidney and ureter
- Classification of renal cysts
- Classification, definitions, pathogenesis and management of urinary tract infections
- The pathophysiology and management of renal and ureteric stone disease
- Trauma to the kidney and ureter
- Presentation and management of renal neoplasms

CONGENITAL DISEASES

Renal agenesis

Complete absence of one kidney occurs in 1 in 3000 live births. The other formed kidney is usually hypertrophic. Reproductive tract anomalies are common in females with unilateral renal agenesis.

Bilateral renal agenesis is incompatible with life.

Ectopic kidney

This occurs when the mature kidney fails to reach its normal location in the lumbar region. The incidence is 1 in 500–1200. An ectopic kidney (***Figure 82.1***) may be found anywhere along the path of ascent: pelvic, iliac, abdominal and rarely thoracic. When the ectopic kidney is located on the contralateral side to its ureteric insertion, it is called crossed ectopia. Renal ectopia may be associated with reflux in the ectopic or orthotopic kidney and with pelviureteric junction (PUJ) and ureterovesical junction (UVJ) obstruction.

Horseshoe kidney

This is the most common renal fusion anomaly, occurring in about1 in 400 live births with a male predominance. The isthmus lies at the level of the fourth to fifth lumbar vertebrae (fused lower poles). This causes failure to ascend and rotate so that the renal pelvis faces anteriorly and vertically with the malrotated calyces pointing posteromedially (***Figure 82.2***). The vascular supply is variable and the ureter may insert high on the renal pelvis. Most horseshoe kidneys (HSKs) are asymptomatic but they are associated with an increased incidence of genital anomalies, PUJ obstruction (PUJO) and stone formation. The incidence of Wilms' tumour is higher in HSK.

Multicystic dysplastic kidney

Multicystic dysplastic kidney (MCDK) is the second most common cause of an abdominal mass in newborns after hydronephrosis due to PUJO. The unilateral incidence is 1 in 1000–4000 live births. It has a 'bunch of grapes' appearance

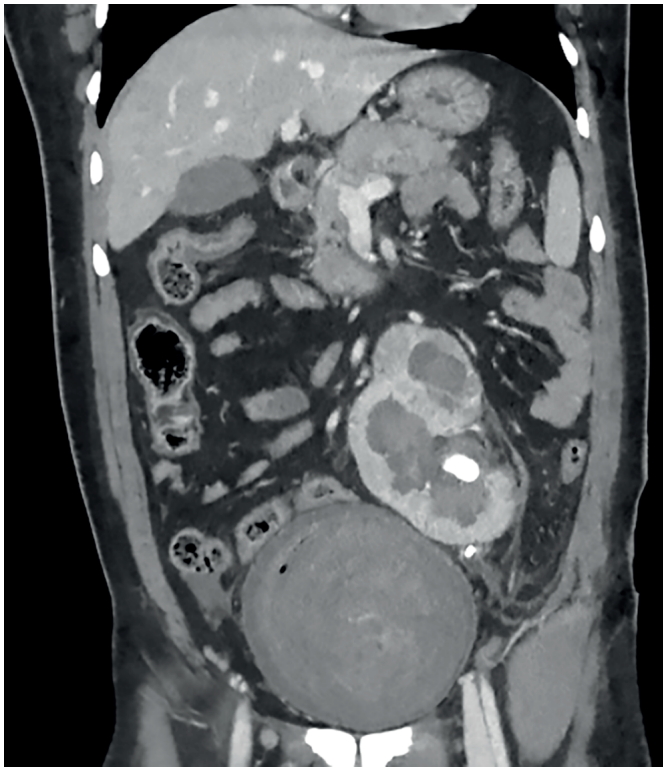

Figure 82.1 Computed tomography scan showing a pelvic kidney with calculus.

Carl Max Wilhelm Wilms, 1867–1918, German surgeon, described Wilms' tumour in 1899.

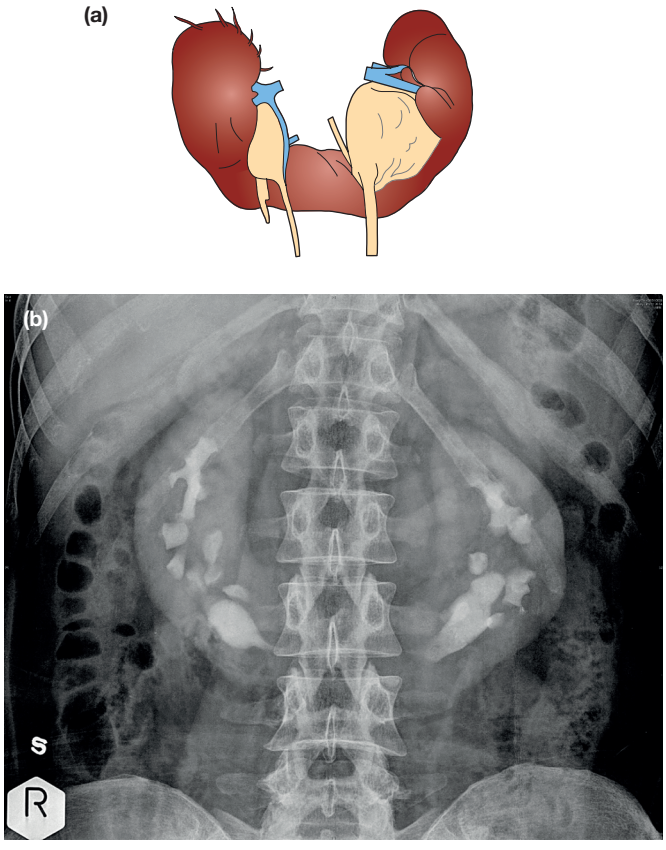

Figure 82.2 (a) Horseshoe kidney (courtesy of Nivedita Kekre and Dr Madhuri Sadanala). **(b)** Intravenous urogram image at 5 minutes, showing horseshoe kidney and posterior orientation of the calyces (courtesy of Department of Urology, Christian Medical College, Vellore, India).

with multiple non-communicating cysts of varying sizes without identifiable renal parenchyma. MCDKs can be diagnosed on antenatal ultrasound (US), with multiple cysts being evident as early as 15 weeks' gestation. Isotope renal scan will show a photopenic area in the renal fossa with surrounding background activity. Newborns may present with a palpable renal mass but nephrectomy is not necessary as the majority undergo involution within 5 years. Bilateral MCKD is incompatible with life.

Ureteral duplication

Duplication of the ureter (***Figure 82.3***) and renal pelvis is a common anomaly, with an incidence of approximately 1 in 150 births. Unilateral duplication is six times more common than bilateral. It is more common in females. The duplication may be incomplete (Y-shaped ureter) or complete. It is associated with vesicoureteric reflux (VUR), PUJO and ureterocele. Incomplete duplex ureters with a 'Y' ureter arise when the ureteric bud bifurcates after its initial development from the Wolffian duct. Complete ureteric duplication occurs when there are two separate ureteric buds that develop into two separate ureters, which drain the upper and lower kidney moieties separately. The lower moiety ureter has a shorter submucosal tunnel and is prone to VUR. PUJO is more common with the upper moiety. The upper moiety ureter may be ectopic and is often associated with a concomitant ureterocele. The upper moiety of the kidney is often dysplastic.

Ectopic ureters

An ectopic ureter is one that drains to regions other than the bladder. Ectopic ureters are almost always associated with ureteric duplication and are bilateral in 10%. The female-to-male ratio is 7:1. In females, the ectopic ureter opens either into the urethra below the sphincter or into the vagina (***Figure 82.3***). Such a child would complain of incontinence of urine despite normal voiding. In contrast, the male child is always continent as the ureter opens above the external urethral sphincter. Computed tomo-urography (CTU) or magnetic resonance urography (MRU) is diagnostic.

Ureterocele

Ureterocele is a cystic enlargement of the intramural ureter, which probably occurs as a result of atresia of the ureteric orifice. It has a female-to-male ratio of 4:1 and occurs bilaterally in 10%. Similar to ectopic ureters, ectopic ureteroceles frequently drain the upper pole and are often associated with dysplastic or non-functional renal tissue. In childhood, they usually present with infection. When large, they can obstruct the bladder neck or even the contralateral ureteric orifice. The classic feature of a ureterocele on an intravenous urogram (IVU) is the 'cobra head' sign. The treatment of simple ureteroceles is surgical excision with reimplantation of the ureter. Endoscopic incision of a ureterocele is the preferred treatment method for simple ureteroceles in infants and small children, but may result in subsequent ureteric reflux. A non-functioning kidney may need nephrectomy.

Congenital megaureter

The normal ureteric diameter in children up to 16 years is 0.50–0.65 mm. If the ureter is dilated by more than 7 mm, it is classed as a dilated or megaureter. This may occur with or without obstruction or reflux. Most cases of megaureter with obstruction present in childhood with severe infections. Renal stones can form easily in the dilated systems. Surgical correction is indicated in symptomatic patients who have recurrent urinary tract infections (UTIs), progressive dilation on US and differential renal function of less than 40%. Surgery involves excision of the stenosed distal ureter and non-refluxing ureteric reimplantation.

Retrocaval ureter

This is due to anomalous development of the inferior vena cava (IVC) with persistence of the posterior subcardinal vein. The right ureter passes behind the IVC rather than lying on its right side and may lead to ureteric obstruction, hydronephrosis and calculi. Most cases remain asymptomatic. Contrast imaging with IVU, CTU, MRU and diuretic renogram aid the diagnosis. The classic sign of a dilated upper ureter at L3/L4 with proximal hydronephrosis and the ureter passing

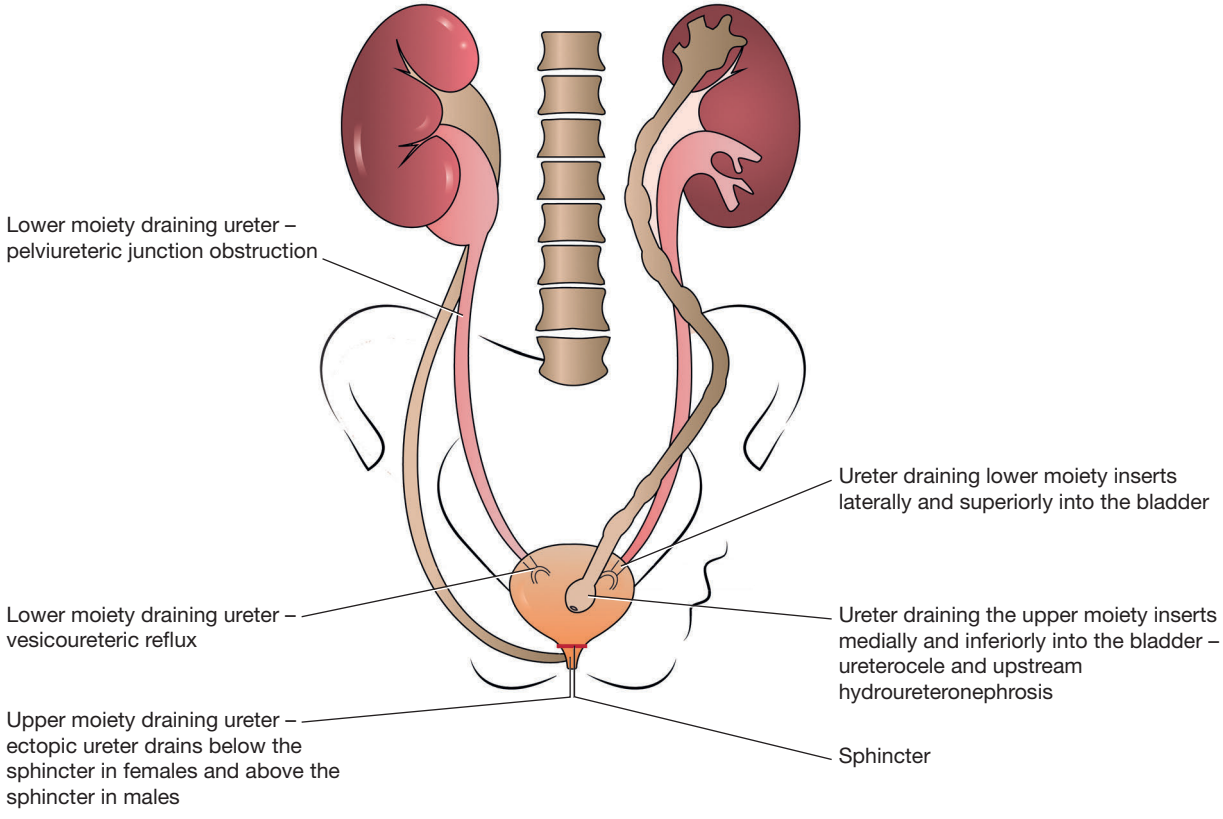

Figure 82.3 Complete duplication of the ureter and associated anomalies (courtesy of Nivedita Kekre and Dr Madhuri Sadanala).

medially behind the IVC is described as the reverse 'J' sign (***Figure 82.4***). Surgical correction is indicated in symptomatic patients with ureteroureterostomy or pyeloplasty depending on the level of obstruction.

Antenatal hydronephrosis

The prevalence of antenatal hydronephrosis (ANH) ranges from 0.6% to 5.4%. The majority of cases of ANH are transient and resolve after birth. The optimal timing of postnatal US in patients with ANH is at least 48 hours after birth. Diuretic renography can be performed after 4–6 weeks of life. ANH is classified into low, intermediate and high risk. A voiding cystourethrogram (VCUG), antibiotic prophylaxis and functional scan are recommended for high-risk infants along with monthly follow-up, whereas 1- to 3-monthly follow-up with US may suffice in low-risk infants.

Congenital pelviureteric junction obstruction

Congenital PUJO is the most common cause of unilateral hydronephrosis with an incidence of 1 in 500 live births. It may result from intrinsic obstruction secondary to an aperistaltic segment at the PUJ due to muscular hypoplasia. Other causes include a high insertion of the ureter into the pelvis and the presence of crossing aberrant vessels at the PUJ. It is more

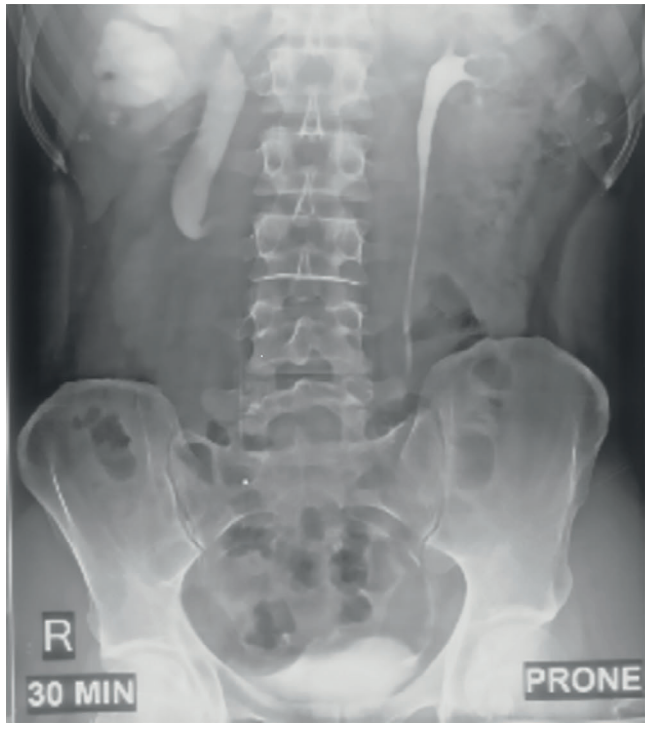

Figure 82.4 Retrocaval ureter with a classic 'reverse J' sign seen on intravenous urogram (courtesy of Department of Urology, Christian Medical College, Vellore, India).

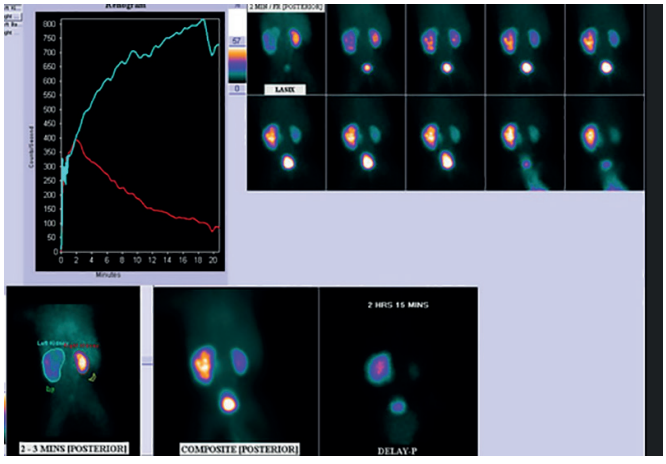

Figure 82.5 Isotope renal scan using diethylenetriaminepenta-acetate showing an obstructive pattern on the time–activity graph with hold-up of contrast of up to 2 hours. This finding is consistent with pelviureteric junction obstruction (courtesy of Department of Urology, Christian Medical College, Vellore, India).

common in males and on the left side. Bilateral obstruction occurs in 10% of cases. Historically, PUJO presented as a palpable flank mass in an infant or a child, but most are now detected before birth with antenatal US. Older children may present with intermittent flank pain, UTI or a flank mass. Adults present with back or flank pain or recurrent pyelonephritis. Rarely, a patient may present with a history of severe flank pain following ingestion of large amounts of fluid, which is relieved after passing a large amount of urine (**Dietl's crisis**).

US may show symmetrical hydronephrosis and a dilated renal pelvis and can provide information on the severity of obstruction by measuring the degree of dilatation, parenchymal thickness and cortical echogenicity. Isotope diuretic renography is the current investigation of choice. Isotope uptake and washout of the isotope can be followed with time to produce a renogram curve. Usually, half of the peak isotope activity is cleared within 10–15 minutes ($T_{1/2max}$). A rising curve following administration of furosemide, a $T_{1/2max}$ of greater than 20 minutes and a differential function of less than 40% on the affected side is suggestive of significant obstruction and is an indication for surgical intervention (***Figure 82.5***). CTU or MRU may also be used in the evaluation of PUJO.

The Anderson–Hynes dismembered pyeloplasty is the procedure of choice with a wide funnelled, dependent anastomosis, maintaining good vascularity of the upper ureter and pelvis and excision of the redundant pelvis (***Figure 82.6***). The indications for pyeloplasty are persistent pain, hypertension, haematuria, secondary renal calculi and recurrent UTIs. Endoscopic management in the form of endopyelotomy is reserved for post-pyeloplasty strictures.

Summary box 82.1

Congenital anomalies

- Congenital anomalies are usually detected incidentally and often only manifest when effected by pathology such as stone disease or malignancy
- Ectopic ureter should be suspected in a female child who presents with continuous incontinence of urine and also voids normally
- **Weigert–Meyer rule**
  - The ureter that drains the upper moiety is at a more inferior and medial position and is prone to obstruction and dysplasia
  - The ureter that drains the lower moiety is at a more superior and lateral position and is prone to VUR
- Most cases of ANH are transient and resolve after birth

RENAL CYSTS

Renal cysts can be broadly classified into sporadic, acquired and genetic causes.

Sporadic renal cysts

Sporadic renal cysts are usually benign. Cysts with thin, sharply defined walls and clear fluid content are known as simple renal cysts. This category of cysts may be diagnosed with certainty by US. Apart from a few thin septa, any variation in the nature of the fluid, thickness of the cyst wall or septa or the presence of either calcification or a solid nodule would require further imaging with either computed tomography (CT) scan or magnetic resonance imaging (MRI) to rule out cystic renal cell carcinoma (RCC). Bosniak proposed a four-tiered classification of the malignant potential of cystic renal lesions. Category I cysts represent benign lesions that require no further follow-up, whereas categories III and IV have a higher probability of malignancy and require surgical excision. Category II cysts can be safely followed up.

Acquired renal cystic disease

Most patients on haemodialysis develop bilateral renal cysts after 10 years. On follow-up one-fifth of these patients with acquired renal cystic disease (ARCD) develop renal cancers.

Genetic renal cysts

These cystic renal lesions have a known genetic inheritance. They are usually accompanied by involvement of other organ systems and present earlier in life than sporadic renal cysts.

Dietl's crisis, first reported by **Josef Dietl**, 1804–1878, in 1864, an Austrian doctor and pathologist known for his work on floating kidneys.
James Christie Anderson, 1899–1984, urologist, Royal Hallamshire Hospital, Sheffield, UK.
Wilfred Hynes, 1903–1991, plastic surgeon, The Plastic and Jaw Department, The Royal Hospital, Sheffield, UK. Anderson and Hynes devised the operation in 1949.
Carl Weigert, 1845–1904, German pathologist and anatomist known for work on cellular staining.
Robert Meyer, 1864–1947, German pathologist and gynaecologist in Berlin, removed from his position for being Jewish, emigrated in 1939 to Minneapolis, MN, USA.
Morton A Bosniak, 1929–2016, Professor of Radiology, New York University (NYU) Langone School of Medicine, New York, NY, USA.

Prerequisite of a good pelviureteric anastomosis:
1. Dependent 2. Wide 3. Funnel shaped 4. Maintain good vascularity
5. Without tension 6. Excise redundant pelvis

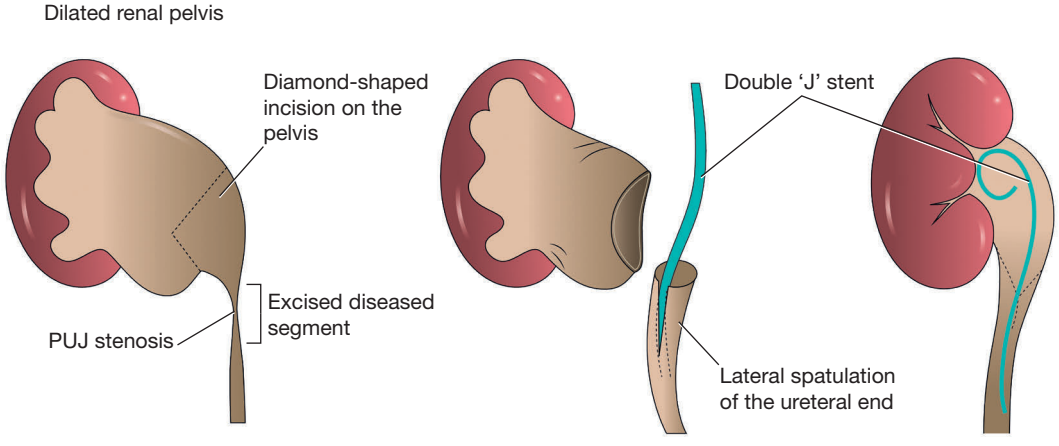

Figure 82.6 Steps of open dismembered pyeloplasty (courtesy of Nivedita Kekre and Dr Madhuri Sadanala). PUJ, pelviureteric junction.

Autosomal dominant polycystic kidney disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common autosomal dominant genetic cystic renal disease causing chronic renal failure requiring dialysis and renal transplantation. It occurs as a result of mutation in one of two genes (*PKD1* on chromosome 16 and *PKD2* on chromosome 4). ADPKD gene loci can be identified in individuals with a family history before the development of cysts begins; this is helpful in screening a potential sibling for kidney donation. ADPKD has variable penetration and approximately 50% of affected individuals eventually develop end-stage renal disease (ESRD). Risk factors for the development of ESRD are:

- early age of presentation;
- hypertension;
- male sex;
- ADPKD gene 1;
- African ethnic group.

ADPKD is associated with cysts in other organs, such as the liver, pancreas, arachnoid membranes and seminal vesicles. It does not usually manifest before the age of 30 years and in some patients it is never diagnosed. Renal symptoms include abdominal pain, haematuria or a palpable mass. Most patients older than 20 years are hypertensive and good control of blood pressure can delay progression to renal failure. Novel agents such as vasopressin antagonists (tolvaptan), somatostatin analogues and mammalian target of rapamycin (mTOR) inhibitors have shown potential to prevent cystogenesis, cyst expansion and declining renal function. Intracranial aneurysms occur in approximately 10–30% of patients with ADPKD and subarachnoid haemorrhage may cause sudden death in young adults.

Summary box 82.2

Renal cystic disease

- Bosniak renal cyst classification is used to grade cysts and probability of malignancy
- ADPKD – autosomal dominant, systemic disease:
  - Rarely manifests before the fourth decade
  - Hypertension, abdominal pain, haematuria or a palpable flank mass are common presentations
  - Control of hypertension can delay progression

INFECTIONS

UTI is very common and affects all ages and both sexes. It can cause significant morbidity and is a rare cause of mortality in patients with serious comorbidities or in patients with urinary tract obstruction. Recurrent UTI is more common in women, affecting 30–40% in the sexually active age group. It can be defined as an inflammatory response of the urothelium (host) to invading bacteria. Asymptomatic colonisation or bacteriuria (ABU) is also common and can be differentiated from a UTI by the absence of symptoms and pyuria (leukocytes in urine).

Classification

UTI is classified as uncomplicated when it occurs in an immunocompetent host with an anatomically normal and functional urinary tract. UTIs may also be classified on their site of origin as pyelonephritis (kidney), cystitis (bladder), urethritis or prostatitis. While acute pyelonephritis indicates an acute infection of the kidney, **chronic pyelonephritis** is only a morphological description of previous infection-related

sequelae such as scarring in the kidney as seen on radiological or nuclear imaging.

Acute pyelonephritis

This commonly occurs as a result of ascending infection from organisms in the lower tract, usually caused by Gram-negative bacteria. Haematogenous spread may be seen in patients with diabetes and in immunocompromised hosts, people who inject drugs and patients with bacterial endocarditis. It is more common in females, especially during childhood, at puberty, after intercourse and during pregnancy. Acute pyelonephritis usually presents with fever, chills, flank pain, nausea and vomiting. Loin tenderness may be present. Symptoms may vary from mild to severe illness with septic shock and renal failure. Pyuria is almost always present and its absence in a patient with pyelonephritis may point towards an obstructed urinary tract. Urine and blood should be collected for culture. *Escherichia coli* and other Gram-negative organisms are commonly responsible. Imaging is necessary when the patient is not responding to antibiotics to rule out pyonephrosis, renal abscess and obstruction. Renal US is often the first imaging modality used. Contrast-enhanced CT (CECT) typically shows decreased patchy opacification of the affected parenchyma.

Pyelonephritis complicating pregnancy

The relaxing effect of progesterone during pregnancy causes ureteral smooth muscle relaxation and dilatation, presumably predisposing pregnant women to ascending upper tract infections. It is associated with fetal growth retardation and preterm delivery. Therefore, all pregnant women must be screened in the first trimester for ABU because, untreated, a third of these patients will develop UTI. Lower tract UTI typically occurs in the first trimester whereas pyelonephritis most often presents in the second or third trimester with acute abdominal pain or premature labour. Pyelonephritis is more common in pregnant women with an underlying urological abnormality or diabetes. A renal US is indicated if response to treatment is poor. Antibiotic use during pregnancy is tailored to avoid fetal harm and typically includes fosfomycin, penicillins or cephalosporins.

Renal and perirenal abscess

A renal abscess results from an ascending UTI in association with an underlying urinary tract abnormality such as obstructive uropathy or VUR. It is usually caused by common uropathogens such as *E. coli* and other Gram-negative bacilli. Renal abscesses may extend and perforate the renal capsule to form a perirenal abscess. Multiple renal abscesses may conglomerate into a solitary suppurative lesion called a renal carbuncle. This is usually caused by *Staphylococcus aureus*, which reaches the kidney by haematogenous spread.

The clinical presentation may be insidious and non-specific but patients usually present with persistent fever, back pain, abdominal pain and costovertebral tenderness. Urine examination may be normal if the abscess does not communicate with the collecting system. CECT scan is the investigation of choice to establish the diagnosis.

Treatment with antibiotics without drainage may be effective in carefully selected patients when the abscess is small (<3 cm) or in a stable patient (up to 5 cm). Empiric antibiotic therapy should be broad spectrum and should cover *S. aureus* and other uropathogens causing complicated UTI. Culture-directed antibiotics may be needed for 2 weeks or longer depending on response.

Percutaneous aspiration or drainage of pus is indicated in abscesses >5 cm and in patients not responding to antibiotics. Open surgical drainage is indicated when percutaneous drainage is inadequate.

Emphysematous pyelonephritis

This is an acute-onset, rapidly progressive, possibly lethal form of pyelonephritis characterised by parenchymal necrosis and gas formation, caused by organisms including *E. coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa* and *Proteus mirabilis*. Most patients have diabetes (up to 90%) and they may have obstruction secondary to calculi or papillary necrosis. Increased glucose levels in those with diabetes may provide a substrate for carbon dioxide production from fermentation. Symptoms are suggestive of pyelonephritis and an abdominal mass may be palpable. CECT of the abdomen is diagnostic and shows gas in the renal parenchyma, collecting system or both, along with other features of infection such as abscess, obstruction and perinephric stranding. Early diagnosis, intravenous broad-spectrum antibiotics and percutaneous drainage of the abscess and obstructed kidneys have improved outcomes in these patients. Emergency nephrectomy is rarely required and is reserved for patients who do not respond to the described measures.

Xanthogranulomatous pyelonephritis

Xanthogranulomatous pyelonephritis (XGP) occurs with severe renal infection in an obstructed kidney and is usually associated with calculi, causing loss of function and parenchymal destruction. Pathological examination typically shows accumulation of lipid-laden foamy macrophages. Patients may present with flank pain, fever with chills, persistent bacteriuria and a flank mass. A history of stone disease may be present. It is usually unilateral. CECT of the abdomen is diagnostic and shows a non-functioning enlarged hydronephrotic kidney around a shrunken pelvis with a calculus, also known as the **bear's paw sign** (*Figure 82.7*). Nephrectomy is the definitive treatment.

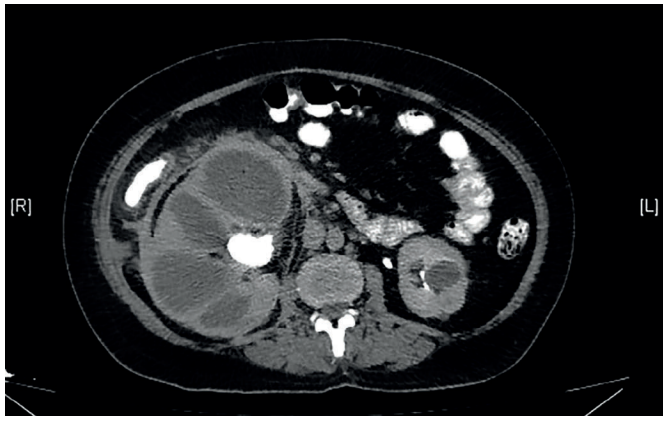

Figure 82.7 Xanthogranulomatous pyelonephritis with the 'bear's paw sign'.

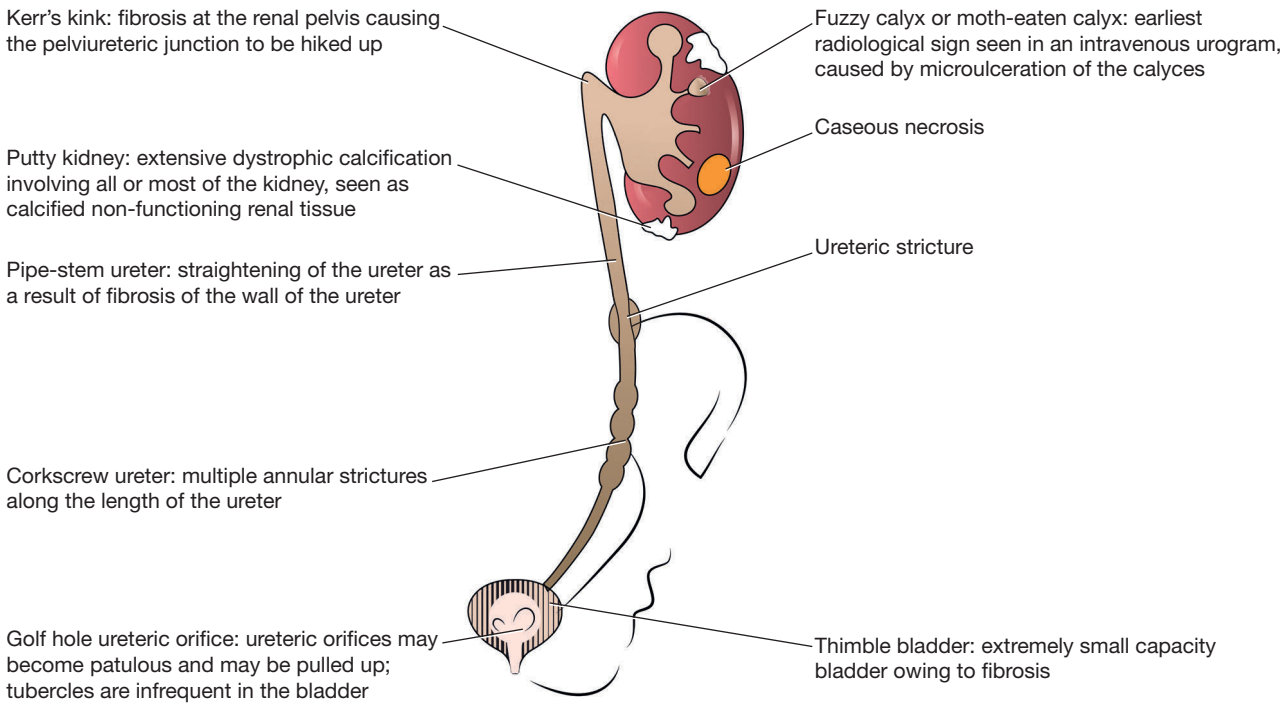

Figure 82.8 Schematic illustration showing the sequelae of urinary tuberculosis (courtesy of Nivedita Kekre and Dr Madhuri Sadanala).

Tuberculosis of the urinary tract

Genitourinary tuberculosis (GUTB) accounts for 15–20% of extrapulmonary cases of TB. It is secondary and caused by haematogenous spread of tubercle bacilli from the thoracic lymph nodes or the lungs. GUTB occurs as a result of either reinfection or reactivation of old TB granulomas. Blood-borne organisms are deposited close to the glomeruli, causing an inflammatory reaction. Macrophages react and granulomas are formed. If bacterial multiplication goes unchecked, caseous necrosis results in the formation of tubercles. Multiple tubercles coalesce and rupture into the collecting system, causing intermittent tuberculous bacilluria and pyuria. The disease spreads through the collecting system with ulceration initially. When bacterial multiplication is halted by the immune system, sequelae due to fibrosis appear (***Figure 82.8***). Tubercular obstructing or destructive lesions in the kidneys and ureters are responsible for renal function loss. Involvement of the bladder is secondary to renal disease. The disease gradually involves the bladder musculature, which is replaced by fibrous tissue, causing a decrease in the size and capacity of the bladder ('thimble' bladder). Urinary bladder involvement is responsible for urinary frequency, which is the most common symptom of GUTB.

Epididymal tuberculosis presents as a painless epididymal nodule, usually involving the tail of the epididymis, or a chronic discharging sinus in the posterior scrotal wall. Patients may present with urinary frequency, colicky flank pain, haematuria and, rarely, fever and constitutional symptoms. They may also present with symptoms suggestive of recurrent UTIs and, rarely, calcified tubercular lesions may be misdiagnosed as urinary tract calculi.

For microbiological confirmation, at least three consecutive early-morning specimens of urine are examined for acid-fast bacilli. The gold standard for microbiological diagnosis is urine culture. Nucleic acid amplification tests (NAATs) provide rapid diagnosis (within hours). When the diagnosis remains uncertain, bladder biopsy, tissue culture and tissue NAATs may be required. Imaging with CTU may also help and can show early signs such as calyceal distortion and papillary necrosis, hydronephrosis, poor function of renal segments secondary to parenchymal destruction, fibrosis and chronic obstruction. Ureteric strictures and proximal dilatation may also be seen. IVU can pick up the earliest signs of disease activity, such as calyceal distortion.

Treatment involves short-course antituberculous therapy (ATT). Rifampicin, isoniazid and pyrazinamide are used sometimes with ethambutol as first-line drugs.

The primary aim of therapy is preservation of renal function and avoidance of fibrotic sequelae. Ureteric strictures may require double J (DJ) stenting to preserve function until definitive reconstruction is attempted. Percutaneous nephrostomy (PCN) is recommended in obliterative strictures to achieve prompt decompression. Definitive surgery is usually done 3–6 weeks after starting ATT. The choice of reconstructive procedure depends on the type and location of sequelae.

Open surgical repair is generally superior to balloon dilatation for tubercular ureteric strictures. Augmentation enterocystoplasty (usually using ileum) for small-capacity bladders,

William 'Bill' K Kerr, a Canadian urologist, described his eponymous sign in 1967.

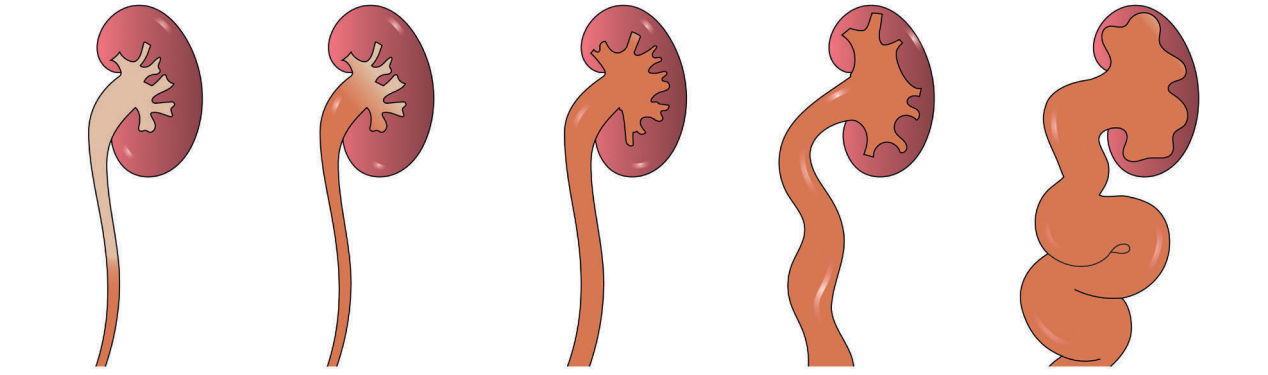

Figure 82.9 Grades of vesicoureteric reflux (courtesy of Nivedita Kekre and Dr Madhuri Sadanala).

ureteric reimplantation with or without a Boari flap (bladder tube) for lower ureteric stricture and ileal replacement of the ureter for multiple long ureteric strictures may be required. Nephrectomy is done for major renal lesions with a poorly functioning kidney.

Urinary infection in childhood and vesicoureteric reflux

All children with UTI must be evaluated for underlying predisposing conditions as recurrent pyelonephritis can cause renal scarring and loss of renal function. UTIs account for 7% of childhood febrile illness. In the age group <3 months, it is more common in males and in the age group >1 year, it is more common in females. Structural and functional abnormalities of the urinary tract such as VUR and posterior urethral valves predispose to UTI. Reflux is considered primary when it is due to an incompetent UVJ and secondary when it is due to increased bladder pressure or outlet obstruction. Presenting symptoms in neonates and infants include febrile illness or sepsis and may not be localised to the urinary tract. The method of urine sampling, especially before toilet training, is crucial and may involve suprapubic aspiration or per urethral catheter collection. A bacterial count of 50 000 colony-forming units per millilitre is generally considered a positive culture result in children, although a lower count from a suprapubic aspirate in a symptomatic child is significant. The most important complication of UTI in a child is renal scarring secondary to renal parenchymal inflammation. US should be performed in all children, and children with recurrent UTIs or a first time UTI with pyelonephritis should be evaluated further. VCUG is the investigation of choice to diagnose reflux and should be performed in high-risk children. ^{99m}Tc dimercaptosuccinic acid (DMSA) radionuclide cortical scan is the best modality to detect parenchymal lesions. VUR is present in approximately 30% of children with UTI and in up to 90% of children with renal scarring. Renal scarring may cause hypertension in up to 20% and is an important cause of renal failure. The grades of VUR are summarised in ***Figure 82.9***, with grades I–III generally resolving spontaneously.

Low-dose nocturnal antibiotic prophylaxis to prevent scar-inducing pyelonephritis is the mainstay of treatment as the majority of reflux cases resolve with time. However, surgery (ureteric reimplantation, periureteric injections of Teflon or collagen) should be considered if episodes of acute pyelonephritis recur despite antibiotic therapy or if severe reflux is accompanied by a surgically correctable malformation such as a paraureteric bladder diverticulum.

Summary box 82.3

Infections

- UTI: inflammatory response of the urothelium (host) to invading bacteria
- ABU: colonisation of urine with bacteria with no evidence of inflammation
- All pregnant women must be screened in the first trimester for ABU because, untreated, one-third of these patients will develop UTI
- GUTB:
  - Always due to either reinfection or reactivation of old tuberculosis
  - Urine examination: sterile pyuria in acidic urine
  - Close monitoring of upper tract during the initial phase of ATT and timely urological intervention may prevent renal loss
- UTI in children:
  - More common in girls after 1 year of age
  - Sample collection method is important to avoid contamination
  - VUR occurs in 30% of children with a UTI
  - Renal scarring is a possible long-term consequence

Achille Boari, nineteenth century urological surgeon from Ferrara, Italy, described the technique of a bladder flap in dogs in 1894; it was first performed in a patient in 1936.

UROLITHIASIS

Urolithiasis is as old as mankind. The first documented cystolithotomy was described by Sushruta, an ancient Indian surgeon in almost 600 BCE. The development of shockwave lithotripsy (SWL) and endourological procedures with multiple efficient energy-generating devices (such as US, pneumatic, electrohydraulic) for stone fragmentation have revolutionised the management of stone disease. Although the incidence of bladder stones has declined progressively owing to the alleviation of poverty and the improvement in basic nutrition, the modern world is witnessing a steady increase in the incidence of renal calculi.

Epidemiology

The lifetime prevalence varies from 1% to 20% and the causes are multifactorial. Recurrence of stone disease is high, with 50% having recurrence within the first decade of diagnosis.

Non-modifiable factors associated with stone formation

- **Age**. The adult peak incidence in men is the fourth to sixth decade; women have a bimodal peak in incidence in the third decade and the postmenopausal period.
- **Gender**. Men are twice as likely to form stones.
- **Ethnic origin**. White people have a higher risk of stone disease than other ethnic groups. Recent evidence suggests that environmental and dietary factors may be more important than ethnic origin.
- **Family history**. Patients with a family history of stone disease are 2.5 times more likely to develop stone disease themselves. Examples of hereditary forms of stone disease include cystinuria, type I renal tubular acidosis (RTA) and primary hyperoxaluria.

Modifiable factors associated with stone formation

- **Environmental factors**. People living in hot and arid regions such as the desert or tropical areas have a higher incidence of stone disease owing to increased perspiratory fluid loss.
- **Drugs**. Drugs can predispose to stone formation through metabolic effects (e.g. corticosteroids, chemotherapeutic agents).

Pathogenesis

Stone formation results from a cascade of events that occur during and after urine formation.

When the concentration of culprit salts such as calcium and oxalate overwhelm inhibitory factors (e.g. citrate, potassium, magnesium, Tamm–Horsfall mucoproteins, pH changes), they precipitate into crystals. These crystal nuclei may be washed off with the flow of urine or they may anchor onto sites like renal papillae to form Randall's plaques. Variations in the pH of urine may also facilitate or inhibit stone growth; acidic pH precipitates the formation of uric acid stones and alkaline pH precipitates the formation of calcium phosphate stones. Hence, the manipulation of pH through medication can help in preventing new stone formation.

Stasis of urine also promotes stone formation. Stasis stones are usually multiple, round and have a smooth surface. These are called 'milk of calcium stones'.

Types of stones

Calcium oxalate stones

This is the most common type of stone, constituting 60–85% of all stones. Hypercalciuria, hypercalcaemia, hyperoxaluria, hyperuricosuria and hypocitraturia are known metabolic abnormalities that can predispose to its formation. Hypercalciuria is the most common metabolic abnormality and occurs as a result of dysregulation of transport at various sites, including the intestine, bone or kidney.

Primary hyperparathyroidism is the most common disease associated with hypercalcaemia and stone disease. Increased parathyroid hormone causes increased bone resorption and increased synthesis of 1,25-dihydroxyvitamin D3. This causes increased intestinal absorption of calcium, leading to hypercalcaemia and hypercalciuria.

Hyperuricosuria causes uric acid crystal formation, especially in association with acidic urine, over which calcium oxalate crystals aggregate.

Calcium phosphate stones

Pure calcium phosphate stones are rare. Common forms seen are apatite and brushite stones. Apatite is seen with infection and brushite stones are usually seen with distal RTA.

Uric acid stones

Hyperuricosuria promotes the formation of both calcium oxalate and uric acid stones. Uric acid precipitates into crystals in acidic urine and remains soluble in alkaline urine. Conditions that can cause hyperuricosuria are gout and myeloproliferative disorders after cytotoxic treatment.

Infection stones

These are struvite and apatite stones. They form as a result of urease-producing bacterial infections, such as those caused by *Proteus*, *Klebsiella*, *Serratia* or *Enterobacter*. Alkalinisation of urine takes place as urease hydrolyses urea to carbon dioxide and ammonium.

Staghorn calculi are infection stones that grow in a branching pattern, taking the form of the pelvicalyceal system.

Sushruta, 600 BCE, authored Suśruta-saṃhitā, considered the father of plastic surgery.
Igor Tamm, 1922–1995, an outstanding cytologist, virologist and biochemist, pioneer in the study of viral replication, professor at the Rockefeller Institute for Medical Research, New York, NY, USA.
Frank Lappin Horsfall Jr, 1906–1971, American microbiologist specialising in pathology, worked at the Rockefeller Institute, New York, NY, USA. The Tamm–Horsfall protein was first purified in 1952 during his work with Igor Tamm.
Alexander Randall, 1883–1951, American urologist, first described the plaques in 1937 as part of a postmortem case series using a hand lens.

They can grow very large before clinical detection and cause significant morbidity, which includes loss of renal function owing to chronic infection and obstructive uropathy. Complete clearance of a staghorn calculus is necessary, as residual fragments after treatment can cause rapid recurrence and persistence of bacteriuria. Long-term chemoprophylaxis is mandatory for a few months after successful removal of infection calculus.

Cystine stones

Cystine stones constitute approximately 1% of stones. Cystinuria is an autosomal recessive inherited disease that causes decreased reabsorption of cystine from the intestine and the proximal tubule of the kidney. Cystine is insoluble even at physiological pH and worsens with increasing acidity. Cystine stones are very hard stones as a result of disulphide bonds and do not fragment with SWL.

Clinical presentation

Incidentally detected asymptomatic stones are increasingly diagnosed because of the widespread use of imaging. The presenting symptoms depend on the location of the stone, the size and type of stone, underlying infections and complications related to stone disease. Haematuria may be gross or microscopic, especially during episodes of renal colic. Calculuria is described as sand or gravel accompanying urine. Ureteric colic is acute abdominal pain caused by hyperperistalsis of the ureteric musculature against the obstructing stone. It manifests as sudden-onset excruciating pain in the flank that can radiate to the groin, scrotum or labia. Lower ureteric stones close to or lodged at the UVJ can cause symptoms of urgency and frequency. Malaise and weight loss can occur in longstanding infection stones or as a manifestation of renal failure. High-grade fever with chills suggests an underlying UTI and should be considered an emergency. During history taking, information about risk factors such as diet, physical activity, fluid intake, history of urinary tract infections, gastrointestinal symptoms, previous surgical history, family history and previous treatment for stone disease should be enquired about.

Complications

Renal and ureteric stones can lead to significant morbidity owing to urinary tract obstruction, infectious complications and loss of renal function. Bilateral obstructing ureteric stones or ureteric calculi in a solitary kidney can present with anuria (calculous anuria). Infectious complications include pyelonephritis, pyonephrosis, renal abscess or septicaemia. Uncommon but serious complications include XGP and pyeloenteric or cutaneous fistulae in neglected cases. Nephron loss can occur as a result of recurrent episodes of infection and obstruction, causing chronic renal failure.

Diagnosis

The diagnostic approach can be classified into investigations done in the emergency setting and those done in the non-emergency setting.

Approach to ureteric colic

The most common acute presentation of stone disease is 'ureteric colic'. Small 3- to 5-mm calculi are usually responsible for ureteric colic and commonly lodge at the UVJ. Non-steroidal anti-inflammatory drugs and paracetamol are effective. Antispasmodic medications are not necessary to alleviate pain. Abdominal examination may reveal renal angle tenderness. Pelvic examination is especially important in women to exclude tubo-ovarian pathology such as an ectopic pregnancy or twisted ovarian cyst. ***Table 82.1*** lists the differential diagnoses.

TABLE 82.1 Differential diagnoses for ureteric colic.

Urinary tract
• Clot colic   ◦ Anticoagulation therapy, haemophilia, vascular tumours • Papillary necrosis   ◦ Diabetes, NSAIDs, sickle cell disease
Other organs
• Acute appendicitis • Ectopic pregnancy • Ovarian torsion • Acute intestinal obstruction • Abdominal aortic aneurysm • Malingering

NSAID, non-steroidal anti-inflammatory drug.

Investigations include urinary examination, blood examination and diagnostic imaging. The majority have microscopic haematuria and pyuria. Pyuria may be sterile pyuria or due to infection. An elevated leukocyte count suggests infection and may be an indication for starting antibiotics.

Pregnancy should be ruled out.

A radiograph of the kidneys, ureters and bladder and US are good first-line tests. Non-contrast CT (NCCT) is the investigation of choice for the diagnosis of stones. It allows for diagnosis of both radio-opaque and radiolucent stones with the exception of indinavir stones. Most patients respond to medication to alleviate pain. However, if the pain does not reduce with analgesics, or if the patient shows features of sepsis or urinary obstruction, emergency urinary decompression should be planned. Blood and urine should be cultured in patients suspected of sepsis, and empirical broad-spectrum antibiotics should be initiated. If the patient is clinically unstable, initial stabilisation in critical care may be warranted. Emergency urinary decompression may be done either with ureteric stenting or with PCN. However, in the absence of infection, in a certain select group of symptomatic but surgically fit patients, removal of stones may be possible by ureteroscopy.

Metabolic evaluation

The extent of metabolic evaluation depends on the risk associated with the recurrence of stone formation.

Urinary examination is done to look at crystals and pH in the non-emergency setting. Urine culture is performed if definitive management is planned. Blood chemistry for serum levels of calcium, phosphorus and uric acid are done to rule out hypercalcaemia, hypophosphataemia and hyperuricaemia.

Further detailed metabolic work-up should be done for high-risk patients.

Non-surgical management of stone disease

This involves watchful waiting, medical expulsive therapy, SWL and stone dissolution therapy.

Watchful waiting

Patients with small (<5 mm), non-obstructive, asymptomatic, lower pole renal calculi with preserved renal function may be kept on follow-up. Up to 90% of 4-mm stones and 50% of 6- to 10-mm stones pass spontaneously.

Medical expulsive therapy

Tamsulosin is an α_1-adrenergic adrenoreceptor blocker (α-blocker) that causes smooth muscle relaxation of the distal ureteric muscle. It can be used for distal ureteric stones larger than 5 mm and to assist passage of fragments following SWL.

Extracorporeal shockwave lithotripsy

SWL is a non-invasive method introduced in 1980 by Christian Chaussy that allowed stones to be treated on an outpatient basis.

Mechanism of action

The stone is localised using either fluoroscopy or US or both. Then acoustic pulse waves are generated and focused on the stone. Stone fragmentation occurs as a result of mechanical stress caused directly by the energy transmitted by the incident shockwave and indirectly by the collapse of bubbles. The efficacy of SWL reduces with an increasing number of stones and volume of stone burden.

Steinstrasse is a German word meaning 'street of stones'. It describes a row of closely gathered stone fragments that line the distal end of the ureter (***Figure 82.10***). This occurs when the stone burden is high or when the stones are hard. These stones are usually asymptomatic and pass spontaneously; however, they may cause obstruction, requiring surgical intervention. 'Clinically insignificant residual fragments' are residual stone fragments of 4 mm in size or less after treatment that are expected to pass spontaneously. However, 20–40% of these fragments may not clear and form a nidus for stone regrowth.

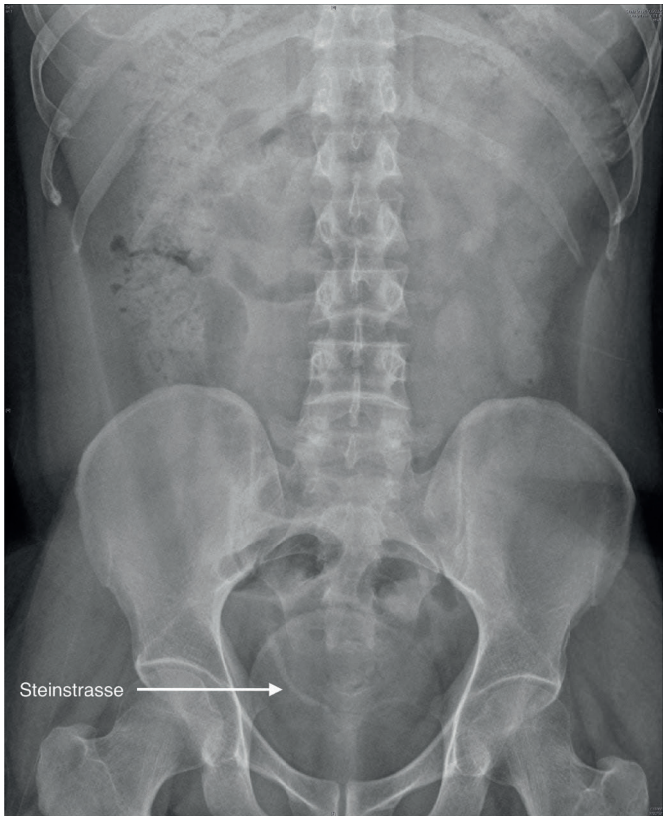

Figure 82.10 Steinstrasse formation after extracorporeal shock wave lithotripsy at the right distal ureter (courtesy of Department of Urology, Christian Medical College, Vellore, India).

Surgical management

Indications for surgical intervention

- Failure of medical management.
- Impaired renal function.
- Chronic infection – staghorn calculi, matrix calculi.
- High-risk occupation or geographical location – pilots, long-distance locomotive drivers, sailors.
- Patient's preference.

The choice of therapy depends on multiple factors such as surgical fitness, body habitus and stone characteristics. The general principle is to choose the least invasive method possible for that particular stone.

Endourology

Endourological procedures are the current preferred mode of treatment owing to their minimal invasive nature, technological advancements in instrumentation and more efficient energy sources for stone fragmentation. Current energy sources are pneumatic, US or laser lithotripsy. The type of energy source depends on the type of surgery and stone characteristics. Laser energy can be delivered via flexible instruments.

Ureterorenoscopy

Ureterorenoscopes (URSs) are long thin scopes that are used to remove ureteric and renal stones. They have working channels that allow for the introduction of energy sources, graspers and baskets. Current models are either semirigid or flexible scopes. A semirigid URS is usually used with a pneumatic lithotripter or laser energy device. Complications include ureteric perforation, avulsion and retropulsion. Ureteric avulsion can be avoided by careful use of baskets under vision. URSs can also be used in patients with bleeding disorders, with a moderate increase in complications.

Christian G Chaussy, b. 1945, German urologist.

Retrograde intrarenal surgery

A slimmer and more flexible URS with active deflection of the tip and laser technology with thinner fibres allows for retrograde access to the kidney via the ureteric orifice. This procedure avoids the morbidity associated with percutaneous nephrolithotomy (PCNL). Laser is used as an energy source for stone fragmentation.

Indications for retrograde intrarenal surgery (RIRS)

- Renal stones <2 cm.
- Lower pole calculi.
- Obesity.
- Musculoskeletal deformities (e.g. kyphoscoliosis) and renal anomalies (HSK or pelvic kidney).
- Bleeding diathesis.

Percutaneous nephrolithotomy

PCNL involves removal of renal stones by creating a track between the skin and the pelvicalyceal system. Typically, this procedure is done in the prone position. Fluoroscopy or US is used for localisation. The posterolateral calyx is commonly chosen for entry. US in conjunction with pneumatic and laser lithotripsy is the most common energy source used. Complications include bleeding, infection and pleural violation in cases of supracostal puncture. Severe bleeding may require selective angioembolisation.

Indications for percutaneous nephrolithotomy

- Renal stones >2 cm.
- Lower pole renal stones with anatomy that is unfavourable for SWL.
- Failed SWL or RIRS for renal calculi.
- Staghorn calculi.

Contraindications to percutaneous nephrolithotomy

- Pregnancy.
- Untreated UTI.
- Bleeding diathesis.
- Current anticoagulation.

Miniaturised percutaneous nephrolithotomy

Miniaturised PCNL (e.g. mini-perc) involves the use of smaller access tracks. The standard PCNL access track is >28Fr compared with miniaturised versions using <22Fr tracks. Miniaturised PCNL is most useful in patients with a smaller stone burden and in children.

Lateral and supine PCNL are associated with fewer anaesthetic complications. Moreover, concomitant flexible ureteroscopy for endoscopic combined intrarenal surgery can be done to address complex renal stones, multiple stones or stones in challenging locations.

Non-endourological surgical management

Open surgery such as pyelolithotomy and anatrophic nephrolithotomy is reserved for complex and infected stones with anatomical abnormalities.

Prevention of recurrent stone disease

High-risk stone formers should be advised to follow preventive measures to reduce recurrence. General measures advised to all patients include:

- fluid intake of more than 2.5 litres per day;
- dietary calcium should not be restricted; supplemental calcium, if necessary, should be taken at meal times;
- reduce intake of animal protein and salt.

Pregnancy

Renal colic is the leading cause of non-obstetric hospital admission in pregnancy.

The physiological changes that take place during pregnancy include an increase in glomerular filtration rate by 50%; increased excretion of calcium, uric acid and sodium; and increased excretion of inhibitors of crystallisation such as citrate and magnesium. Urine pH is alkaline and so the predominant stone type seen in pregnancy is calcium phosphate stones.

US is the primary mode of investigation for renal colic. MRI can be used as a second-line investigation to define the level of obstruction.

Most stones pass spontaneously. However, stones can cause loss of pregnancy and premature labour. Hence, emergency ureteroscopy is a reasonable first-line option in well-selected distal ureteric stones. Internal stenting or PCN can be used in the interim and a definitive procedure can be planned following childbirth. Pregnancy is an absolute contraindication to SWL.

Children

See also *Chapter 20*.

Stones are rare in children. Childhood urolithiasis is more common in males in the first decade and in young adolescent females. Calcium oxalate stones are the most common variety. Genetic disorders are seen in 17% of children with stones. They may be asymptomatic or may present with non-specific symptoms such as crying, irritability and vomiting. Diagnosis and treatment should be planned such that ionising radiation is kept to a minimum. Indications for various modes of treatment are similar to those for adults.

Summary box 82.4

Urolithiasis

- Causes of stone formation are multifactorial, including age, gender, ethnic origin, family history, environmental factors, geography and diet
- Ureteric colic is the most common acute presentation. NCCT is the investigation of choice
- Decreased animal protein intake, decreased salt intake and adequate fluid intake are necessary to prevent recurrence
- Complete removal and long-term antibiotics are important to prevent recurrence of infection stones

TRAUMA TO KIDNEYS AND URETERS

Renal trauma

Kidneys are retroperitoneal structures; they are relatively fixed by their vascular pedicles and are well protected by perinephric fat, strong posterior abdominal wall muscles and the lower rib cage. Renal trauma is usually a part of polytrauma and is present in only 5% of all trauma cases.

Mechanism of injury

Trauma may be penetrating or blunt, the latter being far more common. Common modes of injuries are head-on collisions in road traffic accidents, falls from height and contact sports. Sudden, rapid deceleration can cause avulsion injury to the ureters at the PUJ or renal pedicle. Penetrating injuries cause direct tissue disruption and are usually associated with adjacent organ injuries.

Presentation

Patients with polytrauma may present with loss of consciousness and haemodynamic shock because of associated injuries. Haematuria – gross or microscopic – is pathognomonic of renal trauma; however, its absence does not exclude serious renal trauma. Similarly, the severity of renal trauma does not correlate with the degree of haematuria. Trauma causing lower rib fractures with or without vertebral fractures and abdominal pain with flank contusions should raise suspicion about the underlying renal injury and should be evaluated further.

Management

CECT of the abdomen is necessary to delineate the type and extent of renal injury. It provides information about the presence of parenchymal laceration, its depth, extension into the pelvicalyceal system and the extent of urinary extravasation (***Figure 82.11***). It also provides valuable information about other abdominal injuries and the status of the contralateral kidney. Based on the CECT, renal injuries are classified according to the renal injury scale of the American Association for the Surgery of Trauma (***Figure 82.12***).

Common indications for CECT in abdominal trauma include:

- abdominal trauma with gross haematuria;
- microscopic haematuria with hypotension (systolic <90 mmHg);
- rapid deceleration injury;
- children with microscopic haematuria (>5 red blood cells [RBCs]);
- all penetrating injuries.

Conservative management with close surveillance is sufficient in the majority of cases of isolated renal trauma. Lower grade injuries, sometimes including grade IV, can be managed conservatively with bed rest, antibiotics in case of penetrating injuries and serial haemoglobin estimation. Reimaging is usually done after 2–4 days in cases of falling haemoglobin levels, fever or expanding flank mass. Persistent urinary leak can be managed with an internal DJ stent or PCN.

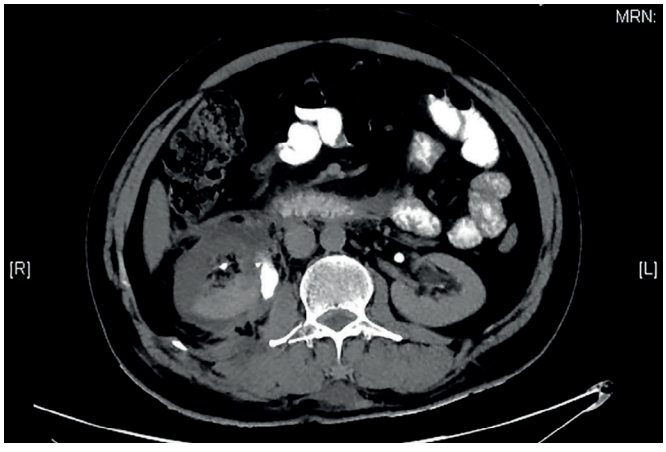

Figure 82.11 Axial image showing pelviureteric injury with contrast in the peripelvic region (courtesy of Department of Urology, Christian Medical College, Vellore, India).

Indications for emergency surgical exploration are:

- expanding or pulsatile retroperitoneal haematoma;
- PUJ avulsion;
- renal pedicle injury;
- haemodynamic instability.

Ureteral trauma

Most ureteral injuries are iatrogenic and occur during surgery near the ureter. Gunshot or penetrating injuries to the abdomen can cause ureteric injury. Management of ureteral injuries as a result of external trauma is dictated by the severity of trauma and associated visceral injuries.

Iatrogenic ureteral injury

The overall incidence of iatrogenic ureteral injury varies between 0.5% and 1.0%. Hysterectomy accounts for most of these cases, followed by ureteroscopy. Common sites of injuries to the pelvic ureter are at the pelvic brim, where it might be injured while ligating the infundibulopelvic ligament; at the bifurcation of the common iliac artery, while ligating the internal iliac artery; or at the paracervical region, while developing the ureteric tunnel or while clamping and dividing the upper vagina.

During open surgery, ureteral injury may be identified intraoperatively. However, most injuries (70–80%) are identified postoperatively. The postoperative course of these patients can be difficult and presentation may include abdominal pain, fever or sepsis. It is not uncommon to miss ureteric injuries; if left unrecognised, they can lead to significant morbidity, such as formation of urinoma, abscess, ureteral stricture and urinary fistula.

Management of iatrogenic ureteral injury

Triphasic abdomen and pelvic CECT is the imaging modality of choice. The choice of treatment is based on the location, type, extent and timing of presentation. If an injury is recognised intraoperatively or in the immediate postoperative period, it should be surgically repaired immediately. The viability of the

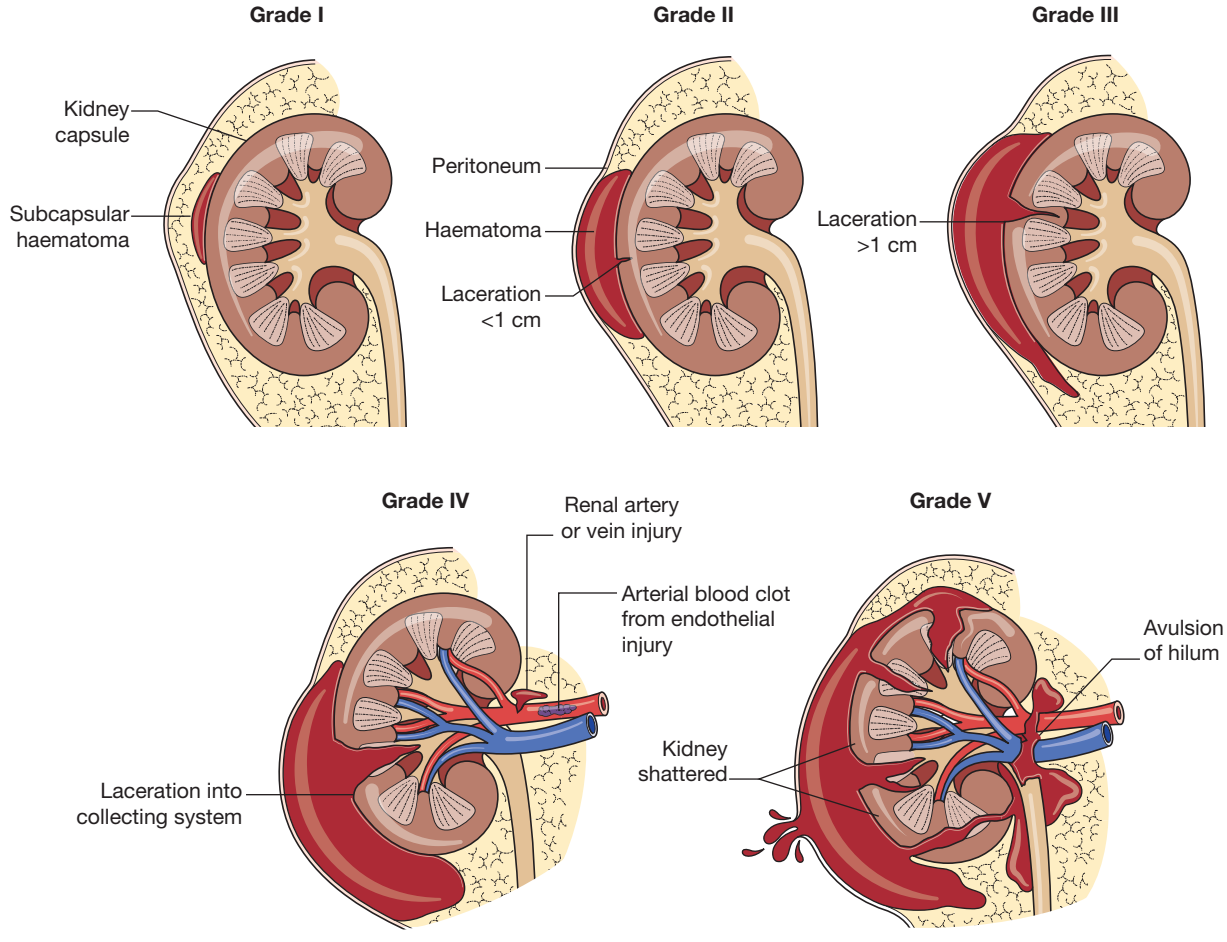

Figure 82.12 Classification of renal trauma.

ureter must be assessed. In cases of contusion, DJ stenting must be performed. In cases of partial transection, primary repair over a DJ stent may be performed. A tension-free spatulated ureteric anastomosis using fine absorbable sutures can be done for short segment loss. This is usually done in upper ureteric injuries (***Figure 82.13***). Longer segment loss, especially in the pelvic ureter, is managed by ureteroneocystostomy with or without a Boari flap. Longer defects up to 15 cm can be repaired by mobilising and hitching the bladder to the psoas major muscle (psoas hitch) with a Boari flap (***Figure 82.14***). Transureteroureterostomy (anastomosing the injured ureter to the contralateral ureter) can be an option in selected situations.

Delay in diagnosis would result in late presentation and delay the definite repair by 2–3 months to allow resolution of urinoma and periureteric inflammation. In such situations an initial endourological approach either with a retrograde ureteric stent or with PCN would decrease the morbidity associated with urinoma and help to preserve renal function.

Summary box 82.5

Urinary tract trauma

- Suspect renal injury in abdominal trauma in adults with modes of injury such as sudden deceleration, penetrating injury directed towards the renal bed, hypotension and haematuria and in children
- Triphasic (arterial, nephrogenic and delayed phase) CT is the investigation of choice to diagnose and grade urinary tract injury in a haemodynamically stable patient
- Most grade I–IV renal trauma (including penetrating injuries) can be managed conservatively
- Most ureteric injuries are iatrogenic and prompt diagnosis will prevent morbidity

TUMOURS OF THE KIDNEYS AND URETERS

Upper tract urothelial cancer

Primary urothelial neoplasms of the renal pelvis and ureter are rare. They account for less than 10% of all urothelial tumours. They are more common in adult men. Important risk factors are tobacco consumption, occupations in the dye, petrochemicals and rubber industries, analgesic abuse, high arsenic content in drinking water, exposure to cyclophosphamide and the presence of chronic inflammation. Chronic inflammatory conditions are also associated with squamous cell carcinoma.

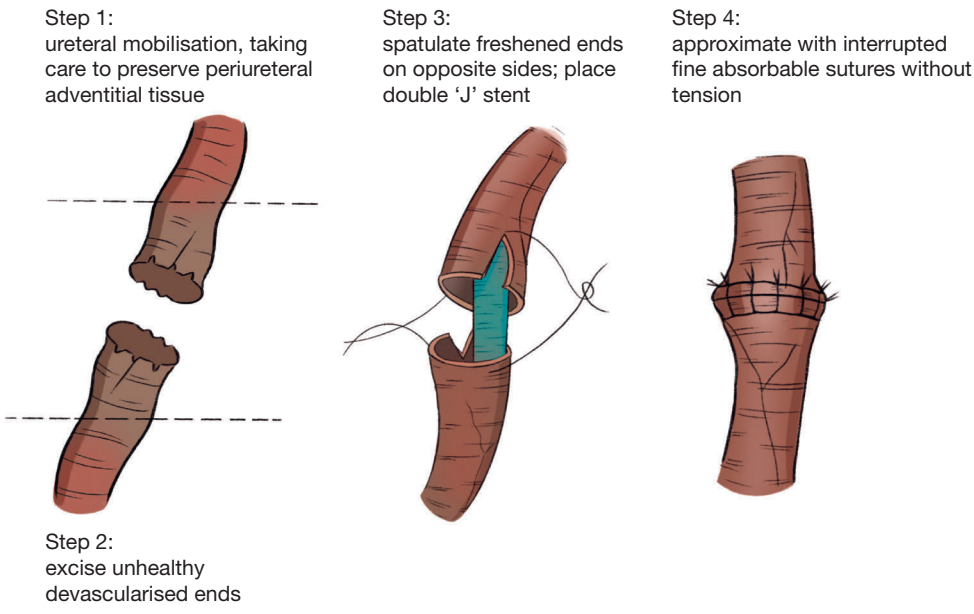

Figure 82.13 Technique for upper ureteric injury repair. Steps 1 and 2: freshen the devascularised edges. Step 3: spatulate both ends and place an internal double J stent. Step 4: approximate both ends with interrupted absorbable sutures (courtesy of Nivedita Kekre and Dr Madhuri Sadanala).

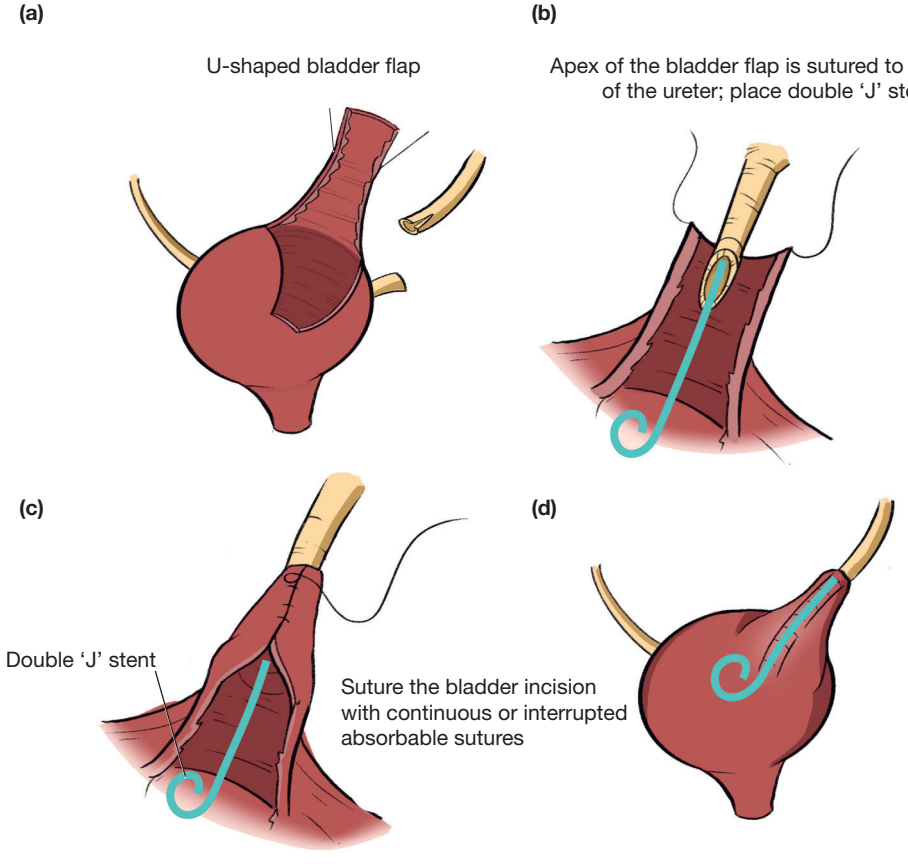

Figure 82.14 Steps of Boari flap creation. **(a)** U-shaped bladder flap. **(b, c)** The apex of the bladder flap is sutured to the ureteric end and an internal DJ stent is placed in the ureter with a distal loop in the bladder. **(d)** Suture the bladder incision with absorbable sutures (courtesy of Nivedita Kekre and Dr Madhuri Sadanala).

Presentation

Patients commonly present with gross haematuria, with or without flank pain and occasionally clot colic. Passage of long, slender, worm-like clots is suggestive of upper tract involvement. Patients with known bladder tumours should always be screened for upper tract tumours. Very few present with advanced constitutional symptoms and a palpable mass. Microscopic haematuria should be evaluated to exclude urothelial malignancy in the high-risk adult (chronic smokers, occupational exposure, older age) population.

Pathology

Both the PCS and the ureter have a thinner muscular layer than the bladder. Therefore, aggressive tumours of the upper tract can easily invade the muscle layers; hence, the prognosis is poor. Most of these tumours are caused by a field change; hence, tumours tend to be multifocal and may be associated with carcinoma *in situ* (CIS) in normal-looking urothelium. This also explains the higher incidence of recurrence of tumours in the bladder after successful treatment of upper tract disease. Therefore, long-term bladder follow-up with cytology and cystoscopy is necessary.

Histological grading is of great prognostic significance. Low-grade tumours follow a relatively benign course with multiple recurrences. High-grade tumours are potentially invasive with a poor prognosis. Histological variants, such as micropapillary, neuroendocrine, sarcomatoid and squamous tumours, have a worse prognosis.

Urothelial tumours can invade surrounding tissues, metastasise to regional lymph nodes and spread haematogenously to lungs, liver and bones.

Squamous cell and adenocarcinoma are rare non-urothelial malignancies involving the upper tract. They usually present at an advanced state and have a very poor prognosis. Squamous cell carcinoma occurs predominantly in the renal pelvis.

Diagnosis

Urinalysis may reveal numerous RBCs and white blood cells. Urine cytology should be obtained. The presence of atypical or malignant cells in a freshly voided sample has a high specificity for urothelial malignancies. CTU, cystoscopy, retrograde pyelogram and flexible ureterorenoscopy are required for diagnosis.

CTU is the investigation of choice. Findings suggestive of urothelial carcinoma are radiolucent filling defects, incomplete visualisation of calyces and the presence of hydronephrosis. CT also provides important staging information about local spread and lymph node involvement. Flexible ureterorenoscopy may be used to visualise the ureter, renal pelvis and collecting system and to biopsy suspicious lesions. URS biopsies can determine tumour grade and help in planning treatment. Incorporation of narrow-band imaging and blue light have improved the diagnostic capability of ureterorenoscopy.

Staging

Staging of upper tract urothelial cancer is similar to that for urothelial bladder cancer by the TNM system.

Prognostic factors

Unifocal, small (<1 cm), low-grade disease with no evidence of invasion on CTU is characterised as a low-risk tumour. Upper tract urothelial cancers that invade the muscle wall usually have poor prognosis. The 5-year survival is <50% and <10% for pathologically proven T2/T3 and T4 tumours, respectively.

Management

The management depends upon the stage, grade and risk stratification.

Low-risk localised tumours may be managed with endoscopic ablation or segmental excision. Kidney-sparing surgery is important in patients with solitary kidney, renal insufficiency and synchronous bilateral tumours.

High-risk tumours warrant radical nephroureterectomy with bladder cuff resection with or without lymphadenectomy.

Locally advanced disease is usually treated with cisplatinum-based neoadjuvant chemotherapy to downstage the disease prior to surgical ablation. Adjuvant chemotherapy has been shown to improve survival.

Benign renal tumours

Incidental detection of renal lesions has increased owing to the widespread use of abdominal imaging. The lesions may be cystic or solid. Solid renal tumours should be considered malignant unless proven otherwise.

Renal oncocytoma

This derives its name from its cellular appearance on histopathology, where uniformly highly granular eosinophilic cytoplasm owing to abundant mitochondria (oncocyte) is seen. It accounts for around 5% of renal tumours. It appears as an enhancing mass on cross-sectional imaging and is difficult to differentiate from RCC. Both RCC and oncocytoma present at around the seventh decade and have a male preponderance. It coexists with RCC in approximately 10% of cases.

The characteristic radiological features on axial imaging are the presence of central stellate scarring and a spoke wheel appearance in the angiographic phase. Nephron-sparing surgery, such as partial nephrectomy, should be the preferred option, whenever feasible. The diagnosis is usually confirmed after removal. Histologically, it can be confused with chromophobe RCC, particularly the eosinophilic variant. They may be differentiated by the use of immunohistochemistry staining, where chromophobe RCC stains positive for cytokeratin-7.

Renal angiomyolipoma

Angiomyolipoma comprises a composite mix of fat tissue with dysmorphic blood vessels and smooth muscle. It is most often detected incidentally and has a female preponderance. Angiomyolipoma may be associated with syndromes such as the tuberous sclerosis complex or it may be sporadic in nature. Spontaneous acute haemorrhage into the mass can present with loin pain. Pregnancy is a potential risk factor for bleeding.

US shows a bright echogenic mass lesion on account of the high fat content. CT scan shows an intralesional fat density of −15 to −20 Hounsfield units (HU) within the mass, which

is the hallmark of an angiomyolipoma radiological diagnosis. Management depends upon the size of the tumour, the risk of haemorrhage and the symptoms. Tumours <4 cm can be followed up. Nephron-sparing surgery such as partial nephrectomy is the preferred option. Angioembolisation is the preferred modality of choice in the setting of acute haemorrhage. Drugs that inhibit this pathway (mTOR pathway), such as everolimus and sirolimus, have recently been shown to have excellent response rates in this subgroup of patients with the tuberous sclerosis complex who have activation of the tumorigenic mTOR pathway.

Juxtaglomerular cell tumour

These are extremely rare tumours that occur at a young age, often presenting with hypertension and hypokalaemia with high renin levels. These tumours are unique in that hypertension resolves with surgery.

Renal cell carcinoma

RCC is the most common solid neoplasm of the kidney. It accounts for around 90% of renal tumours and constitutes 2–5% of all cancers in adult men and 1–3% in adult women. There has been a recent steady increase in the incidence of RCC. It may be sporadic or familial.

Familial renal cell carcinoma

von Hippel–Lindau (VHL) syndrome is the most common familial syndrome associated with RCC.

VHL disease is a rare autosomal dominant disorder that is characterised by multiple pathologies, including clear-cell RCC (ccRCC), phaeochromocytoma, retinal angiomas and haemangioblastomas of the brainstem, cerebellum or spinal cord.

Aetiology

Cigarette smoking, obesity and hypertension are the major risk factors associated with RCC. Others include diuretics, occupational exposure to petrochemicals and dyes and ARCD in patients on long-term haemodialysis.

Clinical presentation

The classic triad of flank pain, haematuria and a palpable mass is now uncommon as most renal masses are detected incidentally. Symptoms and signs may be non-specific. The most common presenting symptom is haematuria. Patients may have constitutional symptoms such as fever, malaise and weight loss in advanced disease. Advanced disease can present with bilateral lower limb oedema or recent-onset non-reducing right-sided varicocele owing to thrombus in the IVC.

Paraneoplastic syndromes (PNSs) are found in up to one-third of patients with RCC. The most common PNS is an elevated erythrocyte sedimentation rate (ESR) followed by hypertension, anaemia and hypercalcaemia. Up to a quarter of the patients may have evidence of metastatic disease on presentation. The most common site of metastasis is the lung and is classically described as **cannon ball** metastases. Metastases may occasionally present as pathological fractures.

Pathology

ccRCC is histologically an adenocarcinoma arising from the proximal renal tubular epithelium. They are slow growing and bulge out of the renal contour (***Figure 82.15***). Most are solitary, but bilateral and multiple tumours are found in familial RCC. The prognosis of ccRCC varies depending on various histopathological features, such as nuclear grading. Other histological variants are papillary RCC, chromophobe RCC and, rarely, collecting duct carcinoma and renal medullary carcinoma. ***Table 82.2*** summarises the salient features of subtypes of RCC.

The tumour can spread directly, invading the perinephric tissue through the capsule or at times directly extending into the renal vein as a tumour thrombus. Vein wall invasion is associated with poor prognosis.

Diagnosis

Laboratory findings

Evaluation should include blood count, ESR, serum creatinine, liver function tests, lactate dehydrogenase (LDH), corrected serum calcium, coagulation markers and urine analysis. Increased alkaline phosphatase should prompt further investigation to rule out liver and skeletal metastases. LDH is useful in risk stratification of metastatic disease.

Figure 82.15 Cut surface of a kidney showing a large, well-demarcated clear-cell renal cell carcinoma in the upper pole with foci of yellowish areas signifying the lipid content of the tumour (courtesy of Dr Vikram Raj Gopinathan, Department of Pathology; photo credit: Sekhar, Christian Medical College, Vellore, India).

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany, first described angiomas in the eye in 1904.
Arvid Vilhelm Lindau, 1892–1958, Swedish pathologist, described angiomas of the cerebellum and spine in 1927.

TABLE 82.2 Classification and salient features of subtypes of renal cell carcinoma (RCC).

RCC subtype	Salient features
Clear-cell RCC	• Most common subtype • Usually sporadic • May be associated with loss of chromosome 3p and a mutated von Hippel–Lindau gene
Papillary (type I and II) RCC	• Second most common • Usually sporadic but may be familial • Type 1 tumour has a better prognosis than type 2
Chromophobe RCC	• Usually sporadic but may be familial • Good prognosis
Collecting duct carcinoma	• Uncommon (1–2%) • Aggressive tumour • Arises from the renal medulla, hence centrally located tumour
Renal medullary carcinoma	• Rare (<0.5%) • Very aggressive • Associated with a younger age and sickle cell trait • Centrally located tumour

Radiological investigations

Although US can diagnose the tumour, triphasic CECT is the investigation of choice for diagnosis and staging. RCC typically shows contrast enhancement after contrast injection (a change of >15 HU is considered significant). The CT also provides additional information on the function of the opposite kidney, primary tumour extension, venous involvement, enlargement of regional lymph nodes, the status of the adrenal glands and intra-abdominal metastatic disease (***Figure 82.16***). MRI provides similar information to CT, but can be superior at detecting tumour infiltration into the vein wall and the level of thrombus.

A chest radiograph should be obtained in all cases. A bone scan is necessary in a patient with elevated alkaline phosphatase, bone pain or hypercalcaemia.

Figure 82.16 Contrast-enhanced computed tomogram showing a left renal mass with left renal vein thrombus extending into the inferior vena cava (IVC) (hypoattenuated linear area within the IVC) (courtesy of Department of Urology, Christian Medical College, Vellore, India).

Tumour staging

The treatment and prognosis of RCC depends on its pathological staging. The most important factors are the size of the tumour and whether it is confined within the renal capsule and Gerota's fascia. Involvement of the lymph nodes, renal sinus and vein wall are associated with a poorer prognosis than the presence of tumour thrombus in the renal vein or IVC. Currently the most commonly used system for staging RCC is the TNM classification (***Figure 82.17***).

Prognostic factors

Currently, the grading system proposed by the International Society of Urological Pathology (WHO/ISUP) is used for grading renal cancer. Anatomical factors such as tumour size, venous invasion, renal capsular invasion and adrenal involvement herald a poorer prognosis. Certain histological types, e.g. sarcomatoid, have a worse prognosis.

Management

Nephron-sparing surgery

Radical nephrectomy remains the gold standard treatment for localised disease. However, with the recent increase in incidental detection of small renal masses (tumours <4 cm), more nephron-sparing surgery is being performed. Partial nephrectomy should be the treatment of choice in tumours less than 4 cm, in well-selected tumours between 4 and 7 cm, in bilateral tumours, in tumours in solitary kidneys and in patients with pre-existing renal dysfunction. Minimally invasive techniques by laparoscopy or robots have reduced postoperative morbidity. Because of the limitation of ischaemia time, minimally invasive techniques should be reserved for tumours with non-complex anatomy, as predicted by nephrometry scores.

Alternative techniques such as surveillance, cryoablation or radiofrequency ablation of small renal tumours may be offered in patients with high surgical risk (e.g. elderly patients, patients with multiple comorbidities). Active surveillance is based on the fact that most incidental tumours detected in the elderly grow slowly and have a low chance of local invasion or metastasis.

Radical nephrectomy

Classically, radical nephrectomy involved removal of the entire kidney enclosed in Gerota's fascia with the ipsilateral adrenal gland and regional lymphadenectomy. Most are now performed laparoscopically and the adrenal is spared if there is no involvement on CT/MRI. Lymphadenectomy is indicated only in high-risk patients with large primary tumours and enlarged lymph nodes.

Dimitrie D Gerota, 1867–1939, Romanian anatomist, physician and radiologist.

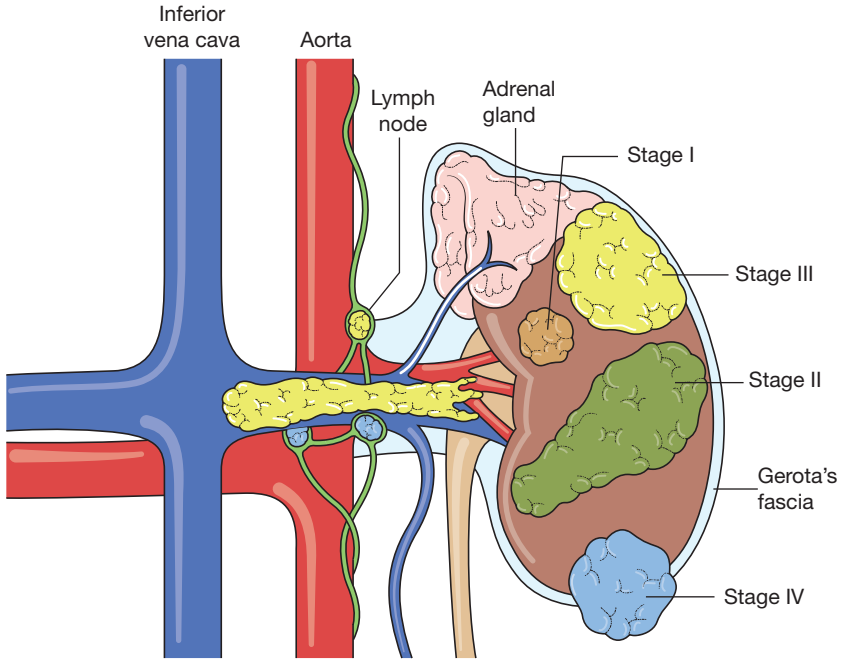

Figure 82.17 Staging of renal cell carcinoma is based on size, position and lymph node involvement:
Stage I: tumour <7 cm in the largest dimension, limited to the kidney.
Stage II: tumour >7 cm in the largest dimension, limited to the kidney.
Stage III: tumour in the major veins or adrenal gland with intact Gerota's fascia, or regional lymph nodes involved.
Stage IV: tumour beyond Gerota's fascia.

Surgical management of inferior vena cava thrombus

Renal tumours are associated with IVC tumour thrombus in 5–10% of cases. Tumour thrombus may extend as far as the right atrium. Thrombus extending to the retrohepatic or suprahepatic segment of the IVC requires full mobilisation of the liver, and thrombus extending to the right atrium may require cardiopulmonary bypass and circulatory arrest.

Management of metastatic renal cell carcinoma

Up to one-third of patients with RCC will present with disseminated disease. The International Metastatic Renal Cell Carcinoma Database Consortium risk stratification classifies a patient with metastases into risk groups based on performance status, time from diagnosis to systemic therapy, haemoglobin levels, calcium levels and platelet and neutrophil counts. The median survival of the good risk group is little more than 3.5 years, compared with just under 2 years in the intermediate-risk group. The expected median survival of the poor risk group is just over 7 months.

Tyrosine kinase inhibitors inhibit vascular endothelial growth factor (e.g. sunitinib, pazopanib) and these drugs have improved survival in metastatic ccRCC. RCC is an immunogenic tumour and responds to immunotherapy. The first generation of agents were interleukins and interferons. More recently, targeted therapy in the form of immune checkpoint inhibitors and anti-programmed death 1/programmed death ligand-1 inhibitors have been used.

Cytoreductive nephrectomy may be beneficial in good and intermediate-risk patients. Palliative nephrectomy may be considered for intractable haematuria, pain and symptomatic PNS. Angioembolisation of renal tumour can be performed in medically unfit patients with intractable haematuria.

Wilms' tumour

See also *Chapter 17*.

This is the most common tumour of childhood, accounting for 5% of all childhood cancers. They are bilateral in 5% of cases and familial in 1%. The tumour has mixed elements derived from the embryonic nephrogenic tissue, namely blastemal or undifferentiated tissue, epithelial tubules and stroma. The typical presentation is a child aged between 1 and 4 years of either gender with a large, palpable abdominal mass that may cross the midline. It may also be associated with haematuria, hypertension, fever and weight loss. Pain is relatively uncommon. The large tumour can rupture and present as an acute abdomen. Other causes of renal masses include neuroblastoma, congenital mesoblastic nephroma, RCC, clear-cell sarcoma and rhabdoid tumour.

US can confirm the renal origin and solid nature of the mass. Further definitive imaging with either CECT or MRI is necessary to stage the disease. Up to 13% of patients have bilateral tumours. The tumours usually infiltrate the kidneys and normal renal parenchyma is compressed at the periphery around the tumour (**claw sign**). A CT of the chest should be obtained as the lung is the most common site of distant metastasis. Current treatment is nephrectomy with pre- or postoperative chemotherapy. Both regimes have a comparable survival of ~90%.

Summary box 82.6

Tumours of the kidney and ureters

- Rule out urothelial malignancy in high-risk adults (chronic smokers, occupational exposure, older age) with microscopic haematuria
- Nephron-sparing surgery should be considered in small renal masses to preserve renal function, more so in patients with compromised renal function
- PNSs are found in up to 30% and IVC tumour thrombus in 5–10% of patients with RCC
- Targeted therapy and immunotherapy have improved survival in metastatic RCC
- Wilms' tumour is the most common renal tumour in children <15 years old and should be treated in a multidisciplinary setting

PART 12 | Genitourinary

CHAPTER

83 The urinary bladder

Learning objectives

To describe:

- The anatomical, embryological and pharmacological features of the bladder
- The physiology of micturition and the neurological basis of lower urinary tract function
- The clinical features, investigations and principles of management of congenital anomalies of the bladder
- The clinical features, investigation and principles of management of urinary incontinence
- The principles of management of acute and chronic retention of urine
- The indications and technique of urethral and suprapubic bladder catheterisation
- The causes, investigations and principles of management of bladder diverticula and bladder stones
- The clinical features, investigations and principles of management of urinary tract infections and chronic inflammatory bladder diseases
- The causes, investigations and principles of management of haematuria
- The clinical features, investigations and principles of management of bladder cancer
- The clinical features, investigations and principles of management of bladder trauma

To describe and distinguish:

- Based on the clinical presentation, the types of bladder dysfunction associated with diseases of the central nervous system

APPLIED ANATOMY OF THE BLADDER

Arterial supply

- Superior vesical artery (from the umbilical artery, which arises from the internal iliac artery).
- Inferior vesical artery (directly from the anterior division of the internal iliac artery, or in females from the vaginal artery, which arises from the internal iliac artery).
- Division of the contralateral superior vesical pedicle can aid cephalad mobilisation of the bladder for psoas hitch procedures.

Venous drainage

Vesical plexuses on the lateral and inferior surfaces of the bladder drain into the internal iliac vein (the prostatic plexus in males and the vaginal plexus in females are continuous with the vesical plexus).

Lymphatics

- Internal iliac, hypogastric, obturator and external iliac chain of nodes.
- Pelvic lymphadenectomy for bladder cancer should include complete clearance of all these nodes.

Fascia and ligamentous supports

- At the posterolateral bladder neck, condensations of fascia pass forward medially and laterally to the ureter to join with the prostatic fascia; this fascia needs to be divided during cystectomy.
- The puboprostatic ligaments are well-defined condensations of the anterior endopelvic fascia; they stretch from the front of the prostate to the periosteum of the pubis and lie lateral to the dorsal vein complex.
- The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying them, are called the median and lateral umbilical ligaments.
- Condensations of fascia also occur around the superior and inferior vascular pedicles.
- The pelvic floor organs are supported by the pelvic floor muscles, which predominantly consist of the levator ani group of muscles. The muscles are covered by endopelvic fascia, which attaches the vagina to the pelvic sidewall and is thickened laterally as the arcus tendineus fascia pelvis (ATFP). The ATFP lies medial to the obturator internus and is an important landmark into which sutures are placed for pelvic organ prolapse surgery.

Bladder

The urinary bladder is a hollow muscular organ that consists of three principal layers: lamina propria, smooth muscle and

TABLE 83.1 Spinal and peripheral innervation of the lower urinary tract.

Nervous system	Origin	Course	Neurotransmitter	Receptor	Action on bladder	Action on bladder outlet
Sympathetic	T10–L2 (thoracolumbar cord)	Hypogastric nerve	Noradrenaline (norepinephrine)	• β3-adrenergic (bladder)	• Relaxation of detrusor smooth muscle	Contraction of smooth muscle of urethra and bladder base
				• α_1-adrenergic (urethra and bladder neck)	• Inhibition of parasympathetic ganglia, thereby inhibiting detrusor contraction	
Parasympathetic	S2–4 (sacral cord 'spinal micturition centre')	Pelvic nerve	Acetylcholine	M3 (smooth muscle of bladder)	Contraction of the detrusor smooth muscle	None
Somatic	S2–4 (sacral cord 'Onuf's nucleus')	Pudendal nerve	Acetylcholine	Nicotinic (striated muscle of external urethral sphincter)	Afferent sensory nerves (stretch, temperature and pain)	Contraction of external urethral sphincter

urothelium. The lamina propria contains a rich plexus of vessels, nerves and lymphatics. The detrusor is made up of a complex haphazard arrangement of smooth muscle, which acts as functional syncytium, and elastic connective tissue, which gives the bladder its viscoelastic properties. The urothelium is an active layer that not only acts as a barrier to protect underlying stroma from irritant urinary toxins and bacteria but also has a role in afferent signalling within the bladder; defects in the urothelial lining are thought to lead to several chronic benign bladder conditions.

The bladder is made up of the bladder body (the area above the level of the ureteric orifices), the bladder base/trigone (the area below the level of the ureteric orifices) and the bladder neck smooth muscle.

INNERVATION OF THE BLADDER

The lower urinary tract (LUT) is innervated by sympathetic, parasympathetic and somatic afferent and efferent nerves, under higher control from the cerebral cortex and pontine micturition centre (PMC). The actions of the spinal and peripheral nerves on the LUT are summarised in ***Table 83.1***.

Coordination of the micturition process is performed by the PMC in the brainstem and is under the control of higher centres in the cortex, thalamus and hypothalamus, which play an important role in delaying voiding until it is socially convenient.

APPLIED PHARMACOLOGY OF THE BLADDER

The two predominant neurotransmitters controlling LUT function are acetylcholine and noradrenaline (norepinephrine). Acetylcholine from the somatic nervous system causes contraction of striated muscle by activating nicotinic receptors, whereas acetylcholine from parasympathetic nerves causes detrusor smooth muscle contraction by activating muscarinic receptors. Noradrenaline is released from the sympathetic nervous system and activates β_3-adrenergic receptors on the smooth muscle of the detrusor to cause relaxation and α_1-adrenergic receptors on the smooth muscle of the bladder base and urethra to cause contraction. The underlying second-messenger mechanisms by which smooth muscle contraction and relaxation occur are shown in ***Figure 83.1***. Smooth muscle contraction is dependent on calcium influx causing contraction via actin and myosin. Smooth muscle relaxation is dependent on calcium efflux back into the sarcoplasmic reticulum, mediated by the cyclic adenosine monophosphate and cyclic guanosine monophosphate pathways.

The commonly used agents, their principal actions and their side effects are summarised in ***Table 83.2***.

Antimuscarinics

There are five types of muscarinic receptor, M1–5, in various organs in the human body (heart, brain, salivary glands, eye, smooth muscle). Although the M2 receptor is most abundant in the bladder, it is the M3 receptor that binds acetylcholine to cause detrusor contraction. The most widely used pharmacological agents to improve bladder function in patients with neurogenic LUT dysfunction or idiopathic overactive bladder are muscarinic receptor antagonists (antimuscarinics).

Mechanism of action

Antimuscarinics reduce bladder storage pressures, treat detrusor overactivity and improve overactive bladder symptoms. Although commonly thought to exert their effect during the voiding phase by antagonising acetylcholine released from parasympathetic nerves and thereby reducing detrusor contraction, they are now thought to exert their primary effects

Onuf's nucleus refers to a group of motor neurones located in the anterior horn of the sacral (predominantly S2) spinal cord; it is named after Bronislaw Onuf-Onufrowicz, 1863–1928, who discovered this group of cells in 1899.

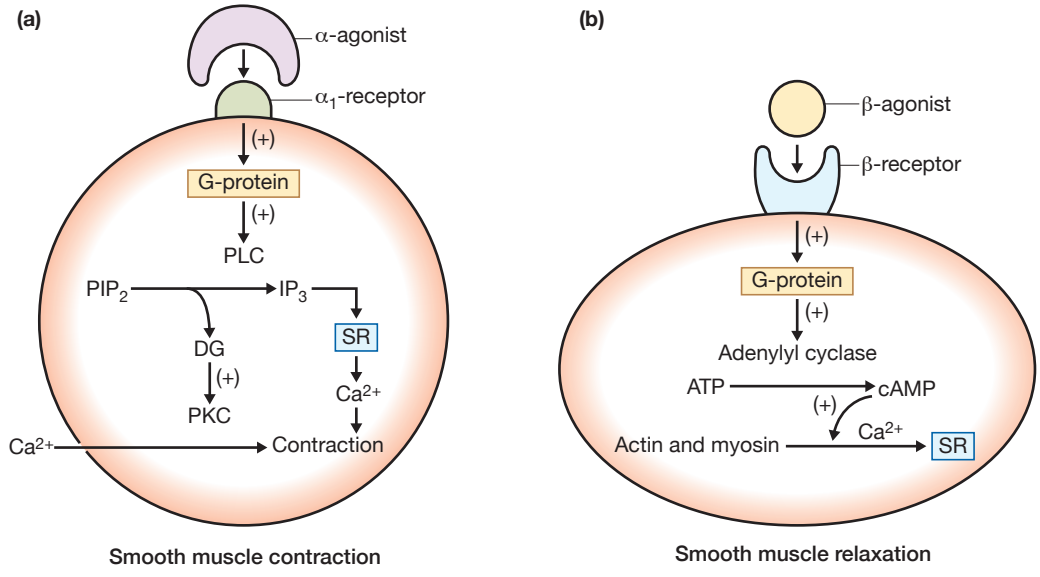

Figure 83.1 Second-messenger systems involved in **(a)** smooth muscle contraction and **(b)** smooth muscle relaxation. ATP, adenosine triphosphate; cAMP, cyclic AMP; DG, diacylglycerol; IP_3, inositol 1,4,5-trisphosphate; PIP_2, phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PLC, phospholipase C; SR, sarcoplasmic reticulum.

TABLE 83.2 Actions and side effects of commonly used pharmacological agents for the bladder.

Class	Examples	Action	Common side effects
Antimuscarinics	• Solifenacin • Oxybutynin • Tolterodine • Fesoterodine • Darifenacin • Trospium	• Reduce bladder storage pressure • Reduce detrusor overactivity • Improve functional bladder capacity	• Dry mouth • Dry eyes • Blurred vision • Constipation • Cognitive decline • Dizziness (postural hypotension) • Cardiac arrhythmia
β_3-agonists	• Mirabegron • Vibegron	• Reduce bladder storage pressure • Reduce detrusor overactivity • Improve functional bladder capacity	• Increased blood pressure • Headaches • Urinary tract infection • Nasal congestion
α_1-antagonists	• Tamsulosin • Alfuzosin • Doxazosin	• Reduce bladder outlet resistance from bladder neck and proximal/ prostatic urethra	• Dizziness (postural hypotension) • Ejaculatory dysfunction • Headache • Nasal congestion

in the storage phase of the micturition cycle. During the storage phase they act as antagonists of acetylcholine released from the urothelium, thereby decreasing activity in bladder afferent nerves and suppressing involuntary detrusor contractions and the sensation of urgency.

β_3-adrenoceptor agonists

β_3-adrenoceptor agonists are relatively new pharmacological agents that are used for the treatment of overactive bladder and neurogenic LUT dysfunction.

Mechanism of action

Similar to antimuscarinics, the β_3-agonists are thought to exert their principal effects during the storage phase of the micturition cycle by reducing bladder afferent activity. It is also thought that activation of β_3-adrenoceptors may downregulate acetylcholine release, resulting in inhibition of parasympathetic activity.

α_1-adrenoceptor antagonists

The α_1-adrenoceptor antagonists are commonly used to improve voiding lower urinary tract symptoms (LUTS) in men.

Mechanism of action

The α_1-receptors are densely prevalent at the bladder base, bladder neck and proximal urethra in males, and antagonism of these receptors inhibits sympathetic-mediated contraction of the bladder outlet, thereby reducing outlet resistance.

APPLIED PHYSIOLOGY OF THE BLADDER

The LUT consists of the bladder and urethra, and its two functions are urinary storage and urinary emptying. These functions depend on coordinated activity between the smooth and striated muscles of the bladder and the outlet (consisting of the bladder neck, urethral smooth muscle, external urethral sphincter and pelvic floor muscles), which is mediated by a complex of neural circuits in the central and peripheral nervous systems.

The micturition cycle

The key characteristics of the two phases of the micturition cycle are (***Figure 83.2***):

1 Urinary storage (filling):
- low pressure (normal compliance) – dependent on viscoelastic properties of the bladder wall and lack of parasympathetic input to the detrusor;
- normal sensation (absence of pain or urgency);
- absence of involuntary contractions (detrusor overactivity);
- a closed bladder outlet to enable continence – dependent on the sympathetic reflex, which increases outlet resistance (α-adrenergic stimulation), inhibits detrusor contractility (through inhibitory effect on parasympathetic ganglia) and reduces bladder smooth muscle tension (β_3-adrenergic stimulation).

2 Urinary emptying (voiding):
- coordinated detrusor contraction of appropriate strength and duration to enable complete bladder emptying – dependent on inhibition of the spinal sympathetic reflexes and activation of parasympathetic efferent pathways to the bladder;
- relaxation of the bladder neck and external urethral sphincter – dependent on inhibition of spinal sympathetic reflexes.

Disorders of the LUT can therefore be related to failure to store urine (due to the bladder or the outlet) or failure to empty (due to the bladder or the outlet).

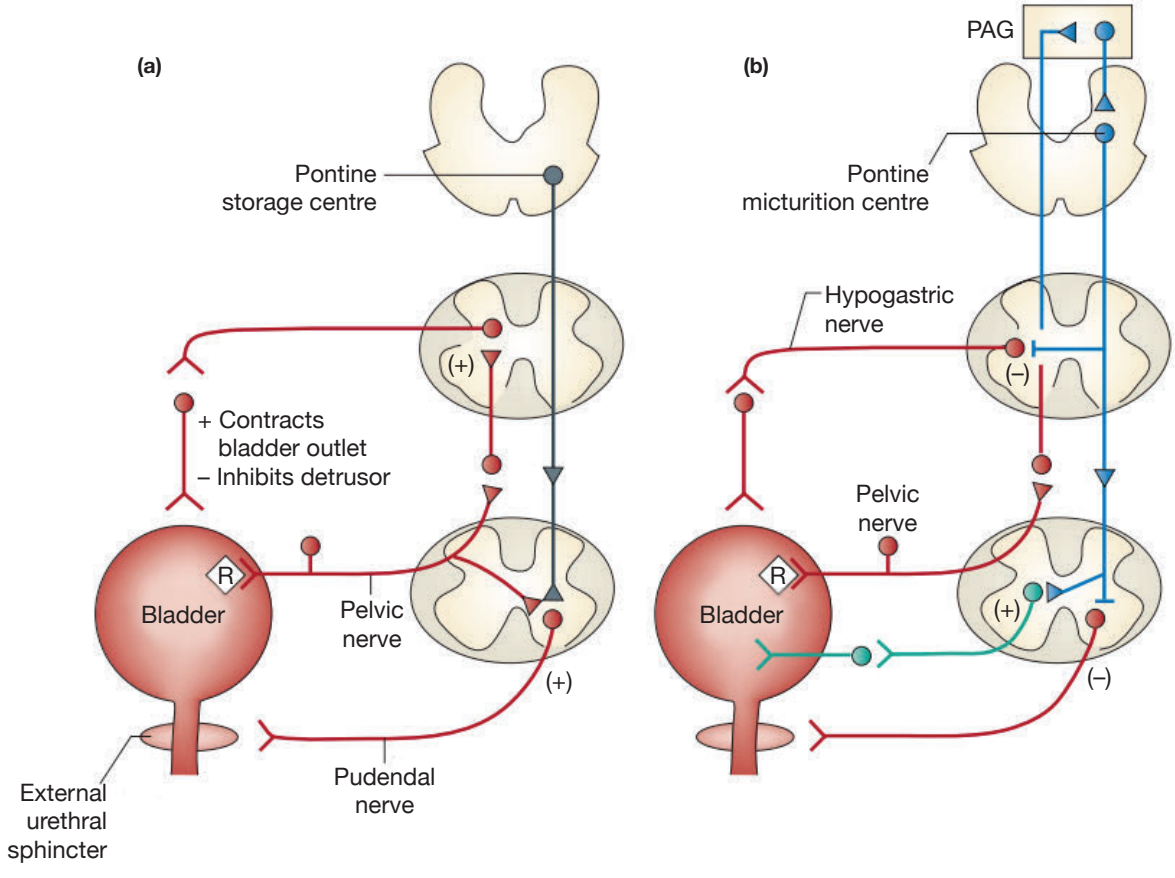

Figure 83.2 The micturition cycle and its neurological control. **(a)** Urine storage reflexes. During bladder filling, increased sympathetic nervous system and pudendal nerve activity leads to contraction of the bladder neck and external sphincter, and relaxation of the detrusor muscle. **(b)** Urine voiding reflexes. During voiding, the pontine micturition centre stimulates detrusor contraction through activation of the parasympathetic outflow to the bladder, with inhibition of sympathetic outflow to the bladder neck and external urethral sphincter. PAG, periaqueductal grey; R, receptor. (Reproduced with permission from Fowler CJ, Griffiths D, de Groat WC. The neural control of micturition. *Nat Rev Neurosci* 2008; **9**(6): 453–66.)

Neural control during the micturition cycle

Storage phase

The storage phase of the micturition cycle requires relaxation of the detrusor to ensure low-pressure filling, and contraction of the smooth and striated muscle of the bladder neck, urethra and external urethral sphincter to ensure continence. The higher centres in the cortex receive low-intensity afferent signals during bladder filling, which in turn induces the PMC to inhibit micturition by inhibiting parasympathetic innervation (resulting in detrusor relaxation) and activating somatic innervation (resulting in closure of the bladder outlet). Glutamate is the principal efferent neurotransmitter involved in activating the pudendal nerve through Onuf's nucleus. Detrusor relaxation and bladder outlet contraction are achieved through sympathetic β_3-noradrenergic activity, resulting in direct relaxation of the detrusor smooth muscle; inhibition of parasympathetic ganglia, resulting in indirect relaxation of the detrusor smooth muscle; and α_1-noradrenergic activity, resulting in contraction of the smooth muscle of the bladder neck and urethra. Furthermore, somatic cholinergic activity results in contraction of the striated external urethral sphincter.

Voiding phase

The voiding phase of the micturition cycle requires coordinated detrusor contraction and relaxation of the bladder outlet to ensure complete bladder emptying. When the desire to void is strong enough, the higher centres in the cortex receive high-intensity afferent signals from the bladder, which in turn switches the PMC to 'voiding' mode. The PMC then activates micturition by activating parasympathetic nerves and inhibiting somatic nerves (by cessation of the glutamate effect on Onuf's nucleus). This is achieved through parasympathetic cholinergic activity via M3 receptors, resulting in detrusor contraction, and central inhibition of somatic and sympathetic nerves, resulting in relaxation of the bladder outlet.

APPLIED EMBRYOLOGY OF THE BLADDER

The bladder originally develops from the cloaca, the endodermis-lined hindgut structure that is the common opening for the urinary, genital and gastrointestinal tracts. Between weeks 4 and 7 of gestation, the cloaca is partitioned into a ventral urogenital tract (the primitive urogenital sinus) and a dorsal anorectal tract by the urorectal septum (***Figure 83.3***). The portion of the primitive urogenital sinus that lies above the entry point of the mesonephric ducts becomes the vesicourethral canal, which gives rise to the bladder and pelvic urethra, whereas the portion of the urogenital sinus caudal to this entry point forms the bulbar and penile urethra in males and the vaginal vestibule in females. Initially, the superior end of the lumen of the bladder is continuous with the allantois, a sac-like structure that is responsible for embryonic nutrition and waste excretion. Between the fifth and seventh week of gestation the allantois is obliterated and becomes a fibrous cord, the urachus, which runs within the umbilical cord and drains the fetal urinary bladder. As the bladder descends into the pelvis during development, this fibrous cord elongates. Postnatally, this obliterated fibrous cord extends from the apex of the bladder to the umbilicus as the median umbilical ligament. The urachus acts as a landmark during radical cystectomy and can be traced to the apex of the bladder; identification of this structure can prevent early entry into a high-riding bladder, and the urachus is then removed en bloc with the bladder specimen.

CONGENITAL BLADDER ANOMALIES

Most congenital bladder anomalies can be detected on antenatal ultrasound after 10–13 weeks' gestation, when the bladder should be visualised in the majority of cases.

Congenital and acquired bladder diverticula

Bladder diverticula can be congenital or acquired (secondary to infravesical bladder outlet obstruction). Acquired bladder diverticula are most commonly seen in adult men with benign prostatic obstruction; acquired diverticula can less commonly be seen in children with infravesical obstruction (e.g. secondary to posterior urethral valves) or in children with neurogenic bladder associated with detrusor–sphincter dyssynergia (DSD).

Primary congenital bladder diverticula develop as a herniation of bladder mucosa through a congenital muscular defect between the intravesical ureter and the roof of the ureteral hiatus, the so-called 'Hutch' diverticulum. Congenital diverticula are therefore typically located in the vicinity of the ureteric orifice and may be associated with vesicoureteric reflux (VUR), both of which are thought to occur as a result of inadequate development of the musculature of the bladder wall or Waldeyer's fascia around the portion of the intravesical ureter, at

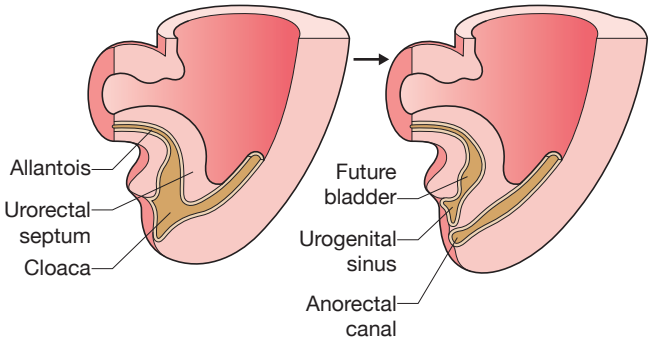

Figure 83.3 Partitioning of the cloaca to form the urogenital sinus and anorectal canal. (Redrawn with permission from Wein AJ, Kavoussi LR, Partin AW, Peters CA. *Campbell-Walsh urology*, 11th edn. Philadelphia, PA: Elsevier, 2016: 2834.)

John Hutch, 1922–1972, American urologist, described paraureteric bladder diverticula in 1961.
Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921, Professor of Pathological Anatomy, Berlin, Germany. Waldeyer's fascia is a layer of fascia that divides the retrorectal space into superior and inferior compartments; it was described by Waldeyer in 1899.

Figure 83.4 Cystogram showing a large bladder diverticulum.

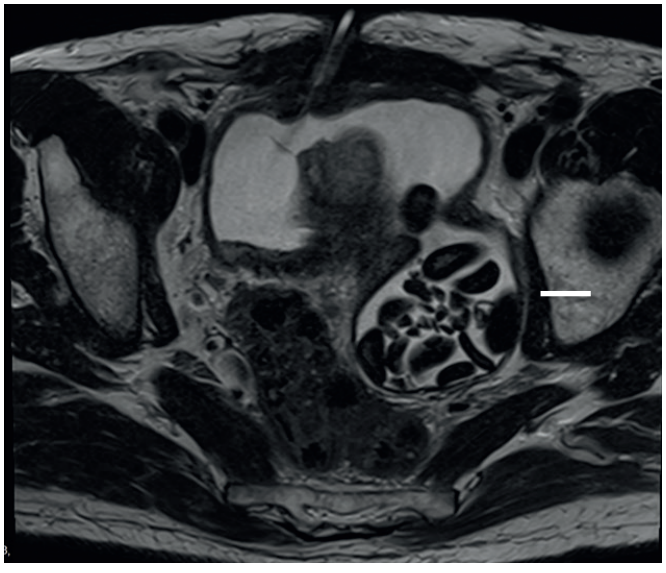

Figure 83.5 Magnetic resonance imaging scan showing a large left-sided bladder diverticulum containing stones (arrow).

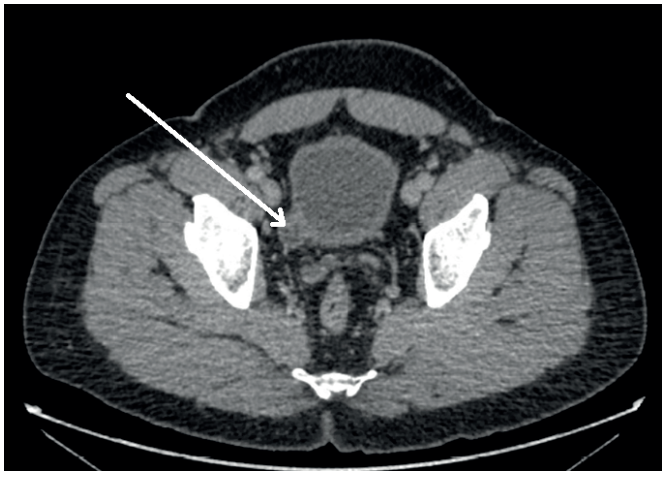

Figure 83.6 Computed tomography scan showing a bladder diverticulum containing soft-tissue material consistent with tumour (arrow).

the embryological junction of the ureteric bud and urogenital sinus. As opposed to acquired diverticula, intravesical pressures in those with congenital diverticula are not elevated and so the bladder is generally thin walled, without trabeculation or multiple diverticula. In adults with acquired diverticula, the intravesical pressures are often elevated, and the bladder is thick walled with trabeculations and multiple diverticula. The raised intravesical pressure causes the lining between the inner layer of hypertrophied muscle to protrude, forming multiple saccules. If a saccule is forced through the bladder wall, it becomes a diverticulum. The diverticulum is made up of mucosa with very few, if any, muscle fibre coverings. As a result, it does not contract to empty and therefore holds residual urine, which can lead to the complications described below (***Figure 83.4***).

Clinical features

Small congenital bladder diverticula are often asymptomatic. Haematuria (due to infection, stone or tumour) is a symptom in about 30%.

Common symptoms or complications include:

- recurrent urinary tract infections (UTIs);
- bladder stones (***Figure 83.5***);
- urinary retention – due to extrinsic compression of the bladder outlet by a large diverticulum;
- hydronephrosis – due to extrinsic ureteral compression by a large diverticulum;
- neoplasm (***Figure 83.6***) – account for 1% of all bladder tumours; the lack of a muscular layer to the diverticulum affects pathological staging of bladder tumours as there is, by definition, no T2 stage. Therefore, any invasion beyond the lamina propria in a bladder diverticular tumour should be staged as T3.

Investigation

The diagnosis is made on imaging (ultrasound, computed tomography [CT], magnetic resonance imaging [MRI] or cystogram) or through direct vision at cystoscopy (***Figure 83.7***). Bladder outlet obstruction should be confirmed with urodynamics if suspected.

Surgical treatment of bladder diverticula

Congenital bladder diverticula should only be treated if symptomatic, or if there is concern regarding malignant transformation. Bladder outlet obstruction should be excluded by flow rate or urodynamic studies prior to any surgical intervention, and this should be treated prior to consideration of bladder diverticulectomy. Even large diverticula do not require treatment if there is no evidence of bladder outlet obstruction and the patient is asymptomatic with none of the above complicating factors.

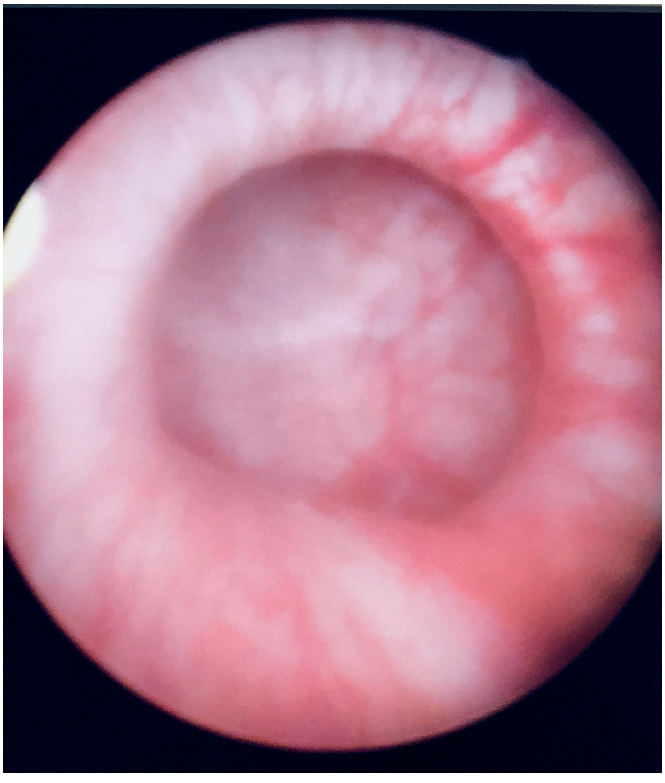

Figure 83.7 Bladder diverticulum seen cystoscopically.

Figure 83.8 Bladder diverticulum following excision.

Surgical excision of a bladder diverticulum can be performed through an open approach (Pfannenstiel or low midline abdominal incision) or through minimally invasive (laparoscopic or robotic) techniques. Depending on the proximity of the neck of the diverticulum to the ureteric orifice, patients should be counselled about the possible need for concomitant ureteric reimplantation. Repair can be performed purely extravesically, or through a combined extravesical and intravesical approach (***Figure 83.8***).

Summary box 83.1

Bladder diverticula

- Can be congenital or acquired
- Complications include infection, stones, renal obstruction and rarely malignancy
- Bladder outlet obstruction should be identified and, if present, treated prior to bladder diverticulectomy

Bladder exstrophy

Bladder exstrophy is a congenital disorder in which failure of development of the lower abdominal wall leads to an abdominal wall defect through which the bladder is exposed (***Figure 83.9***). Diastasis of the pubic symphysis and an anterior opening of the urethra (epispadias) can coexist. The condition forms part of a spectrum of conditions ranging from epispadias to bladder exstrophy or to more severe cloacal exstrophy, the so-called exstrophy–epispadias complex. During development, mesenchymal ingrowth between the ectodermal and endodermal layers of the cloacal membrane leads to formation of the lower abdominal wall muscles and pelvic bones. However, failure of this mesodermal ingrowth leads to premature rupture of the cloacal membrane and results in epispadias, bladder exstrophy or cloacal exstrophy depending on the developmental stage at which rupture occurs. The incidence of bladder exstrophy is approximately 1 in 46 000 live births, with a male-to-female ratio of 2.3:1.

Clinical features

Exstrophy of the bladder can be associated with a spectrum of anomalies affecting the external genitalia, urinary system, bony pelvis, abdominal wall, rectum and anus.

Male external genitalia

Shortened penis due to diastasis of the pubic symphysis resulting in wide separation of the crural attachments, and congenital deficiency of the corporeal tissue.

Female external genitalia

- Shortened, stenotic and anteriorly displaced vagina.
- Bifid clitoris.

Hermann Johann Pfannenstiel, 1862–1909, gynaecologist, Breslau, Germany (now Wrocław, Poland), described this 'bikini-line' suprapubic horizontal incision in 1900.

Figure 83.9 Bladder exstrophy. (Reproduced with permission from Wein AJ, Kavoussi LR, Partin AW, Peters CA. *Campbell-Walsh urology*, 11th edn. Philadelphia, PA: Elsevier, 2016: 2424.)

Urinary system

- Incompetent bladder neck continence mechanism.
- VUR due to lack of obliquity of the vesicoureteric junction.

Bony pelvis

- Widening (diastasis) of the pubic bones due to malrotation of the innominate bones, leading to a waddling gait.
- External rotation of the anterior and posterior segments of the bony pelvis, leading to outward rotation of the lower limbs.

Abdominal wall

- Low-set umbilicus with a triangular-shaped fascial defect of the lower abdominal wall.
- Higher incidence of indirect inguinal hernia owing to the lack of oblique muscle fibres of the inguinal canal and large internal and external inguinal rings.

Anorectum

- Shortened perineum and anteriorly displaced anus.
- Imperforate anus (absence of the normal anal opening) or rectal stenosis.
- Rectal prolapse.

Surgical treatment of bladder exstrophy

The aim of surgical treatment is to preserve renal function, achieve urinary continence and create functional and cosmetically acceptable external genitalia. The modern staged repair of exstrophy consists of bilateral iliac osteotomies with bladder exstrophy and abdominal wall closure in the neonatal period, followed by epispadias repair and phallic reconstruction at 6 months to 1 year of age, and finally bladder neck reconstruction and bilateral ureteric reimplantation (to treat VUR) at age 5–7 years. More recently, complete primary repair of exstrophy in the neonatal period has been advocated in an attempt to optimise outcomes with fewer procedures and without a formal bladder neck closure procedure.

Congenital neuropathic bladder

Neurogenic lower urinary tract dysfunction (NLUTD) refers to the spectrum of bladder dysfunction that can arise from congenital or acquired abnormalities of those parts of the nervous system that are responsible for normal bladder function (***Table 83.3***).

The most common congenital cause of NLUTD is abnormal development of the spinal canal (neural tube defects). The neural tube develops in early gestation (closure of the spinal canal is complete by day 35) and maternal folic acid deficiency is one of the primary risk factors for incomplete closure. Spina bifida, the most common neural tube defect, ranges in severity from mild (spina bifida occulta), in which there is only mild separation of the spinal vertebrae but no neurological involvement, to severe (myelomeningocele), in

TABLE 83.3 Common congenital and acquired causes of neurogenic lower urinary tract dysfunction.

Congenital	Acquired
• Neural tube defects • Sacral agenesis • Anorectal malformations (e.g. VACTERL syndrome) • Central nervous system tumours • Transverse myelitis	• Central nervous system tumours • Inflammatory/infective conditions of the central nervous system (encephalitis, transverse myelitis) • Vascular conditions affecting the central nervous system (infarct, haemorrhage) • Spinal cord injury • Neurodegenerative and demyelinating diseases (e.g. multiple sclerosis, Parkinson's disease) • Other encephalopathy (e.g. cerebral palsy) • Iatrogenic – pelvic/spinal/cerebral surgery • Lesions of the peripheral nervous system (e.g. diabetes)

VACTERL, vertebral defects, anal atresia, cardiac defects, tracheo-oesophageal fistula, renal anomalies and limb abnormalities.

James Parkinson, 1755–1824, general practitioner of Shoreditch, London, UK, published *An essay on the shaking palsy* in 1817.

which the neural elements and meningocele sac are everted and exposed onto the skin of the lower back.

Clinical features

The clinical features of myelomeningocele can be variable, depending on which nerves have been everted in the meningocele sac. Infants will have a visible cutaneous abnormality overlying the lower spine. In cases of spina bifida occulta, any suspicion of lower spinal cutaneous abnormality warrants further investigation with spinal ultrasound or MRI. In some cases, cutaneous lesions may be absent and, as the child grows with increasing age, tethering of the cord (fixation of the lower spinal cord due to scarring from surgery, lipoma or deep skin dimples, leading to stretching of the cord with growth of the child) can lead to the development of symptoms. Therefore, spinal investigation should be considered in any infant presenting with bladder or bowel dysfunction, failure to toilet train or lower extremity weakness, as this may be a sign of occult spinal dysraphism.

An associated Arnold–Chiari malformation with hydrocephalus is commonly seen with myelomeningocele, resulting in developmental brain abnormalities. Infants may develop urinary infections, dribbling of urine and incomplete bladder emptying.

End-stage renal disease (ESRD) is the commonest cause of death in infants with spina bifida and so early identification, surveillance and treatment of those at risk for ESRD is the cornerstone of management.

Investigation

Myelomeningocele requires surgical closure of the spinal defect immediately after birth, and so urological investigations are delayed until the patient has recovered from surgery.

- Renal tract ultrasound and postvoid residual urine measurement are required.
- Video urodynamics should be performed as soon as feasible (usually in the first 2–3 months of life) to assess bladder function.
- In the presence of VUR, a dimercaptosuccinic acid (DMSA) renal scan is recommended at 3 months to provide accurate measurement of renal function.
- In those with risk factors for renal deterioration (hydronephrosis, elevated postvoid residual, poor compliance, detrusor overactivity and DSD) early treatment should be initiated. All infants should undergo lifelong surveillance, initially with 6-monthly renal tract ultrasound and postvoid residual, and yearly urodynamics for the first 2 years to detect any deterioration in renal drainage and bladder function.

Treatment

Bladder management aims to prevent deterioration in renal function. This is dependent on achieving low-pressure storage and voiding, with complete bladder emptying.

Treatment of NLUTD depends on the baseline urodynamic findings (***Table 83.4***). The management of incomplete bladder emptying, high-pressure storage, detrusor overactivity and high-pressure voiding is centred around clean intermittent self-catheterisation (CISC) in combination with antimuscarinic therapy to reduce bladder pressure. If this fails, then intravesical botulinum toxin A (BTX-A) is injected into the bladder wall. Augmentation enterocystoplasty, in which the bladder is bivalved and enlarged using a segment of ileum, is reserved for those with ongoing risk factors for renal deterioration despite the above treatments. Patients, or parents, who are unable to perform urethral CISC should be considered for a continent urinary diversion with appendicovesicostomy, in which the appendix is used as a channel to connect the bladder with the skin of the umbilicus through which the patient can perform self-catheterisation. These management options are discussed in more detail later in this chapter.

Disorders that cause NLUTD often also lead to neuropathic bowel dysfunction (constipation or faecal incontinence) and so this should also be addressed in all children presenting with NLUTD.

Summary box 83.2

Congenital neuropathic bladder

- The pattern of NLUTD depends on the site, severity and type of neurological lesion
- The bladder and sphincter may be overactive, normoactive or underactive
- The combination of an overactive bladder and overactive sphincter represents the highest risk of renal deterioration
- An overactive bladder is treated with pharmacotherapy, intravesical BTX-A, sacral neuromodulation or augmentation enterocystoplasty
- An underactive bladder is managed primarily with CISC, or if urethral catheterisation cannot be performed, then appendicovesicostomy
- An overactive sphincter is primarily treated with intrasphincteric BTX-A or sacral neuromodulation
- Bladder and bowel dysfunction often coexist and should be addressed together

Enuresis

Enuresis, or bedwetting, describes urinary incontinence during sleep in any child over the age of 5 years, in the absence of congenital or acquired neurological disorders. Monosymptomatic enuresis (MSE) is defined as enuresis without any other urinary symptoms; primary MSE describes those who have never achieved night-time continence, whereas secondary MSE refers to those who develop enuresis after a dry period of at least 6 months. Enuresis with any daytime LUTS is defined as non-monosymptomatic enuresis (NMSE).

By 15 years of age 1–2% will suffer from enuresis and the prevalence in adults is 0.5%.

Julius Arnold, 1835–1915, Professor of Pathological Anatomy, the University of Heidelberg, Heidelberg, Germany, described this condition in 1894.
Hans Chiari, 1851–1916, Austrian, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France in 1918 after the end of the First World War), gave his account of this condition in 1891. The Arnold–Chiari malformation refers to a structural defect in the cerebellum characterised by ventral herniation of the cerebellar tonsils through the foramen magnum of the skull.

TABLE 83.4 Management of neurogenic lower urinary tract dysfunction.

Storage-phase disorder	Treatment options
Low compliance/ detrusor overactivity/low capacity[a]	• CISC • Overnight catheter drainage • Pharmacological therapy ◦ Antimuscarinic ◦ β_3-agonist • Minimally invasive therapy ◦ Intravesical BTX-A • Surgical therapy ◦ Augmentation cystoplasty ◦ Urinary diversion
Low outlet resistance	• Bladder neck bulking agent injection • Bladder neck sling or bladder neck reconstruction • Artificial urinary sphincter
Voiding-phase disorder	
Detrusor–sphincter dyssynergia[a]	• CISC • Overnight catheter drainage • Pharmacological therapy ◦ Antimuscarinic ◦ β_3-agonist • Minimally invasive therapy ◦ Intravesical and intrasphincteric BTX-A ◦ Neuromodulation • Surgical therapy ◦ Augmentation cystoplasty • Urinary diversion
Detrusor underactivity	• CISC • Overnight catheter drainage • Neuromodulation

BTX-A, botulinum toxin A; CISC, clean intermittent self-catheterisation.

[a]Risk of renal function deterioration.

Investigation

Three underlying pathophysiological mechanisms are predominantly implicated in enuresis and should be evaluated clinically.

1 **Nocturnal detrusor overactivity and reduced nocturnal bladder capacity**. Up to half of all children with enuresis are found to have isolated nocturnal detrusor overactivity or reduced functional capacity, in the absence of nocturnal polyuria. Patients should be investigated initially with a bladder diary to assess daytime and night-time frequency and incontinence episodes, as well as to assess functional capacity. Urodynamics should be reserved for those who fail initial therapy; if detrusor overactivity is present then patients should be managed with antimuscarinics or β_3-agonists.

2 **Nocturnal polyuria**. Increased nocturnal urine production (defined as a nocturnal urine output exceeding 130% of expected bladder capacity for age), which may be due to increased intake or underlying medical conditions, should be identified on a bladder diary and investigated further if present (e.g. diabetes insipidus, obstructive sleep apnoea).

3 **Arousal and sleep disorders**. Children with enuresis are typically unable to wake from sleep to void, and it is thought that arousal disorders may account for part of the pathogenesis of this condition. Evaluation by a sleep specialist should be considered as part of the management strategy for children in whom sleep disorders are suspected.

Treatment

The treatment of enuresis consists initially of behavioural management techniques. These include fluid modification (night-time fluid restriction, reducing sugary, caffeinated and fizzy drink intake), bedwetting alarms, star charts and rewards systems, and maintaining regular bowel habits.

If this fails to improve symptoms and the child is experiencing distress from these symptoms, pharmacological therapy should be considered. Desmopressin, a synthetic analogue of antidiuretic hormone, is best suited for those with nocturnal polyuria with normal bladder function, whereas antimuscarinics and β_3-agonists should be considered for those with low functional capacity or those who have failed to respond to desmopressin.

Urachal anomalies

Urachal anomalies are often detected after birth with symptoms of umbilical discharge or bleeding (***Figure 83.10***). However, asymptomatic urachal anomalies may be incidentally found on abdominal imaging in adults. There are four principal

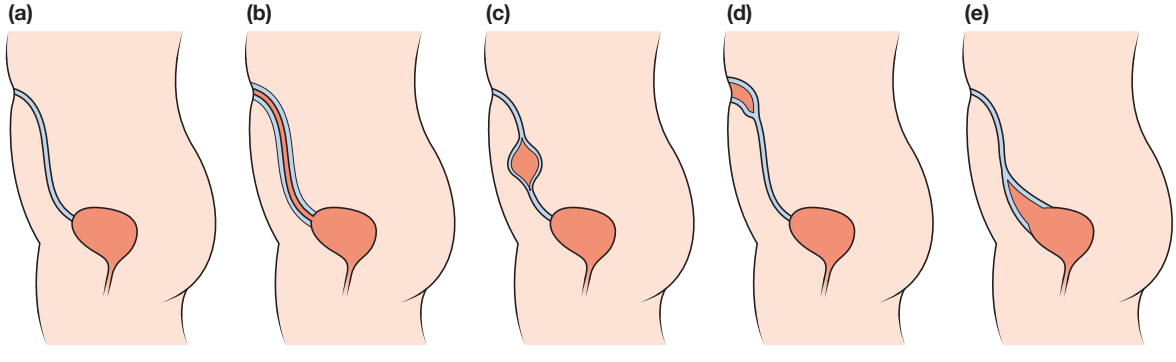

Figure 83.10 Urachal anomalies. **(a)** Normal; **(b)** patent urachus; **(c)** urachal cyst; **(d)** urachal sinus; **(e)** urachal diverticulum.

anomalies. A patent urachus is the result of failure of obliteration of the urachus, resulting in a connection between the bladder and umbilicus. A urachal cyst occurs when a portion of the urachus does not obliterate but there is no connection between the bladder and umbilicus. A urachal sinus occurs when the urachus fails to obliterate close to the umbilicus, resulting in a blind-ending tract from the umbilicus into the urachus. A urachal diverticulum occurs when the urachus fails to obliterate close to the bladder, resulting in a blind-ending tract from the bladder into the urachus.

Clinical features

Depending on the anomaly, symptoms include:

- umbilical discharge or bleeding;
- enlarged or oedematous umbilicus;
- lower abdominal pain;
- UTI;
- haematuria.

Investigation

In children, ultrasound or micturating cystography will demonstrate a patent urachus. In adolescents and adults, MRI will clearly demonstrate the anomaly (***Figure 83.11***). If patients present with UTIs or haematuria, thorough investigation with renal tract imaging, cystoscopy and postvoid residual measurement should be performed to exclude other more common causes for these symptoms.

Treatment

Urachal anomalies have a small risk of malignant transformation to adenocarcinoma, with high mortality rates. Complete surgical excision is therefore recommended for both symptomatic and asymptomatic cases. Surgical excision can be performed through open or minimally invasive (laparoscopic or robotic) approaches. Cystoscopy and insertion of a small catheter into the patent urachal tract can aid identification during surgery. The principle is to excise the urachus with a wide bladder cuff. The bladder is then closed in two layers. The urachus can be circumscribed and removed at the umbilicus, leaving the umbilicus intact for optimal cosmesis.

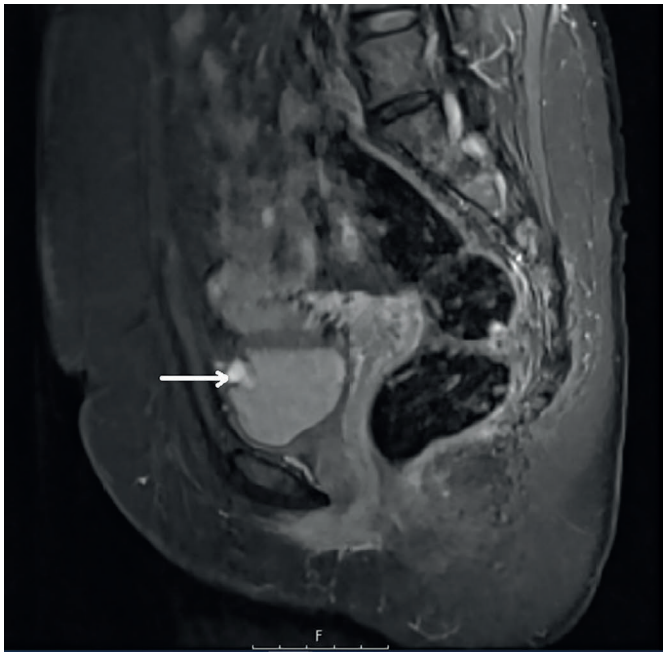

Figure 83.11 Magnetic resonance imaging scan showing a urachal cyst (arrow).

URINARY INCONTINENCE

Urinary incontinence refers to the involuntary leakage of urine. It can be classified into several different subtypes based on the circumstances leading to episodes of leakage.

- **Stress urinary incontinence (SUI)** refers to involuntary leakage on effort or exertion, or on sneezing or coughing.
- **Urgency urinary incontinence (UUI)** refers to involuntary leakage accompanied by or immediately preceded by urgency (a sudden compelling desire to pass urine which is difficult to defer).
- **Mixed urinary incontinence (MUI)** refers to involuntary leakage associated with urgency and also with exertion, effort, sneezing or coughing.
- **Continuous urinary incontinence** refers to the continuous involuntary loss of urine (this warrants investigation for anatomical pathology such as ectopic ureter or fistula from the ureter, bladder or urethra to the vagina).
- **Nocturnal enuresis** refers to involuntary leakage during sleep.
- **Incontinence associated with chronic urinary retention** refers to leakage in conditions where the bladder does not empty completely.
- **Functional incontinence** refers to leakage that results from an inability to reach the toilet because of cognitive, functional or mobility impairments in the presence of an intact LUT system.
- **Overactive bladder (OAB)** refers to symptoms of urgency with or without UUI, usually with frequency and nocturia. It can be neurogenic (secondary to a neurological condition) or idiopathic (without identifiable cause).

Urinary incontinence can occur in isolation, but more commonly is associated with other LUTS. The International Continence Society classifies LUTS based on the phase of the micturition cycle in which they occur, as storage (frequency, urgency, nocturia), voiding (hesitancy, slow stream, intermittency, straining to void, splitting of the stream, terminal dribble) and post micturition (feeling of incomplete emptying, postmicturition dribble).

Epidemiology

Urinary incontinence is highly prevalent, affecting 25–45% of men and women, and this increases with age. In men, the most common cause of SUI is radical prostatectomy for prostate cancer, with prevalence estimates of 5% at 24–36 months after surgery.

Pathogenesis

Continence is primarily dependent on normal bladder compliance, an intact urethral sphincter, strong urethral support by the pelvic floor and a leakproof mucosal seal.

Compliance is the ability of the bladder to expand in volume without any significant rise in pressure, and during the normal storage phase the bladder pressure remains low until maximum capacity is reached. This enables normal renal drainage and is dependent on the viscoelastic properties of the bladder wall (low collagen levels). However, detrusor overactivity during the storage phase, bladder muscle hypertrophy or increased levels of bladder wall collagen (e.g. due to fibrosis) can all reduce compliance and lead to incontinence and deterioration in renal drainage. This may occur as a result of pelvic surgery, irradiation, neurological conditions, chronic inflammatory bladder conditions leading to bladder fibrosis or longstanding bladder outlet obstruction.

Deficiencies in the active urethral sphincter mechanism, the urethral mucosal seal and the pelvic floor support contribute to varying degrees of SUI. Hypermobility of the bladder base and proximal urethra due to laxity of the usual supporting 'hammock', consisting of endopelvic and pubocervical fascia attached to the ATFP and levator ani, is thought to lead to displacement of the urethra out of the pelvis. As a result, during stress manoeuvres the raised intra-abdominal pressure is not transmitted to the urethra and so incontinence occurs. Laxity of the vaginal wall and pubourethral ligaments is thought to contribute to this deficiency in urethral support. These theories are the basis for retropubic suspension and mid-urethral sling procedures to treat SUI. Intrinsic sphincter deficiency occurs when the normal submucosal vascularity of the urethra and sphincter muscle tone are deficient. This may occur as a result of previous surgery, causing fibrosis, irradiation and nerve injury, or loss of oestrogenisation. Hypermobility and intrinsic sphincter deficiency exist on a spectrum and most women with SUI have elements of both.

TABLE 83.5 Predisposing and exacerbating factors for urinary incontinence (UI)

Predisposing	Exacerbating
• Familial (increased risk in those with family history of UI) • Congenital or acquired anatomical abnormalities (e.g. ectopic ureter, urinary tract fistulae, urethral diverticulum) • Neurological conditions (e.g. spina bifida, spinal cord injury, Parkinson's disease, stroke, multiple sclerosis) • Pregnancy and childbirth • Pelvic surgery • Pelvic radiotherapy • Chronic inflammatory conditions resulting in bladder fibrosis (tuberculous cystitis, ketamine cystitis, interstitial cystitis)	• Age • Obesity • Increased intra-abdominal pressure (chronic cough, straining due to constipation, exercise) • Cognitive impairment • Restricted mobility • Urinary tract infection • Drugs (e.g. diuretics) • Menopause causing atrophic vaginitis • Fluid intake (e.g. excess caffeine)

Evaluation

When evaluating patients with urinary incontinence, the history should ascertain whether symptoms are predominantly SUI, UUI or MUI, and should assess their impact on the patient's quality of life. Predisposing and exacerbating factors should be treated where possible (***Table 83.5***). The body mass index (BMI) should be noted and patients advised to lose weight if this is elevated. Abdominal examination to identify a palpable bladder suggestive of chronic urinary retention, and vaginal examination to assess pelvic floor tone and oestrogenisation status and to identify pelvic organ prolapse, should also be performed. Neurological examination to assess anal tone and sensation and lower limb function will aid identification of a neurological lesion.

Investigation

Investigation should aim to identify predisposing or exacerbating factors for urinary incontinence, as well as any features that may have a detrimental outcome on treatment (e.g. BMI). The following investigations are recommended:

1. Urinalysis – to identify UTI.
2. Flow rate and postvoid residual measurement – to identify voiding dysfunction or urinary retention.
3. Three-day bladder diary – to assess daytime and nighttime frequency episodes, polyuria (the production of >2.8 litres of urine in 24 hours in adults), nocturnal polyuria (>20–33% of urine production occurs at night), functional capacity (based on voided volumes) and incontinence episode frequency.

The following investigations should be considered if conservative and pharmacological measures have failed to improve symptoms, if there is suspicion of underlying anatomical or neurological pathology based on the history and examination or in cases of recurrent urinary incontinence after previous surgery.

1. CT urogram or MRI will identify an ectopic ureter or ureterovaginal or vesicovaginal fistula (VVF). MRI should be performed if there is suspicion of a urethral diverticulum.
2. Cystourethroscopy in cases where fistula or iatrogenic bladder or urethral pathology is suspected (e.g. following previous incontinence surgery).
3. Urodynamics/video urodynamics – this test is used to assess the pressure–volume relationship of the bladder during the storage and voiding phases of the micturition cycle. In the investigation of urinary incontinence, urodynamics is recommended in the following situations:
   - MUI (SUI with UUI or overactive bladder symptoms);
   - suspicion of voiding dysfunction or neurological LUT dysfunction;
   - previous failed anti-incontinence surgery;
   - prior to invasive treatment.

Urodynamics (filling and voiding cystometry)

Urodynamic investigation is used to measure the detrusor pressure during filling and voiding. The detrusor pressure cannot

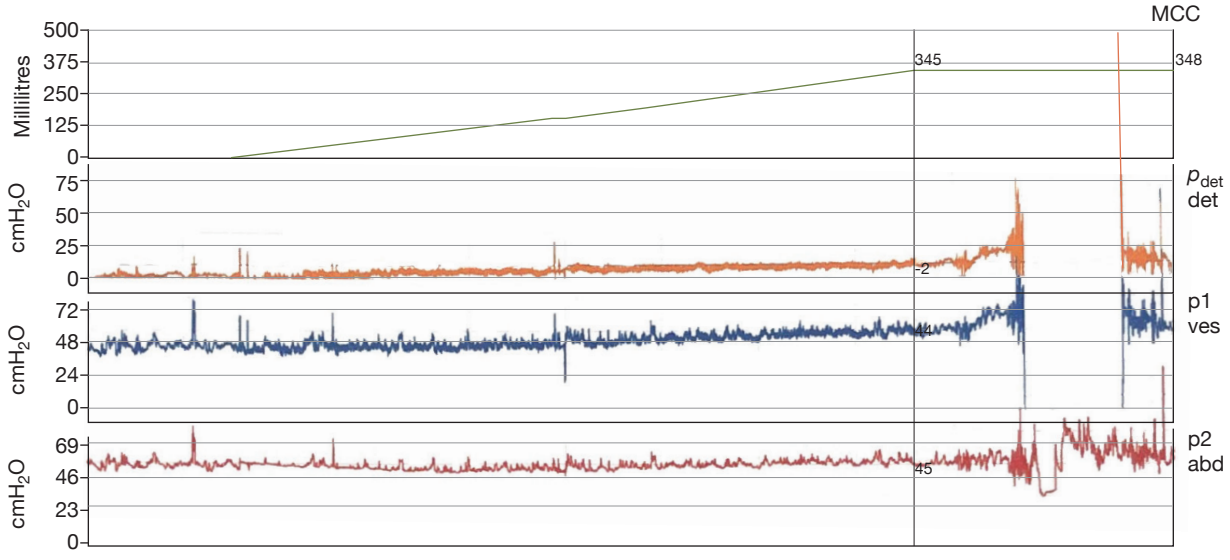

Figure 83.12 Urodynamic trace showing normal bladder storage and voiding. The red line represents intra-abdominal pressure (p_{abd}) and the blue line intravesical pressure (p_{ves}). The subtracted pressure – the detrusor pressure (p_{det}) – is shown by the orange line. During filling, there is no rise in p_{det}, which represents a normal bladder storage phase. abd, intra-abdominal; det, detrusor; MCC, maximum cystometric capacity; p1, pressure 1; p2, pressure 2; ves, intravesical.

be measured directly and so it is derived from subtracting the intra-abdominal pressure from the intravesical pressure (***Figure 83.12***).

- **Technique**. A 6Fr or 8Fr transurethral pressure-measuring catheter is inserted into the bladder to measure the intravesical pressure (p_{ves}), and another is inserted into the rectum (or vagina) to measure the intra-abdominal pressure (p_{abd}). The detrusor pressure (p_{det}) can then be derived by subtracting intra-abdominal pressure from intravesical pressure.
- **Storage phase**. The bladder is filled with saline through the transurethral catheter at a steady rate (usually 50 mL/min in non-neurogenic patients) and the following observations are recorded: cystometric capacity, compliance of the bladder (the relationship between the change in bladder volume and the change in detrusor pressure), bladder sensations and the presence of phasic rises in detrusor pressure (detrusor overactivity) (***Figure 83.13***). Any incontinence associated with phasic rises in detrusor pressure represents UUI. Stress tests (e.g. cough) are also performed throughout the filling phase and any leakage associated with increases in intra-abdominal pressure, in the absence of an increase in detrusor pressure, represents SUI.
- **Voiding phase**. When the patient has reached a strong desire to pass urine, bladder filling is stopped and the patient is asked to void. During voiding, a high detrusor pressure with corresponding low flow rate represents bladder outlet obstruction (***Figure 83.14***). Several nomograms to identify bladder outlet obstruction based on pressure–flow criteria exist for men and women.
- **Video urodynamics**. The addition of fluoroscopic imaging enables the diagnosis of VUR and anatomical abnormalities (bladder or urethral diverticula or fistulae) and can classify the type of SUI (***Table 83.6***). In this case, the bladder is filled with radiographic contrast.

TABLE 83.6 Blaivas–Olsson classification of stress urinary incontinence.

Type	At rest	On stress
0	• Bladder neck closed • Situated above the superior margin of the pubic symphysis	Rotational descent, bladder neck open, but no leak demonstrated
I	• Bladder neck closed • Situated above the inferior margin of the pubic symphysis	Descent less than 2 cm, bladder neck open and leak seen. No cystocele
IIA	• Bladder neck closed • Situated above the inferior margin of the pubic symphysis	Descent more than 2 cm, bladder neck open and leak seen. Cystocele seen
IIB	• Bladder neck closed • Situated below the inferior margin of the pubic symphysis	May or may not be further descent, but bladder neck opens and leak seen
3	• Bladder neck and proximal urethra open at rest (in the absence of a detrusor contraction)	Obvious gravitational incontinence in the absence of significant mobility

Positions at rest and on stress refer to the bladder neck and proximal urethra.

Jerry G Blaivas, b. 1943, American urologist.
Carl A Olsson, contemporary, American urologist, with Jerry G Blavias described the radiographic classification of stress urinary incontinence in 1988.

Treatment

Conservative

The recommended initial treatment for urinary incontinence consists of lifestyle interventions (weight loss, fluid modification, smoking cessation, treat constipation), behavioural therapy (timed voiding and bladder training) and pelvic floor muscle training.

Pharmacological therapy

Pharmacotherapy with antimuscarinics and β_3-agonists is the mainstay of management. Antimuscarinics should be used with caution in the elderly or in those who take multiple medications with antimuscarinic activity owing to the association with dementia with long-term use.

The aim of pharmacological treatment of SUI is to increase the urethral closure pressure by increasing smooth and striated muscle tone. Duloxetine, a selective serotonin and noradrenaline reuptake inhibitor, has been shown to increase sphincteric muscle activity and therefore improve urinary incontinence. However, pharmacological treatment for SUI is less commonly used than for OAB because of high discontinuation rates and reports of serious adverse events, such as mental health disorders and suicide, with duloxetine.

Invasive treatment of stress urinary incontinence in women

Several surgical options for the treatment of SUI are available, and the choice of therapy depends upon the pathophysiology of the incontinence (relative degree of hypermobility and intrinsic sphincter deficiency) and individual patient preferences.

Intraurethral injection therapy

The least invasive surgical option for the treatment of SUI is the injection of bulking agent into the urethral submucosa to improve the urethral closure mechanism and hence restore continence. This is particularly beneficial for those with a greater degree of intrinsic sphincter deficiency (type 3 SUI) rather than those with predominant hypermobility.

The procedure can be performed as an outpatient and involves injecting bulking agent into different aspects of the urethra, at the level of the bladder neck or mid-urethra, in order to obtain visual urethral coaptation (***Figure 83.15***).

Although less invasive than other surgical treatments, success rates are generally lower, with patient-reported improvement rates of approximately 60% in the short term; repeat injections are often required.

Synthetic mid-urethral sling

The synthetic mid-urethral sling has been the most commonly performed surgical procedure for SUI over the past three decades. Its less invasive nature compared with the autologous sling and retropubic suspension procedures in addition to its relative ease of insertion have contributed to its popularity. Synthetic slings are made of type 1 macroporous polypropylene mesh and can be inserted through the retropubic or transobturator routes.

Figure 83.15 Urethral mucosal coaptation following intraurethral injection of bulking agent. The urethral mucosa can be seen to be bulging at the site of bulking agent injection, thereby occluding the urethral lumen.

A 1-cm incision in the anterior vaginal wall at the level of the mid-urethra is made, and the paraurethral space is dissected bilaterally to the pubic bone. With an empty bladder, the sling is placed through the retropubic space, exiting on the lower abdominal wall approximately 2–3 cm lateral to the midline bilaterally. Cystoscopy should be performed after sling placement to ensure that the mesh has not perforated the bladder or urethra. The sling is placed without tension. The transobturator sling is placed in a similar manner, but the sling is placed through the obturator foramen, exiting in the groin crease at the level of the clitoris.

Success rates are high with an almost 90% cure rate at 17-year follow-up, and efficacy is similar between retropubic and transobturator slings. However, increasing concerns about serious long-term mesh-related complications (erosion; chronic pelvic, groin, perineal and vaginal pain; sexual dysfunction) have led surgeons in many countries to abandon the use of these devices.

Retropubic suspension procedures

Colposuspension aims to restore the bladder neck and proximal urethra to their normal intra-abdominal position, thereby allowing equal pressure transmission to the bladder and proximal urethra at times of raised intra-abdominal pressure, and so improve SUI by augmenting the urethral closure pressure. It is recommended for those with demonstrable hypermobility and concomitant cystocele.

The procedure is traditionally performed through a Pfannenstiel incision, although minimally invasive approaches (laparoscopic, robot assisted) have been described in recent years in an attempt to reduce morbidity. The procedure involves dissection of the retropubic space (space of Retzius), the relatively avascular space between the pubic symphysis and

Anders Retzius, 1796–1860, Swedish anatomist.

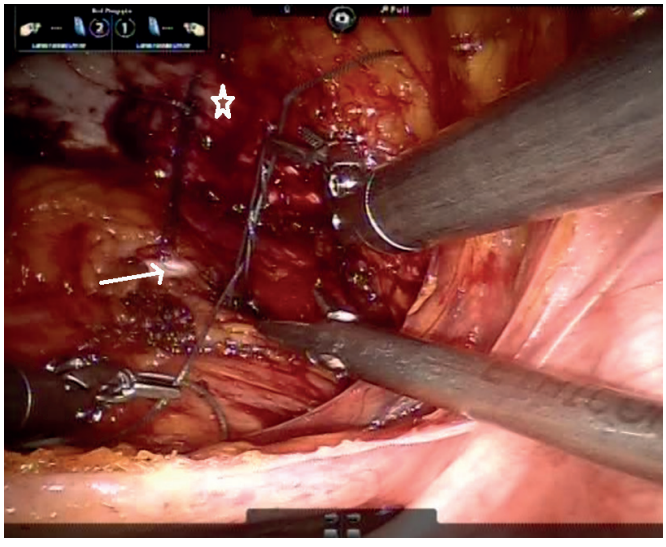

Figure 83.16 Burch colposuspension showing the suture position from the vaginal fascia (arrow) to the iliopectineal (Cooper's) ligament (star).

Figure 83.17 Autologous rectus fascial sling harvested and attached to non-absorbable sutures ('sling on a string').

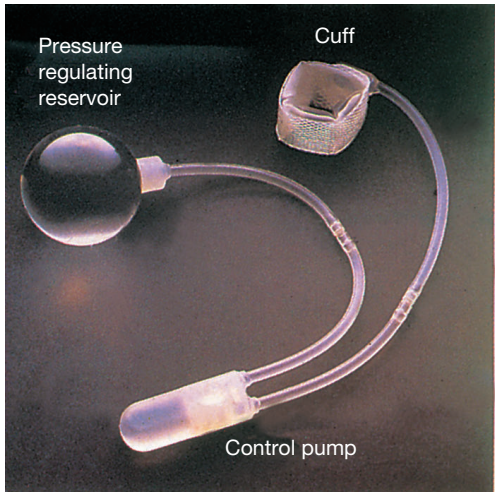

Figure 83.18 The AMS 800 Artificial Urinary Sphincter.

bladder. The vaginal fascia at the level of the bladder neck and proximal urethra is exposed bilaterally and two to four non-absorbable sutures are placed 2–3 cm lateral to the bladder neck (proximal suture) and proximal urethra (distal suture) on each side. These sutures are then attached to the iliopectineal ligament (Cooper's ligament) and the knots tied gently in order to achieve elevation without tension (***Figure 83.16***). Cystoscopy should be performed following the procedure to ensure that the sutures have not been passed through the bladder.

The Burch colposuspension has good long-term efficacy with cure rates of 70–90% at 5-year follow-up. However, risks of posterior pelvic organ prolapse are higher than with sling procedures.

Autologous fascial sling

The autologous pubovaginal sling aims to improve SUI by adding strength to the mid-urethral posterior supporting 'hammock'. It is an effective and durable treatment for SUI and can be inserted 'tension-free', similar to the synthetic mid-urethral sling, or can be inserted under tension in order to provide a compressive effect on the urethra for those with intrinsic sphincter deficiency. As this sling is not a foreign body, there is very low risk of urethral erosion.

Most commonly, a strip of rectus fascia (8 × 2 cm) is harvested through a small Pfannenstiel incision, although if this cannot be used then fascia lata can be harvested from the leg using a fascial stripper. The sling is then attached to a 0 polydioxanone (PDS) suture on each side (***Figure 83.17***) and passed into the retropubic space in a similar manner to the synthetic mid-urethral sling. In patients with a greater degree of intrinsic sphincter deficiency the sling can be inserted under a greater degree of tension.

Success rates of 75% at 10-year follow-up are reported. The pubovaginal sling is a suitable option for those who have failed previous SUI surgery, irradiated patients or those with urethral fibrosis from previous urethral pathology (e.g. urethral diverticulum, fistula, mesh erosion). However, there is a higher risk of voiding dysfunction requiring CISC with this technique, as well as new onset OAB symptoms.

Artificial urinary sphincter

The artificial urinary sphincter (AUS) is considered for women with severe recurrent SUI due to intrinsic sphincter deficiency that has failed to improve after previous surgical intervention. This three-piece device consists of a cuff that is placed around the urethra at the level of the bladder neck, a pressure-regulating balloon placed in the extraperitoneal space and a control pump placed in the labia majora (***Figure 83.18***). Recent advances in minimally invasive surgery have reduced the morbidity associated with the traditional open approach,

Sir Astley Paston Cooper, 1768–1841, surgeon, Guy's Hospital, London, UK, described the ligament that runs on the pectineal line of the pubic bone in 1804.
John C Burch, 1900–1977, gynaecologist, Vanderbilt University, Nashville, TN, USA.

but the technique still requires long-term evaluation of efficacy and safety in randomised trials.

Evidence of efficacy is limited to case series from specialist centres. One of the largest series of 376 AUS implantations reported a cure rate of 85.6% at a mean of 9.6 years of follow-up, but this was at the expense of a 10-year revision rate of 30%.

TABLE 83.7 Factors contributing to post-prostatectomy incontinence.

Patient factors	Surgical factors
• BMI • Age • Prostate size • Membranous urethra length • Pre-existing LUTS • Previous TURP • Previous radiotherapy	• Fibrosis • Urethral stricture • Technique of prostatectomy (non-nerve-sparing) • Laxity of posterior support • Neurovascular bundle damage • Devascularisation

BMI, body mass index; LUTS, lower urinary tract symptom; TURP, transurethral resection of the prostate.

Invasive treatment of stress urinary incontinence in men

Post-prostatectomy incontinence is the commonest cause of SUI in men. Several factors may contribute (*Table 83.7*).

Pharmacological treatment with duloxetine has a limited role; the mainstay of treatment is surgical, with the male suburethral sling or the AUS.

The male transobturator suburethral sling is recommended for men with mild to moderate SUI and those who have not had prior radiotherapy. In cases of severe SUI or recurrent SUI or in those who have had prior radiotherapy, the AUS is the gold standard treatment. The male sling repositions the bulb of the urethra in a retrourethral position, providing additional support to the existing sphincter without causing obstruction. The AUS is occlusive. Both approaches require a midline perineal incision through the bulbospongiosus muscle. For placement of the male suburethral sling, a helical trocar is used to pass the polypropylene mesh through the obturator foramina bilaterally. Placement of the AUS requires circumferential mobilisation of the proximal bulbar urethra for insertion of the cuff, and a separate inguinal incision for insertion of the pressure-regulating balloon into the extraperitoneal space (*Figure 83.19*). The control pump is connected and inserted into a subdartos pouch in the scrotum through this inguinal incision.

The transobturator suburethral sling has reported cure rates of 66% at 3-year follow-up whereas the AUS has long-term satisfaction rates of 80–90%. Reoperation with the AUS is required in 26% in the long term for infection, erosion or mechanical failure.

Invasive treatment of overactive bladder and urgency urinary incontinence

If pharmacological therapy for idiopathic or neurogenic OAB fails, intravesical injection of BTX-A and sacral nerve stimulation (SNS) have demonstrated high efficacy in randomised trials. For those who prefer a less invasive alternative, percutaneous tibial nerve stimulation (PTNS) may be useful. Failure to respond to these minimally invasive treatments often leads to surgical treatment with augmentation enterocystoplasty or urinary diversion for end-stage incontinence.

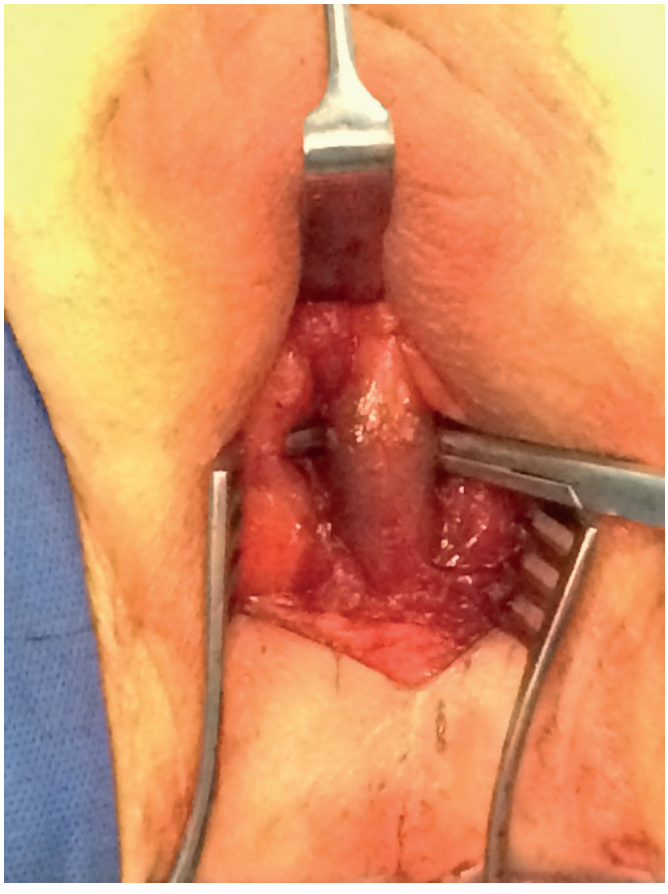

Figure 83.19 Perineal approach demonstrating exposure of the corpus spongiosum.

Intravesical injection of botulinum toxin A

BTX-A is a neurotoxin produced by the anaerobic bacterium *Clostridium botulinum*. There are seven subtypes (A–G) and type A is most clinically useful because of its longer duration of action. It is thought to have both afferent and efferent mechanisms of action.

The procedure is performed under local anaesthesia with a flexible cystoscope. Risks include UTI and voiding dysfunction requiring CISC in approximately 10%. Furthermore, symptoms typically return after around 6 months owing to regeneration of new nerve terminals, so the treatment needs to be repeated at regular intervals.

High-quality randomised trials have demonstrated the efficacy of BTX-A for both idiopathic OAB and neurogenic detrusor overactivity, with success rates of approximately 60–90%.

Sacral nerve stimulation

This treatment involves implantation of an electrical pulse generator to stimulate the S3 sacral nerve root, thereby improving OAB symptoms. The mechanism of action is not

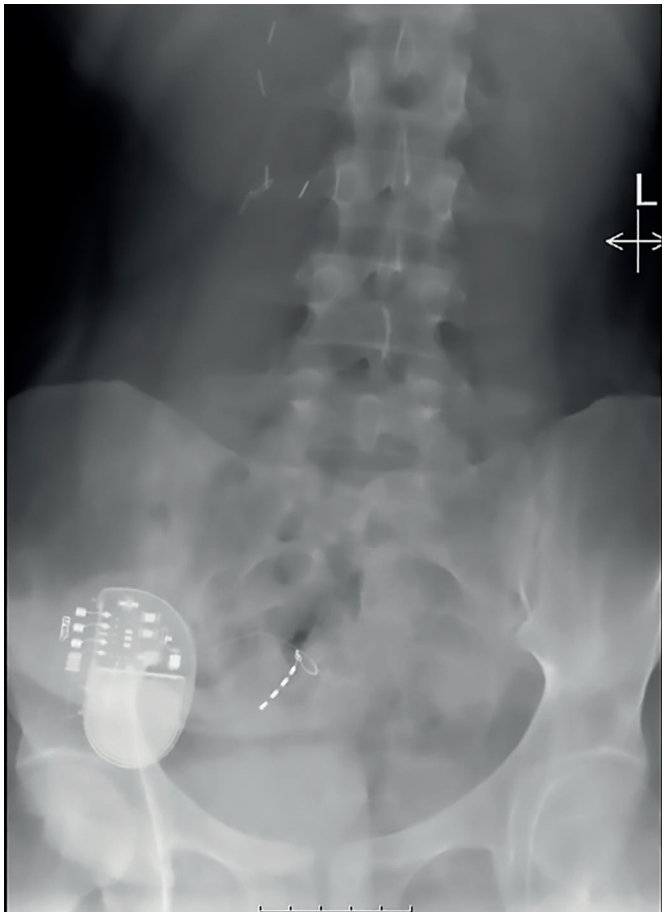

Figure 83.20 Radiograph demonstrating correct lead placement of the tined lead in the S3 foramen and the implant in the buttock.

completely understood but it is thought that afferent stimulation modulates reflex pathways involved in the micturition cycle.

The procedure is typically performed in two stages. The first, known as the 'first stage tined lead', involves insertion of a lead with four electrodes percutaneously, under fluoroscopic guidance, to the S3 foramen via a posterior approach. Electrical current is then applied to achieve stimulation of the sacral nerve, and correct lead placement is identified by the typical motor responses of plantarflexion of the great toe and inward movement of the intergluteal fold due to contraction of the levator ani (anal reflex). This lead is then kept in place for approximately 2 weeks; if clinical efficacy (based on at least 50% improvement in bladder diary parameters) has been achieved then the second stage involves insertion of a permanent implant (***Figure 83.20***).

Efficacy rates of 70–80% have been reported with this technique for both idiopathic OAB and NLUTD, and there is no significant difference in terms of efficacy between BTX-A and SNS. Complications include lead migration, device infection and implant site pain.

Percutaneous tibial nerve stimulation

PTNS is a minimally invasive form of peripheral neuromodulation that is recommended for patients who are unsuitable for, or who decline, intravesical BTX-A injections or SNS. It is thought to improve symptoms of idiopathic OAB through stimulation of the sacral plexus S2–4, indirectly via the tibial nerve. Success rates are lower than those reported for BTX-A and SNS (approximately 50%), and patients require weekly treatment sessions over 12 weeks. However, there are no significant side effects related to this treatment.

Augmentation enterocystoplasty

Augmentation enterocystoplasty is reserved for those with high-pressure detrusor overactivity, poor compliance and reduced bladder capacity who have failed to respond to the above treatments. It is recommended for patients with both idiopathic and neurogenic bladder dysfunction. The aim is to create a low-pressure reservoir with increased functional capacity, thereby preserving renal function.

The procedure can be performed through a Pfannenstiel or lower midline abdominal incision with an extraperitoneal approach to mobilise the bladder from the peritoneum. The bladder is then bivalved in the coronal plane to a point 1 cm anterior to the ureteric orifices bilaterally. Although several gastrointestinal segments have been used, ileocystoplasty is the most common. A 25-cm segment of ileum is isolated, opened along its antimesenteric border and attached to the bivalved bladder, thereby increasing the bladder capacity (***Figure 83.21***). A suprapubic catheter is placed, and the patient undergoes a cystogram 3 weeks after surgery to ensure that the enterocystoplasty segment has completely healed prior to catheter removal.

Augmentation cystoplasty is an effective option with continence and satisfaction rates of over 90%, as well as considerable improvements in urodynamic parameters (detrusor overactivity, compliance, maximum detrusor pressure). However, this is a major surgical undertaking with risks of UTI, need for CISC, metabolic disturbances, mucus and stone formation, spontaneous perforation and possibly a small long-term risk of malignancy.

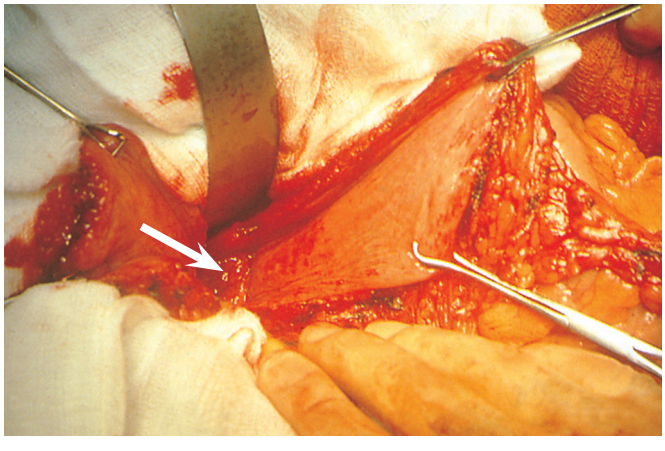

Figure 83.21 Augmentation ileocystoplasty. One of the ureteric orifices can be seen with the interureteric bar (arrow).

Urinary diversion

In those with so-called 'end-stage' incontinence that has failed to respond to the above measures, urinary diversion remains a last resort to improve quality of life. Ileal conduit urinary diversion, with or without cystectomy, is most commonly performed. When performed for benign indications, overall revision rates approach 40% (incisional or parastomal hernia, stomal complications, ureteroileal anastomosis revision or secondary cystectomy for refractory pyocystis).

Summary box 83.3

Urinary incontinence

- Urinary incontinence should be classified as UUI, SUI or MUI
- Initial management for urinary incontinence of any type is with behavioural modification, bladder training and pelvic floor muscle training
- OAB and UUI can be managed in a stepwise manner with pharmacotherapy, intravesical BTX-A, SNS or augmentation enterocystoplasty
- SUI in women is initially managed with bulking agents, mid-urethral slings (synthetic or autologous) or colposuspension
- SUI in men is managed with the suburethral sling or AUS
- Urinary diversion is a last-resort option for those with end-stage urinary incontinence

NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

NLUTD refers to bladder and/or urethral sphincteric disorders that result from neurological lesions. Discrete neurological lesions will affect LUT storage and voiding in a consistent manner depending on the site of the lesion, the nature of the lesion (destructive, inflammatory, irritative) and the extent of the lesion (complete or incomplete). Neurological lesions can be classified based on location as suprapontine, spinal (infrapontine–suprasacral) and sacral/infrasacral. Each has characteristic clinical and urodynamic features (***Figure 83.22***). Suprapontine lesions (e.g. cerebrovascular accident, Parkinson's disease, brain injury) lead to storage LUTS owing to loss of inhibition from higher brain centres. This results in neurogenic detrusor overactivity, but since local sacral micturition refluxes are preserved the voiding phase is intact. Spinal lesions (e.g. spinal cord injury [SCI], myelitis, disc herniation) can have the most serious impact as they can lead to both detrusor overactivity and sphincteric overactivity (DSD), resulting in high-pressure voiding, which risks deterioration in renal function. Furthermore, patients with spinal lesions above the T6 spinal cord level are at risk of developing autonomic dysreflexia (see ***Autonomic dysreflexia***). Sacral and infrasacral lesions are relatively safe as they result in low-pressure underactive bladder and/or sphincter function. Patients predominantly

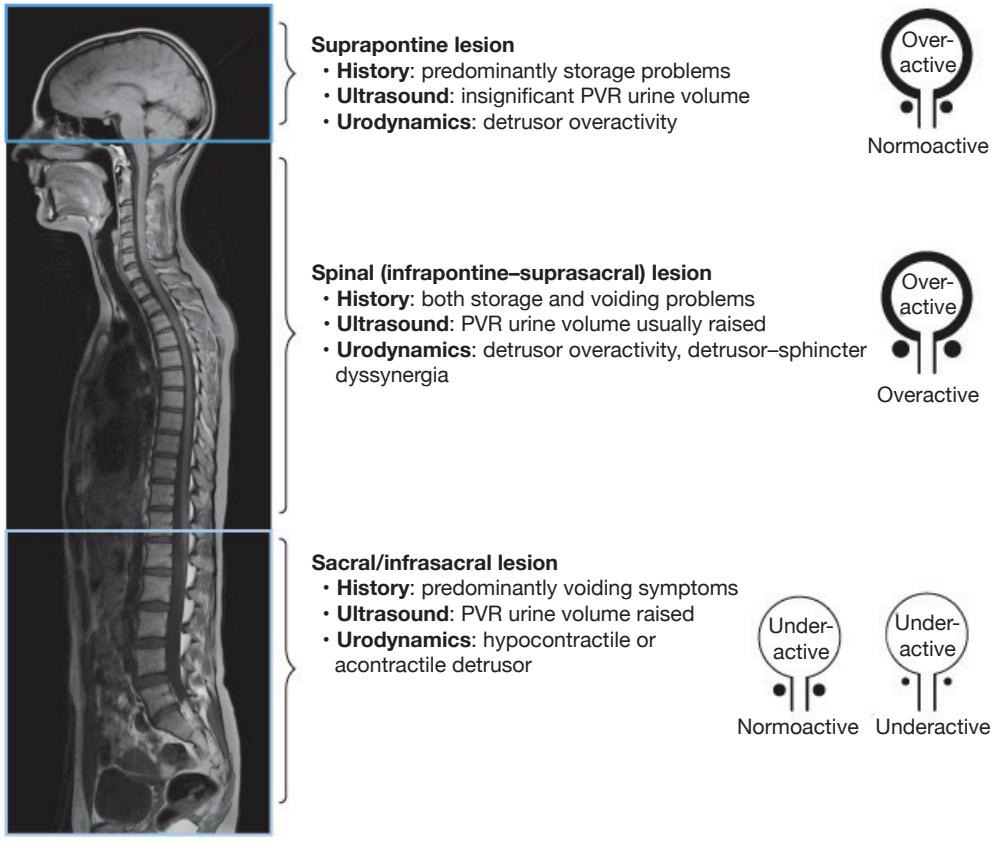

Figure 83.22 Characteristic lower urinary tract disorders arising from neurological disease. (Reproduced with permission from Panicker JN, Fowler CJ, Kessler TM. Lower urinary tract dysfunction in the neurological patient: clinical assessment and management. *Lancet Neurol* 2015; **14**(7): 720–32.)

suffer from voiding symptoms (reduced flow, incomplete bladder emptying) and SUI.

The aims of treatment in NLUTD are to:

1. preserve renal function by ensuring low-pressure storage and voiding;
2. achieve continence;
3. prevent UTI.

Treatment of detrusor overactivity and poor compliance in order to attain low-pressure storage is achieved through the conservative, medical and surgical treatment pathways outlined above for the treatment of UUI. Treatment of sphincteric overactivity or DSD to attain low-pressure voiding is typically achieved by CISC, although sphincteric overactivity can be treated with intrasphincteric BTX-A, sacral neuromodulation, SNS or direct sphincterotomy. If these methods are ineffective or unsuitable for the patient, continent diversion (appendicovesicostomy) can be performed to prevent high-pressure voiding. Detrusor underactivity is managed with CISC and sphincteric underactivity is treated as described above for SUI. Several factors should be considered when managing patients with NLUTD. These relate to patient factors (body habitus, hand function, motivation and level of compliance, mental status, values and preferences, support network) and neurological disease factors (prognosis).

Spinal cord injury

SCI often results in significant LUT dysfunction with a high risk of UTI/sepsis, renal function deterioration, renal and bladder calculi and autonomic dysreflexia. Urinary tract complications and renal failure were the leading causes of death in this population, but thorough evaluation and early definitive management have considerably improved urinary tract outcomes in patients with SCI.

Immediately after SCI, a period of 'spinal shock' occurs in which there is a marked reduction in all spinal reflex activity below the level of the lesion. This results in an areflexic and acontractile bladder; urinary retention lasts 6–12 weeks in complete SCI but may be shorter in incomplete lesions. Patients are managed with indwelling catheterisation or CISC during this phase. Return of function is characterised by spasticity (detrusor overactivity and DSD) and should be managed as described under ***Urinary incontinence, Treatment***.

Autonomic dysreflexia

Autonomic dysreflexia is a sudden and exaggerated autonomic (primarily sympathetic) response to various stimuli in patients with SCI or spinal dysfunction above the cord level of T6–8 (the sympathetic outflow). Stimuli below the level of the lesion (commonly a distended bladder or rectum) lead to symptoms of headache, hypertension (varying from mild headache to seizures or cerebral haemorrhage) and flushing or sweating of the face and body above the level of the lesion.

Autonomic dysreflexia is thought to occur as a result of an unopposed sympathetic response to noxious stimuli. Nociceptive afferents elicit reflex sympathetic outflow, resulting in piloerection, sweating and arteriolar vasoconstriction, leading to hypertension. The peripheral vasoconstriction activates baroreceptors, which results in a parasympathetic surge originating in the central nervous system to counteract the sympathetic outflow. The resulting vagal outflow causes bradycardia, but this parasympathetic signal is unable to transmit below the level of the spinal cord lesion. This leads to bradycardia, vasodilatation and flushing above the level of the lesion, but hypertension and pale, cold skin due to ongoing vasoconstriction below the level of the lesion.

Initial treatment involves sitting the patient upright, removing any constricting clothing and identifying and removing the source of stimulation (urinary retention, blocked catheter, loaded rectum). Regular blood pressure monitoring should be performed; if the systolic blood pressure remains elevated (>150 mmHg), patients should be treated with fast-acting antihypertensives such as sublingual nifedipine or glyceryl trinitrate.

URINARY TRACT FISTULAE

A fistula is an abnormal or surgically made passage between a hollow or tubular organ and the body surface, or between two hollow or tubular organs. The most common cause of urinary tract fistulae in less economically developed countries is traumatic labour; in well-resourced countries, fistulae are most commonly iatrogenic, resulting from pelvic surgery (hysterectomy accounts for the majority) or radiotherapy, or they can be due to advanced pelvic malignancy, inflammatory conditions (e.g. tuberculosis [TB]), congenital disorders or foreign body erosion.

Vesicovaginal fistulae

VVF is the most common urinary tract fistula. In developing countries, obstetric fistula account for the majority of cases. Lack of adequate prenatal care, younger age at first marriage, short stature, low socioeconomic status and illiteracy are risk factors for developing obstetric fistulae. These fistulae are due to prolonged obstructed labour resulting in ischaemic pressure necrosis to the anterior vaginal wall, bladder and urethra, and large areas of the bladder neck and urethra may be involved. Concomitant rectovaginal fistulae may also be present, making these fistulae very complex to manage. In developed countries, iatrogenic VVF most commonly occurs after hysterectomy, usually thought to be due to an unrecognised bladder injury near the vaginal cuff. Other mechanisms include diathermy injury resulting in delayed tissue necrosis or a suture placed through the bladder and vaginal wall during closure of the vaginal cuff. Abdominal hysterectomy is three times more likely to result in fistula than vaginal hysterectomy, although the overall rate of VVF after hysterectomy is low at 0.1–4%.

Clinical features

The most common presenting symptom is constant urinary leak from the vagina. This may be intermittent in cases of very small fistulae, and so other causes of urinary incontinence (SUI, UUI) must be excluded. Post-hysterectomy VVF may be recognised in the first few days after surgery, or 1–3 weeks later after catheter removal. Post-irradiation VVF may not manifest until years later.

Figure 83.23 Computed tomography scan showing a vesicovaginal fistula from the posterior wall of the bladder to the vagina.

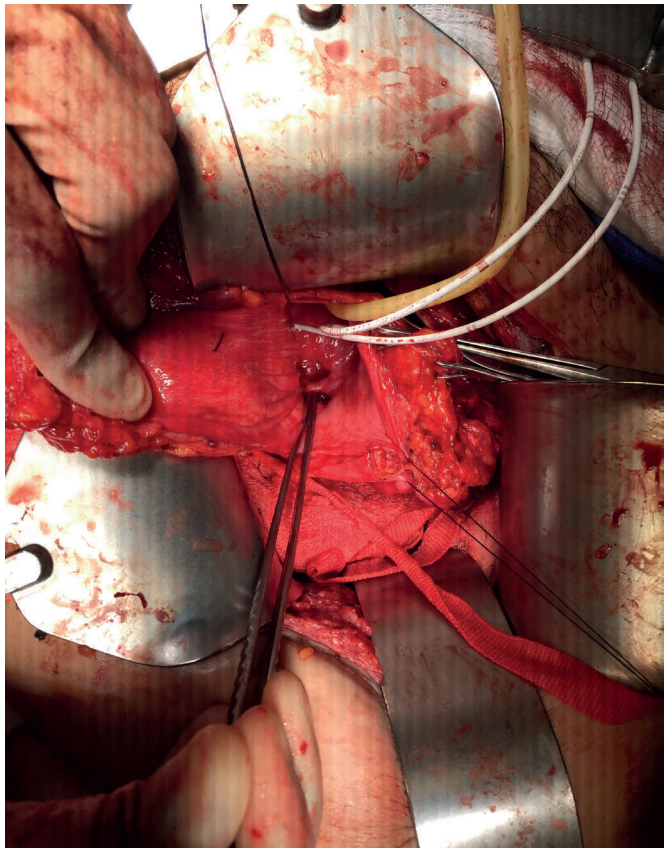

Figure 83.24 Transabdominal approach showing a vesicovaginal fistula (VVF) on the posterior wall (forceps in VVF). White ureteric catheters have been inserted into the ureteric orifices and there is a catheter in the urethra.

Physical examination may demonstrate the fistula site, typically on the anterior vaginal wall at the vaginal cuff, and leakage of urine may be seen. Instillation of blue dye into the bladder may aid visual identification of the fistula site.

Investigation

1. **Cross-sectional imaging** with CT urogram, MRI with gadolinium contrast or cystogram will aid diagnosis of the fistulous tract and exclude concomitant ureteric injury (*Figure 83.23*).
2. **Cystoscopy**, bilateral retrograde ureteropyelography and examination under anaesthesia should be performed to assess the fistula site, location, size, proximity to ureteric orifices, vaginal size, depth and mobility. This will aid surgical planning and help to determine whether an abdominal or vaginal approach will be most suitable. Furthermore, biopsy of the fistula tract to exclude recurrent malignancy can be performed in cases of prior history of pelvic malignancy.
3. **'Three-swab' test**. This investigation can be performed in cases where fistula is suspected but cannot be identified on the investigations above. Three numbered gauze swabs are placed into the vagina, with swab number 1 placed most proximally, swab number 2 in the middle and swab number 3 most distal in the vagina. A blue dye is then instilled into the bladder through a catheter, and the catheter removed. Blue staining of swab 1 or 2 suggests VVF whereas blue staining of swab 3 suggests a urethra–vaginal fistula or SUI. If swab 1 is wet but not stained blue, this suggests the presence of a ureterovaginal fistula.

TABLE 83.8 Principles of surgical repair of a vesicovaginal fistula.

- Adequate exposure of the fistula tract and debridement of ischaemic tissue
- Adequate separation of involved organs
- Watertight closure, multilayer closure, tension-free, non-overlapping suture lines
- Use of well-vascularised tissue flaps (omentum, peritoneum, Martius labial fat pad)
- Adequate postoperative urinary drainage
- Treatment and prevention of infection
- Meticulous haemostasis

Treatment

Conservative treatment with urethral catheter drainage is rarely successful, but in certain situations (e.g. very small VVF in the absence of radiotherapy) may be warranted for an initial 2- to 6-week period. If this fails to heal the fistula surgical treatment is required. The approach can be vaginal, transabdominal (open or minimally invasive) or a combination of both (*Figure 83.24*). Principles of surgical repair are shown in *Table 83.8*. Vaginal repair relies on adequate exposure of the fistulous opening. The fistula is circumscribed, and the bladder

TABLE 83.9 Causes of urinary retention in men and women

Mechanism	Men	Women
Anatomical bladder outlet obstruction	• Benign prostatic obstruction • Malignant enlargement of prostate • Bladder neck obstruction • Urethral stricture • Urethral rupture (e.g. following pelvic fracture)	• Urethral ◦ Stricture ◦ Diverticulum ◦ Meatal stenosis ◦ Carcinoma • Prolapse • Extrinsic compression ◦ Paraurethral cyst ◦ Pelvic mass (e.g. large fibroids) ◦ Gynaecological malignancy • Iatrogenic ◦ Anti-incontinence surgery ◦ Urethral reconstruction
Functional bladder outlet obstruction	• Idiopathic high-tone non-relaxing external urethral sphincter	• Idiopathic high-tone non-relaxing external urethral sphincter (Fowler's syndrome) • Dysfunctional voiding • Primary bladder neck obstruction
Detrusor underactivity	• Pelvic surgery • Peripheral neuropathy • Diabetic cystopathy • Secondary to longstanding bladder outlet obstruction	
Neurological disease	• Detrusor–sphincter dyssynergia (any cause of suprasacral spinal cord disease) causing obstructed voiding • Sacral nerve lesion or cauda equina causing detrusor underactivity	
Drugs	• Antimuscarinics or β_3-agonists • Sympathomimetic drugs • Anaesthetic agents • Opioids	
Transient causes	• Following spinal or general anaesthesia • Pain • Faecal impaction due to constipation • Blood clot secondary to haematuria	

side is adequately separated from the vaginal side. The bladder is closed in two layers and a Martius labial fat pad is then harvested to cover the fistula. The vaginal wall is then closed, and a labial drain is placed for 1–2 days. Abdominal repair is typically performed transvesically. The bladder is opened, and the fistulous site identified and circumscribed to separate it from the vaginal wall. If the ureteric orifices are in close proximity, then ureteric catheters are placed intraoperatively. The vaginal wall is closed and then the bladder is closed in two layers after insertion of omentum or peritoneum between the fistula margins. The patient is discharged with a urethral catheter *in situ*; this is typically removed 3 weeks later after a pericatheter urethrogram confirms absence of leak.

Summary box 83.4

Urinary tract fistulae

The principles of surgical repair of VVF are:

- Adequate exposure of the fistula tract
- Tension-free, watertight, multilayer closure with non-overlapping suture lines
- Interposition with a well-vascularised flap
- Urinary tract drainage postoperatively to allow healing

URINARY RETENTION

Urinary retention is defined as the inability to pass urine despite persistent effort. It can be classified as acute (painful inability to pass urine with relief of pain on catheterisation) or chronic (painless, elevated residual volume after passing urine).

The causes of urinary retention in men and women are given in ***Table 83.9***.

Catheterisation

The immediate treatment for urinary retention of any cause is urethral catheterisation. Other indications for catheterisation are shown in ***Table 83.10***. In chronic urinary retention, patients may have a postobstructive diuresis producing >200 mL of urine per hour for three consecutive hours. If this is the case, patients should be managed with strict fluid balance monitoring, postural blood pressure checks to detect postural hypotension and daily serum electrolyte monitoring

Heinrich Martius, 1885–1965, German surgeon, described a labial flap of bulbocavernosus muscle (Martius modified labial fat pad) in 1928.
Clare Juliet Fowler, contemporary, Professor of Uroneurology, National Hospital for Neurology and Neurosurgery, London, UK.

TABLE 83.10 Indications for catheterisation.

Drainage	• Urinary retention (acute and chronic) • Fluid management/monitoring in critically unwell patients • Palliative management for urinary incontinence where other measures have failed or are unsuitable • Following urological surgery to allow healing of the bladder or urethra
Therapeutic drug delivery	• Non-muscle-invasive bladder cancer (e.g. mitomycin C, gemcitabine, BCG) • Chronic cystitis such as UTI and interstitial cystitis (e.g. GAG-layer replacement therapies, antibiotics)
Diagnostic	• Micturating cystourethrogram • Urodynamics • To obtain a catheter specimen of urine for analysis

BCG, bacillus Calmette–Guérin; GAG, glycosaminoglycan; UTI, urinary tract infection.

and occasionally may require intravenous fluid replacement to match the loss if the patient is unable to take enough orally.

Types of catheter

Catheters can be classified based on their size (French scale), number of channels or composition (latex-coated or silicone) (*Figure 83.25*).

Size

The French scale refers to the external diameter of the catheter, and 1Fr is 0.3 mm in diameter. The standard catheter size for uncomplicated urethral catheterisation in women is 12Fr or 14Fr, and in men 16Fr. In patients with urethral stricture, a smaller size catheter should be considered. In cases of haematuria with 'clot retention', a 22Fr catheter is typically used to aid drainage of thick clots. Coudé tip catheters have a curved tip to allow easier passage past an enlarged prostate.

Number of channels

Single-channel catheters consist of a single drainage channel only and are used for CISC as these catheters do not require an indwelling retention mechanism. The Foley catheter consists of two channels – a drainage channel and a channel for inflation of a balloon at the tip, which allows the catheter to be retained in the bladder. This is the standard catheter used for uncomplicated cases of urinary retention. The 'three-way' catheter has an additional channel for bladder irrigation and is used for patients with haematuria and 'clot retention' and following transurethral prostate or bladder surgery.

Urethral catheterisation

1. Aseptic technique – handwashing, sterile gloves, sterile catheter pack.
2. Clean urethral meatus with antiseptic solution.
3. Instil lidocaine gel into the urethra and hold for 2–3 minutes. In men, the penis should be held perpendicular and taught. In women, the labia should be held apart to provide adequate exposure of the urethral meatus.
4. The catheter should be inserted as far as the 'hilt' of the catheter and should pass freely (the type of catheter is dependent on the indication). If there is any resistance catheterisation should be stopped and assistance sought. The patient may require a coudé tip catheter if the obstruction is thought to be a large prostate, or a cystoscopy to negotiate a false passage or stricture.
5. The position in the bladder is confirmed with the drainage of clear urine and the balloon should be inflated with 10 mL of sterile water. The catheter bag should then be attached.
6. Details regarding the type and size of catheter, and residual volume, should be clearly recorded.

Suprapubic catheterisation

Suprapubic catheterisation (SPC) carries a small but significant risk of bowel injury, especially in those who have undergone previous abdominal or pelvic surgery, and so should be performed under ultrasound and cystoscopic guidance. SPC should be considered for those who require long-term catheterisation, as it is often more comfortable with no risk of urethral trauma compared with long-term urethral catheterisation, as well as for those in whom urethral catheterisation is not suitable or possible. Contraindications to SPC insertion include known or suspected bladder carcinoma, abdominal wall infection at

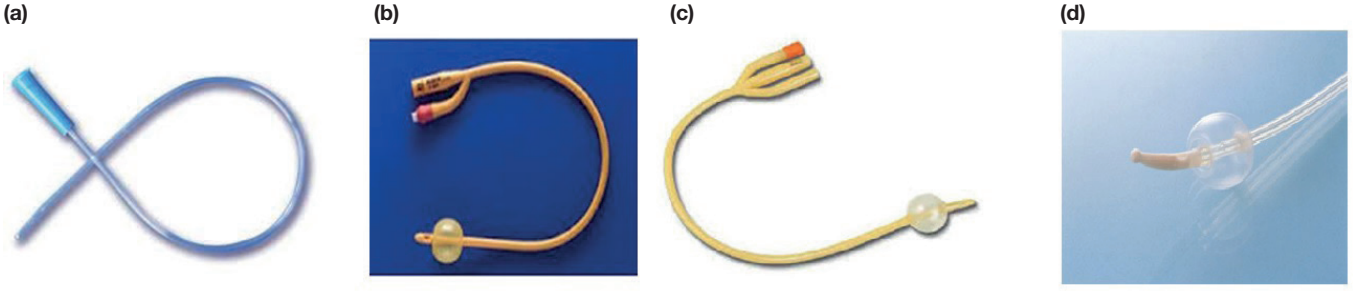

Figure 83.25 Types of urethral catheter. **(a)** Single-lumen catheter used for self-catheterisation; **(b)** standard urethral catheter with an inflatable balloon retention mechanism; **(c)** a three-way catheter with an extra channel for irrigation; **(d)** coudé tip catheter.

Frederic Eugene Basil Foley, 1891–1966, urologist, Anker Hospital, St Paul, MN, USA.

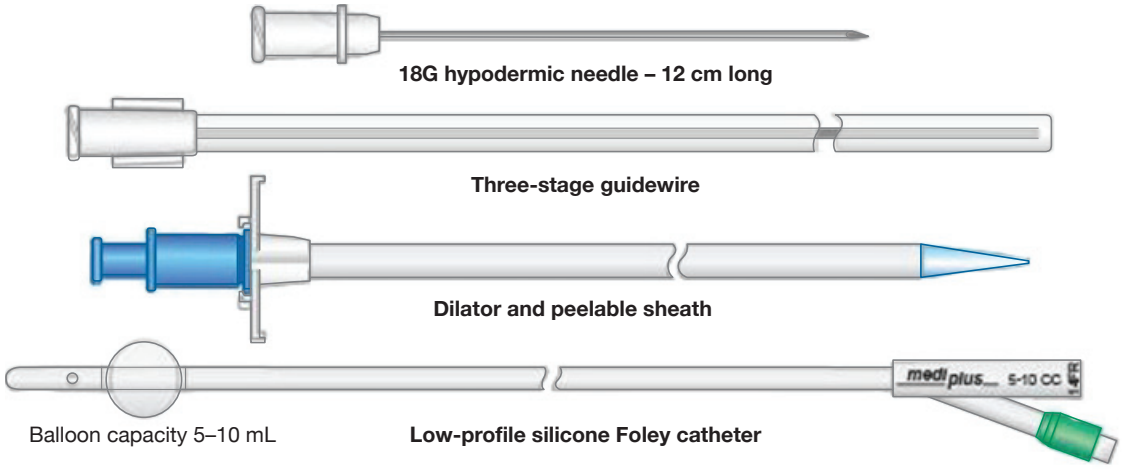

Figure 83.26 A suprapubic 'Seldinger' catheter kit.

the site of insertion, uncorrected coagulopathy or the presence of a vascular graft in the suprapubic region.

The procedure requires infiltration of local anaesthesia (1% lidocaine) to the skin and fascia of the suprapubic region, two fingerbreadths above the pubic symphysis in the midline. This procedure should only be performed in those with a palpable bladder. A Seldinger technique of insertion is the safest for percutaneous insertion (***Figure 83.26***). A long needle is inserted in a perpendicular direction into the bladder and aspiration of clear urine confirms correct entry. A guidewire is placed through the needle, and the needle removed. A small skin incision at the site of the guidewire allows a trocar to pass over the guidewire and into the bladder, thereby dilating the tract. Through this trocar, a 16Fr catheter is placed and the balloon inflated. The trocar is removed and the catheter bag attached. If the bladder cannot be confidently identified, or in those with extensive abdominal or pelvic surgery, an open cystotomy should be performed to safely enter the bladder and ensure that there is no bowel in the path of the catheter.

BLADDER STONES

Bladder stones account for 5% of all urinary tract stone disease. They can be classified as primary (without underlying urinary tract pathology) or secondary (due to underlying renal tract pathology). Primary bladder stones are commonly seen in children in the developing world and are due to nutritional deficiency in vitamins A and B6, magnesium and phosphate and a reduced protein–carbohydrate ratio. Secondary bladder stones are most commonly related to urinary stasis from elevated postvoid residual volume due to bladder outlet obstruction (***Table 83.11***).

TABLE 83.11 Aetiology of bladder stones.

	• Nutritional deficiency
• Urinary stasis (elevated residual volume)	• Bladder outlet obstruction • Detrusor underactivity • Bladder augmentation or substitution • Neurogenic lower urinary tract dysfunction
• Foreign body	• Suture or mesh from previous prolapse/continence/pelvic surgery • Stone from upper tract • Indwelling catheter or ureteric stent • Migrated intrauterine devices
• Infection	
• Drugs	• Indinavir • Triamterene

Composition

Primary endemic bladder stones in children are usually composed of ammonium urate and calcium oxalate. Secondary stones due to bladder outlet obstruction are typically smooth and yellow-brown in colour and are composed of uric acid. Infection-related stones tend to be triple phosphate (magnesium ammonium phosphate) and are white in colour (***Figure 83.27***).

Clinical features

- May be asymptomatic.
- Haematuria.
- Dysuria.
- Frequency and urgency.
- Suprapubic pain.
- Hesitancy and intermittency.

Sven Ivar Seldinger, 1921–1998, Swedish radiologist, introduced this technique in 1953.

Figure 83.27 Smooth uric acid bladder stones.

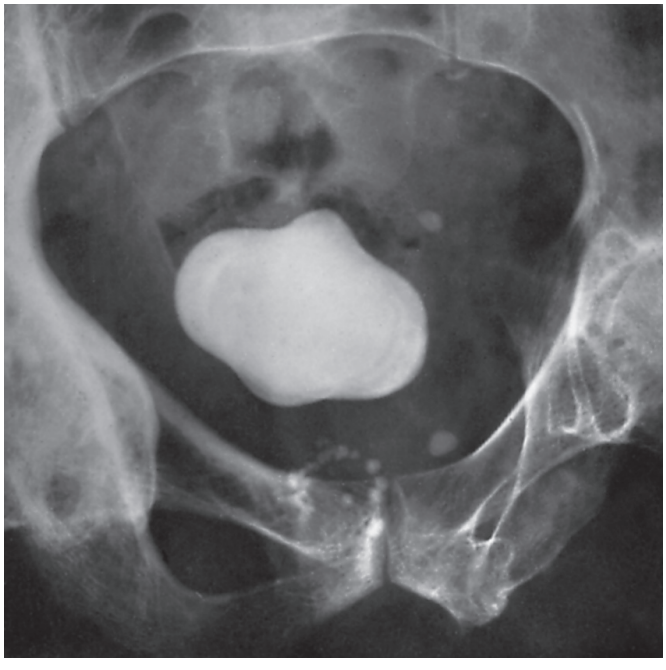

Figure 83.28 Radiograph showing a vesical calculus (no contrast has been used).

Investigation

Plain radiograph of the bladder, renal tract ultrasound or CT will confirm the diagnosis and provide an estimation of size to aid treatment planning (***Figure 83.28***).

Treatment

The cause of the stone should be sought and treated; this may include bladder outlet obstruction, incomplete bladder emptying in patients with neurogenic bladder dysfunction or the presence of a foreign body that should be excised simultaneously (***Figure 83.29***).

The majority of stones can be managed endoscopically with a stone punch, ultrasound lithotripsy or holmium laser lithotripsy (***Figure 83.30***). In those in whom urethral access is not possible (e.g. reconstructed LUT), percutaneous cystolithotomy can be performed using a similar technique to percutaneous nephrolithotomy.

The open approach (open cystolithotomy) is reserved for those with very large bladder stones that cannot be treated with endoscopic means.

Figure 83.29 Stone on a vaginal sling that had eroded into the bladder.

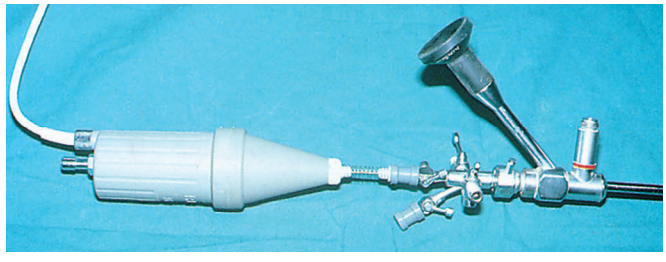

Figure 83.30 An endoscopic ultrasound probe, which is used to fragment bladder or kidney stones.

URINARY TRACT INFECTION

UTI is the inflammatory response of the urothelium to bacterial invasion, usually associated with bacteriuria (the presence of bacteria in the urine) and pyuria (the presence of white blood cells in the urine). Pyuria in the absence of bacteriuria (sterile pyuria) indicates an inflammatory response that may still be related to UTI or that may be a response to another pathology such as fastidious organisms (e.g. TB, gonorrhoea), carcinoma *in situ* (CIS) bladder stones or other inflammatory conditions. UTIs can be classified as **uncomplicated** (occurring in a healthy patient with a structurally and functionally normal urinary tract) or **complicated** (occurring in a patient with an anatomical or functional urinary tract abnormality, in an immunocompromised patient or with more virulent or resistant bacteria). Factors that suggest a complicated UTI are shown in ***Table 83.12***. An **isolated** UTI is one in which there has been an interval of at least 6 months between infections. A **recurrent** UTI (rUTI) is defined as ≥2 episodes in 6 months or ≥3 episodes in 12 months. Infections can also be classified based on their site (urethritis, prostatitis, cystitis, pyelonephritis). This chapter focuses on cystitis.

TABLE 83.12 Factors that suggest a complicated urinary tract infection.

Patient factors	• Functional or anatomical abnormality of the urinary tract • Sex (male gender) • Age (postmenopausal) • Pregnant • Immunosuppressed (e.g. diabetes, transplant, steroids) • Indwelling catheter
Bacterial factors	• Increased virulence (hospital-acquired infection) • Antimicrobial resistance (recent antibiotic use)

Half of all women have been estimated to experience a UTI in their lifetime, and up to 50% of these will have recurrent infection within the following 6-month period.

Pathogenesis

The most common route of infection is ascending UTI; contamination of the vaginal and periurethral area with uropathogenic organisms originating from the gastrointestinal tract leads to adherence and migration of bacteria into the urethra and bladder. Once in the bladder, adherence of the bacteria to the urothelium triggers a process of bacterial internalisation into the urothelial cell and the subsequent formation of intracellular bacterial communities (IBCs) and quiescent intracellular reservoirs (QIRs), which may remain viable for months and act as a source of rUTI. These IBCs and QIRs act in a similar way to a biofilm, protecting bacteria from the host immune response and from the action of antimicrobial agents.

Less common routes of infection include haematogenous spread (seen with *Staphylococcus aureus* and fungal infections) or direct infection from retroperitoneal abscess or inflammatory bowel disease.

The commonest organisms implicated in uncomplicated UTI are *Escherichia coli* (85%), *Staphylococcus saprophyticus, Enterococcus faecalis, Proteus* and *Klebsiella*. Complicated UTIs are caused by *E. coli* (50%), enterococci, *S. aureus* and *Pseudomonas*.

Successful infection depends on the bacterial virulence relative to the host defence mechanisms. The common bacterial virulence factors and host defence mechanisms are shown in ***Table 83.13***.

Clinical features

The classic symptoms of UTI include dysuria, suprapubic pain, urinary frequency and urgency. Patients may also present with haematuria, loin pain, fevers, nausea and vomiting. A physical examination should be performed to check for a palpable bladder, for renal angle tenderness and for evidence of pelvic organ prolapse, urethral diverticulum and atrophic vaginitis.

TABLE 83.13 Bacterial virulence factors and host defence mechanisms.

Bacterial virulence factors	Host defence mechanisms
• Adherence mechanisms (fimbrial and afimbrial) • Immune evasion (lipopolysaccharide O, capsule K) • Anti-IgA proteases, toxin production, β-lactamase • Resistance to antimicrobial bactericidal activity (alteration of antimicrobial binding sites) • Iron acquisition	• Commensal organisms (lactobacilli) • Mechanical integrity of mucous membranes • Antibacterial secretions (lysozyme, lactoferrin, IgA) • Antegrade flow of urine causing flushing effect • Tamm–Horsfall protein (binds to bacterial adhesion molecules) • Composition of urine (low pH, high urea) • Immune system integrity

IgA, immunoglobulin A.

Investigation

Initial investigation is with urinalysis (a dipstick test checks for the presence of red cells, white cells and nitrites), urine microscopy, culture and sensitivity, flow rate assessment and measurement of postvoid residual volume. In those with rUTI, renal tract ultrasound to exclude anatomical pathology should be performed; cystoscopy is reserved for those with atypical symptoms, haematuria or other features that raise suspicion of underlying pathology (e.g. bladder cancer, stones, urinary tract fistula).

Current methods of microbiological UTI diagnosis are based on the identification of a 'significant' pure growth of a known uropathogen in the urine. A cut-off of $\geq 10^3$ colony-forming units/mL is commonly used to diagnose acute uncomplicated cystitis in women, but it is becoming increasingly clear that patients can develop symptoms of UTI with much lower concentrations of urinary bacteria; the minimum concentration required to cause UTI or rUTI has not yet been defined.

Treatment

Acute UTI should be treated with an appropriate antimicrobial agent based on local antibiograms and resistance patterns. Following treatment of an acute UTI, non-antimicrobial measures to prevent future UTI should be considered (e.g. increasing fluid intake, probiotics, methenamine hippurate, d-mannose, vaginal oestrogen therapy for postmenopausal women). Episodes of rUTI can be treated with antimicrobial prophylaxis, postcoital antimicrobial use for those with sex-linked infections or intermittent self-start antimicrobial therapy.

Igor Tamm, 1922–1995, American virologist.
Frank Horsfall, 1906–1971, American microbiologist, together with Igor Tamm first purified the Tamm–Horsfall protein in 1952.

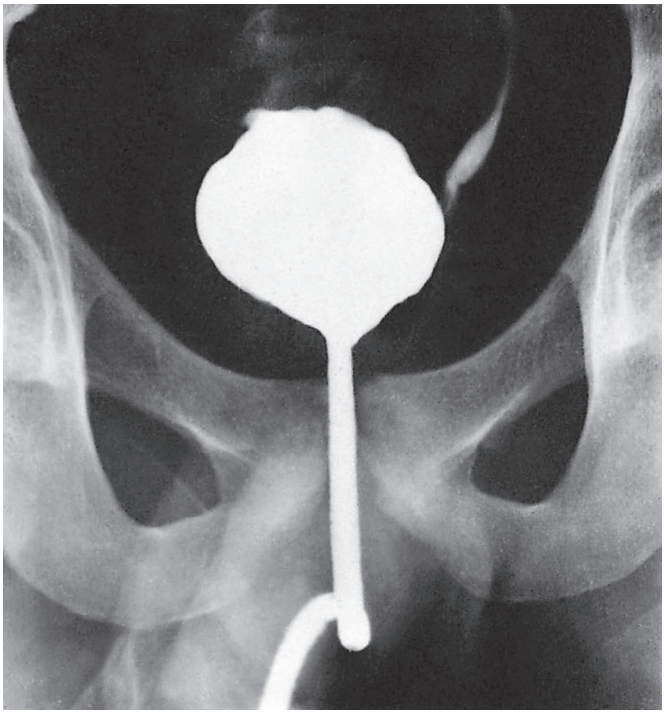

Figure 83.31 Retrograde cystography showing a small 'thimble' bladder due to tuberculosis.

Special cases

Genitourinary tuberculosis

Genitourinary tuberculosis (GU-TB) caused by *Mycobacterium tuberculosis* can affect any part of the urinary tract. Renal calcification and ureteric strictures are typical in the upper urinary tract. In the bladder, initial manifestations include a red, oedematous bladder wall with ulceration and visible tubercles (yellow lesions with a red halo). This typically starts around the ureteric orifices and trigone. As the disease progresses, fibrosis and contraction of the bladder occur ('thimble bladder'), as well as calcification and fistula formation (***Figure 83.31***).

Patients may present with fevers, weight loss, night sweats, UTI symptoms or haematuria. Investigation may reveal a sterile pyuria, and cystoscopy with biopsy will confirm the diagnosis. Three early morning urine samples for acid-fast bacilli or polymerase chain reaction of the urine can be used for diagnosis of TB infection. Cross-sectional imaging with a CT urogram should be performed to evaluate the kidneys and ureters as they are likely to also be affected.

Treatment consists of antituberculous therapy with isoniazid, rifampicin, pyrazinamide and ethambutol. Severe bladder disease may require surgical treatment following completion of antituberculous therapy. Options include augmentation enterocystoplasty, cystectomy and orthotopic bladder substitution, or ileal conduit urinary diversion. However, the choice of treatment will depend upon the concomitant upper tract involvement and patient preferences.

Schistosomiasis

Parasitic infection with the trematode *Schistosoma haematobium* originates from infection with freshwater snails. The disease is endemic in Egypt, parts of Africa, Israel, Syria, Saudi Arabia, Iran, Iraq and the shores of China's great lakes. The parasite penetrates the skin and travels to the liver (as schistosomules), where it matures. Adult trematodes migrate to vesical veins and lay eggs (containing miracidium larvae), which leave the body by penetrating the bladder and entering the urine. The active phase is when eggs are actively being laid, whereas the inactive phase is when the adult has died but there is an ongoing reaction to the remaining eggs.

At the time of infection, a local inflammatory response leads to irritation of the skin ('swimmer's itch'). Acute fever (Katayama fever) may ensue at the onset of egg laying (3 weeks to 4 months after infection) with fever, lymphadenopathy, splenomegaly and eosinophilia. When the eggs are deposited in the bladder, the typical bladder symptoms of intermittent painless haematuria and terminal dysuria occur. Chronic infection can lead to a small, contracted, fibrotic bladder similar to that seen with tuberculous cystitis. Patients are at increased risk of developing ureteric strictures, urethral strictures and squamous cell carcinoma of the bladder.

Investigation with midday (to coincide with the time of maximum egg shedding) urine microscopy may show characteristic eggs with terminal spines (***Figure 83.32***). Cystoscopy may show characteristic 'sandy patches' at the trigone (due to calcified dead ova with degeneration of the overlying urothelium), ulceration or papillomas. In advanced cases, carcinoma may be present. Bladder or rectal biopsies may identify eggs.

Figure 83.32 *Schistosoma haematobium* eggs with terminal spines. (Reproduced with permission from Ray D, Nelson TA, Fu CL *et al*. Transcriptional profiling of the bladder in urogenital schistosomiasis reveals pathways of inflammatory fibrosis and urothelial compromise. *PLoS Negl Trop Dis* 2012; **6**(11): e1912.)

In cases where suspicion remains high but eggs have not been identified, serology (enzyme-linked immunosorbent assay [ELISA]) has high sensitivity and specificity. A CT urogram should be performed to assess for obstructive uropathy secondary to a scarred, contracted bladder.

Treatment is with praziquantel 20 mg/kg in two divided doses 4–6 hours apart. A small, contracted bladder may require reconstruction with augmentation enterocystoplasty, cystectomy and orthotopic bladder substitution, or ileal conduit urinary diversion.

Summary box 83.5

Urinary tract infections

- UTIs can be classified as uncomplicated or complicated
- Patients should undergo evaluation for TB and schistosomiasis if suspected based on the history or presence of persistent sterile pyuria

CHRONIC INFLAMMATORY CONDITIONS OF THE BLADDER

Chronic inflammatory conditions of the bladder are of multifactorial aetiology but present with a similar clinical picture of urinary frequency, urgency and pain, with or without haematuria (***Table 83.14***). The principles of management are to exclude a malignant cause for the symptoms, to preserve upper tract function and to improve symptoms and quality of life.

TABLE 83.14 Common chronic inflammatory bladder diseases.

Idiopathic	Interstitial cystitis
Infective	• Chronic bacterial UTI • Fastidious organisms and parasites (*Chlamydia*, *Gonorrhoea*, tuberculosis, schistosomiasis)
Radiation therapy	Radiation cystitis
Drugs	• Ketamine cystitis • Cyclophosphamide cystitis
Iatrogenic	BCG cystitis
Autoimmune	Lupus cystitis

BCG, bacillus Calmette–Guérin; UTI, urinary tract infection.

Bladder pain syndrome/interstitial cystitis

Bladder pain syndrome (BPS) is a chronic condition characterised by pelvic pain or pressure that is perceived to be originating from the bladder, accompanied by one or more urinary symptoms, including frequency, urgency and nocturia. The diagnosis is made once other confusable diseases that could cause similar symptoms have been excluded. The term interstitial cystitis (IC) is often used interchangeably with BPS but represents a distinctive bladder organ-specific phenotype with characteristic cystoscopic and histopathological features as opposed to the systemic phenotype of BPS. The precise aetiology of BPS/IC is unknown.

Clinical features

Patients present with disabling bladder or pelvic pain, urinary urgency and severe urinary frequency and nocturia. Those with BPS may have other associated chronic medical conditions (e.g. fibromyalgia, irritable bowel syndrome, migraines).

Investigation

Urine analysis and culture, testing for sexually transmitted infections and urine cytology should be performed to exclude an infective or malignant cause for symptoms. Pelvic imaging should be performed if an alternative diagnosis, such as endometriosis, is suspected. Cystoscopy should be performed to exclude other pathology and also to aid accurate phenotyping of BPS (bladder capacity, presence of Hunner lesions). The aim of phenotyping is to separate those with clear bladder pathology (small capacity, Hunner lesions, chronic inflammation) from those with anatomically normal bladders as treatment options vary. In those with Hunner lesions, bladder biopsy shows a chronic pancystitis, often with marked infiltration with lymphocytes and macrophages and mast cell infiltration. The 'INPUT' classification system allows patients' symptoms to be described in five different clinical domains in order to guide multimodal therapy: Infection, Neurological/systemic, Psychosocial, Ulcers and Tenderness of muscles. The aim of the evaluation is to assess the relative contribution of each of these factors to the patient's symptoms.

Treatment

Treatment of BPS/IC consists of conservative, pharmacological, intravesical and surgical options.

Conservative

Patient education about the chronicity of the condition, behavioural modification (timed voiding, bladder training), stress reduction, dietary alteration (avoidance of caffeine and spicy and acidic foods) and physical therapy should be the initial management for all patients.

Pharmacological

Several pharmacological therapies have been studied for BPS/IC, all with variable efficacy. Neuropathic analgesics (e.g. amitriptyline, pregabalin) are used for those with a significant pain component, whereas antimuscarinics and β_3-agonists are used for frequency, nocturia and urgency symptoms. Oral pentosan polysulphate (Elmiron), a glycosaminoglycan (GAG) layer replacement treatment, has demonstrated efficacy in pain and urinary symptoms but recent reports of ophthalmic adverse events with long-term exposure may limit its use. Evidence for other oral therapies (e.g. antihistamines and immunosuppressants) is mixed.

Guy Hunner, 1868–1957, American surgeon, first described the characteristic inflammatory lesions of the bladder in 1915.

Intravesical

Direct instillation of GAG layer replacement therapies are thought to repair the defective GAG layer, which may be part of the pathophysiology of BPS/IC. Although the evidence base is weak, they are widely used with satisfactory outcomes in some patients without the side effects seen with oral therapies. Intravesical 'cocktails' with combinations of alkalinised local anaesthetic, steroid and GAG layer therapies may be useful for acute flares.

Surgical

Several surgical options have been studied. For those with Hunner lesions, fulguration or laser to these lesions can be beneficial. Cystodistension as a treatment has variable evidence for success. Minimally invasive treatment with intravesical BTX-A or SNS should be offered after the above measures have failed. If these options fail to improve symptoms major surgical reconstruction can be considered in selected cases. This is more suitable for those with clear evidence of bladder pathology (small capacity, fibrotic, ulcerated bladder). The aim is to increase the capacity of the bladder or divert the urinary stream, with options including bladder augmentation cystoplasty, cystoplasty with or without subtrigonal resection or urinary diversion with or without cystectomy. It is generally thought that cystectomy with orthotopic bladder reconstruction or ileal conduit urinary diversion is the best option as any form of bladder preservation risks ongoing pain in the remnant bladder segment with requirement for secondary cystectomy in up to 65%.

Radiation cystitis

Radiation cystitis is a common complication of pelvic radiotherapy with incidence rates ranging from 23% to 80%. Radiation treatment causes endothelial cell damage and perivascular fibrosis, resulting in ischaemia and obliterative endarteritis. Haematuria is more pronounced than that seen in BPS/IC. The end stage is a small, fibrotic bladder with poor compliance and a risk of upper tract compromise, as for other chronic inflammatory bladder diseases.

Emergency admission with haematuria requires resuscitation, catheterisation and bladder washout and blood transfusion as required. Cystoscopic management with fulguration or laser to bleeding vessels should be performed initially to stop bleeding. Intravesical GAG layer replacement therapies can be considered, and hyperbaric oxygen therapy has shown benefit in severe, refractory cases of haemorrhagic cystitis. Radiological arterial embolisation can also be considered for refractory cases, but ischaemic complications occur in 10–63% (e.g. skin or bladder necrosis, gluteal paresis, perineal or buttock pain). Finally, urinary diversion with or without cystectomy can be performed for end-stage cases, but perioperative morbidity is almost 50% and mortality is 16%.

Ketamine cystitis

Ketamine is an *N*-methyl-d-aspartate (NMDA) antagonist. It has been used for decades as an anaesthetic agent but has become increasingly popular as a recreational 'street drug' because of its euphoric and psychedelic effects. As a result of long-term ketamine abuse, up to 30% develop the condition of ketamine cystitis – a chronic inflammatory bladder condition characterised by a small, contracted, inflamed bladder with ureteric stricture and hydronephrosis in advanced cases. The severity of the inflammatory effect is related to the duration of abuse.

The clinical presentation is very similar to that of BPS/IC and investigation with cystoscopy, bladder biopsy and CT urogram should be performed to exclude other inflammatory or infective conditions (e.g. TB, schistosomiasis) and to evaluate the effect on the upper urinary tract (***Figure 83.33***).

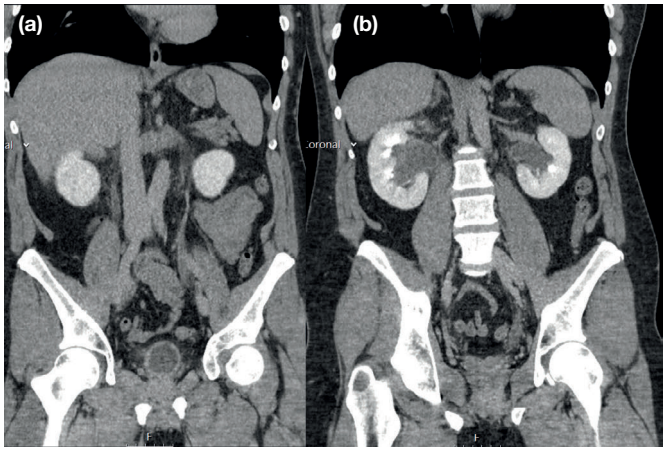

Figure 83.33 Computed tomography showing a thickened bladder **(a)** and bilateral hydroureteronephrosis **(b)** secondary to ketamine cystitis.

Initial management is centred around the cessation of ketamine use as surgical intervention should not be performed in those continuing to use ketamine. If patients have upper tract obstruction due to ureteric involvement in the inflammatory process, renal drainage with stent or nephrostomy will be required as a temporising measure to preserve renal function. Management of LUTS and pain follows the same pathway of oral and intravesical therapies as for BPS/IC, although regimes for analgesia consisting of co-codamol, amitriptyline and buprenorphine patches have proved particularly beneficial in this condition.

Surgical approaches are similar to those for the other chronic inflammatory conditions, namely augmentation enterocystoplasty, supratrigonal cystectomy and ureteric reimplantation, total cystectomy with orthotopic neobladder, heterotopic neobladder with appendicovesicostomy or urinary diversion with or without a cystectomy. However, the rate of perioperative complications with major reconstructive surgery in this population is high; those with upper tract involvement at presentation are likely be at higher risk of postoperative complications.

Summary box 83.6

Chronic inflammatory conditions of the bladder

- Patients with chronic inflammatory bladder conditions should have a bladder biopsy to identify a treatable cause (e.g. TB)
- Upper tracts should be evaluated with cross-sectional imaging to identify renal obstruction due to a high-pressure bladder
- Management is aimed at symptomatic improvement and maintaining low bladder pressure

HAEMATURIA

Haematuria is the presence of blood in the urine. It can be classified as visible (VH, or macroscopic) and non-visible (NVH, microscopic or dipstick). Microscopic haematuria is defined as the presence of red blood cells (RBCs) on microscopic examination of the urine and is variably defined as three or more or five or more RBCs per high-power field. A few RBCs can be found in the urine of healthy people, especially after rigorous exercise, sexual intercourse or from menstrual contamination, with an upper limit of 1 million RBCs per 24 hours considered normal. Overall, 30–60% of patients with NVH are found to have an underlying cause, depending upon the age and risk factors of the population studied and the type of investigation performed, but the rate of malignancy is around 5% for those with NVH compared with almost 20% for those with VH.

Both VH and NVH can arise from anywhere in the renal tract, including renal parenchyma, renal pelvis, ureter, bladder, prostate and urethra. Certain diseases outside the renal tract may also lead to haematuria (***Table 83.15***).

There is a lack of consensus between national guidelines regarding who should be investigated for haematuria. However, all patients should have a digital rectal examination to evaluate prostate size and consistency, urine culture to exclude infection and urine cytology to aid diagnosis of urothelial malignancy in those at higher risk (smokers, occupational history, family history, elderly). Serum estimated glomerular filtration rate (eGFR) should be assessed, and prostate-specific antigen (PSA) testing should be discussed in men with a 10- to 15-year life expectancy to assess prostate cancer risk. Those with visible haematuria should undergo evaluation of the LUT with cystoscopy and upper urinary tract with CT urogram. Patients with NVH should have the urine microscopy repeated on three occasions, and only be investigated if the haematuria is persistent. Patients with NVH who are over 40 years old should also undergo evaluation with flexible cystoscopy and renal tract ultrasound in younger patients deemed to be at low risk of urothelial malignancy. In those with NVH and proteinuria, where the above urological investigations are negative, nephrological causes should be sought.

Summary box 83.7

Haematuria

- Patients with haematuria require upper tract investigation with CT urogram and lower tract investigation with cystoscopy

TABLE 83.15 Common causes of haematuria.

	• Cancer (renal cell, urothelial, squamous cell, adenocarcinoma) • Stones • Infection • Trauma • Cystic diseases (e.g. medullary sponge kidney, polycystic kidney disease) • Vascular disorder (e.g. vascular malformations, renal vein thrombosis) • Nephrological causes (IgA nephropathy, glomerulonephritis, vasculitis, Henoch–Schönlein purpura) • Papillary necrosis
	• Cancer (urothelial) • Stones • Infection • Trauma • Benign diseases (PUJ obstruction, stricture)
	• Cancer (urothelial, squamous cell, adenocarcinoma) • Stones • Infection (bacterial, TB, schistosomiasis) • Trauma • Chronic inflammatory conditions (IC, radiation cystitis, ketamine cystitis, cyclophosphamide cystitis)
	• Cancer • Benign prostatic enlargement • Infection
	• Bleeding disorders (e.g. sickle cell, thrombophilia) • Anticoagulation therapy
	• Urethral instrumentation • Nephrostomy

IC, interstitial cystitis; IgA, immunoglobulin A; PUJ, pelviureteric junction; TB, tuberculosis.

BLADDER CANCER

Bladder cancer is a highly prevalent disease with 540 000 cases worldwide and 188 000 deaths reported in 2015. Risk factors for developing bladder cancer are shown in ***Table 83.16***.

Pathology

The commonest type of bladder cancer is transitional cell (urothelial) carcinoma (***Table 83.17***). Squamous cell carcinoma occurs secondary to chronic inflammation (e.g. indwelling catheter, stone, schistosomiasis), and primary adenocarcinoma usually originates in the urachus (dome of the bladder) or in

Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, published his description of this form of purpura in 1837.

TABLE 83.16 Risk factors for bladder cancer.

Smoking	2–5 times increased risk
Occupational exposure (aromatic hydrocarbons)	• Tanner • Rubber • Paint and dyes • Gas and tar • Hairdressers • Plumbers • Painters
Environmental carcinogens	Arsenic in drinking water
Chronic inflammation of bladder	• Indwelling catheter • Stones • Schistosomiasis (predisposes to squamous cell carcinoma) • Recurrent infections leading to keratinising squamous metaplasia
Drugs	• Phenacetin • Cyclophosphamide
Pelvic radiotherapy	

those with bowel in the urinary tract (augmentation enterocystoplasty, bladder exstrophy repair). Histological variants (e.g. micropapillary, sarcomatoid, plasmacytoid, nested variant) can coexist with urothelial carcinoma and generally signify aggressive tumours with poorer prognosis than pure urothelial carcinoma.

TABLE 83.17 Common histological subtypes of bladder cancer.

Type	Frequency
Transitional cell carcinoma	>90%
Squamous cell carcinoma	1–7%
Adenocarcinoma	2%
Rare: Melanoma, lymphoma, sarcoma, small cell carcinoma, phaeochromocytoma	<1%
Metastatic adenocarcinoma (colorectal, prostate, kidney, ovary)	<1%

Grading and staging

Bladder cancer is graded as well differentiated (G1), moderately differentiated (G2) and poorly differentiated (G3). Stages Tis, Ta and T1 are non-muscle-invasive (NMIBC) and stages T2, T3 and T4 are muscle-invasive (MIBC) or locally advanced (***Figure 83.34***). Approximately 70% of tumours are NMIBC at presentation, whereas 30% are MIBC or metastatic.

Presentation

Patients most commonly present with painless haematuria (in 85%). Storage LUTS of frequency, urgency, dysuria and recurrent UTI may be present. Rarely, patients may present

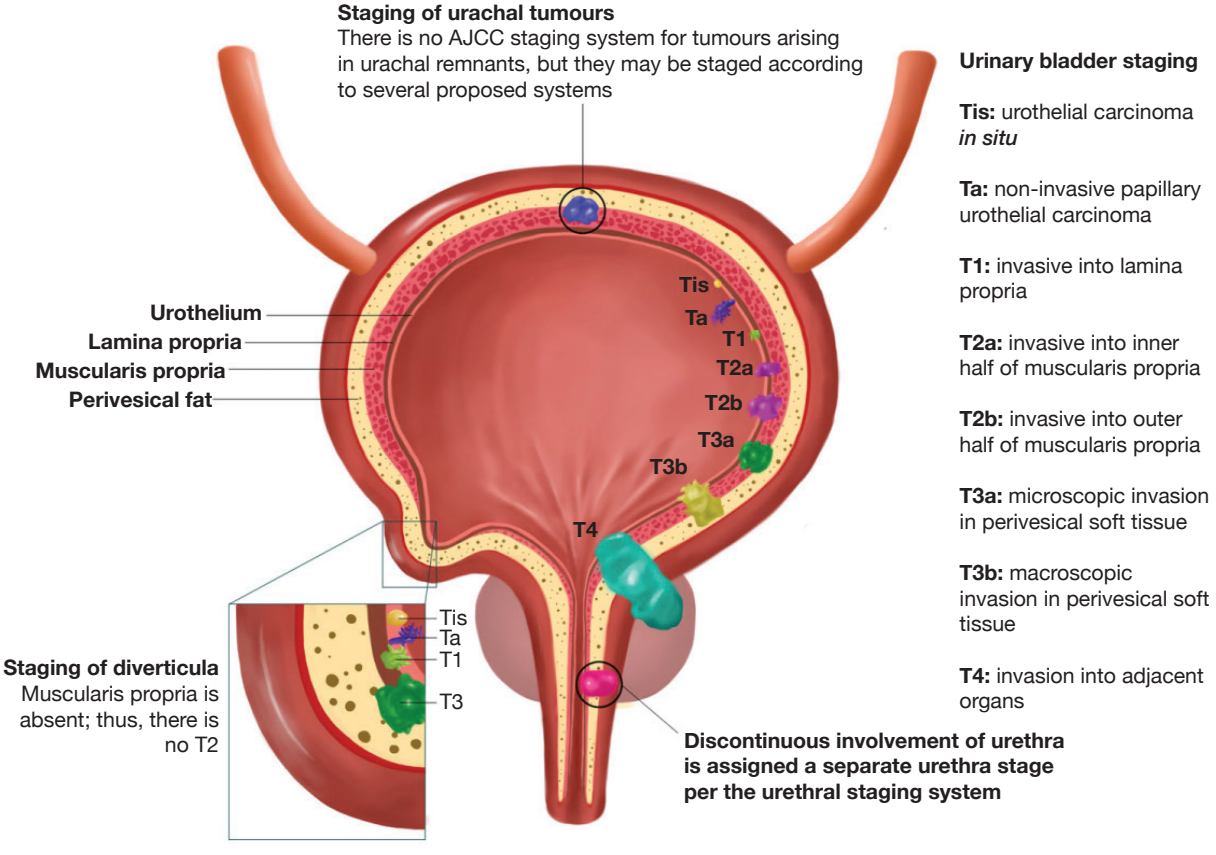

Figure 83.34 Staging of the primary tumour in bladder cancer. (Reproduced with permission from Magers MJ, Lopez-Beltran A, Montironi R *et al*. Staging of bladder cancer. *Histopathology* 2019; **74**(1): 112–34.)

with flank pain, weight loss, pelvic or bone pain and lower limb oedema in advanced cases.

Investigation

Urine

Urine should be cultured and examined cytologically for malignant cells. An increasing number of urinary biomarkers based on panels of epigenetic markers are being studied, but none has been shown to surpass the accuracy of cystoscopy and so are not routinely used.

Cross-sectional imaging: CT urography and MRI of the bladder

CT urogram is the gold standard evaluation for upper tract disease (including hydronephrosis) and assessment of nodal metastases (***Figure 83.35***). MRI of the bladder can be useful in staging of the primary tumour. Imaging should ideally be performed prior to transurethral resection of the bladder tumour (TURBT) as false-positive T3 disease can be diagnosed if cross-sectional imaging is carried out too soon after TURBT. CT of the chest should be performed in confirmed bladder cancer cases for complete staging.

Cystourethroscopy

Flexible cystourethroscopy under local anaesthetic is the mainstay of diagnosis and should always be performed on patients with haematuria (***Figure 83.36***). The diagnostic accuracy of conventional 'white' light cystoscopy has been improved by optical enhancement techniques such as narrow-band imaging (NBI) and photodynamic 'blue' light cystoscopy (PDD), which relies on the photosensitiser hexaminolevulinate. These techniques are recommended in patients with a high suspicion of cancer and negative initial findings, or in those with positive cytology but negative 'white' light cystoscopy.

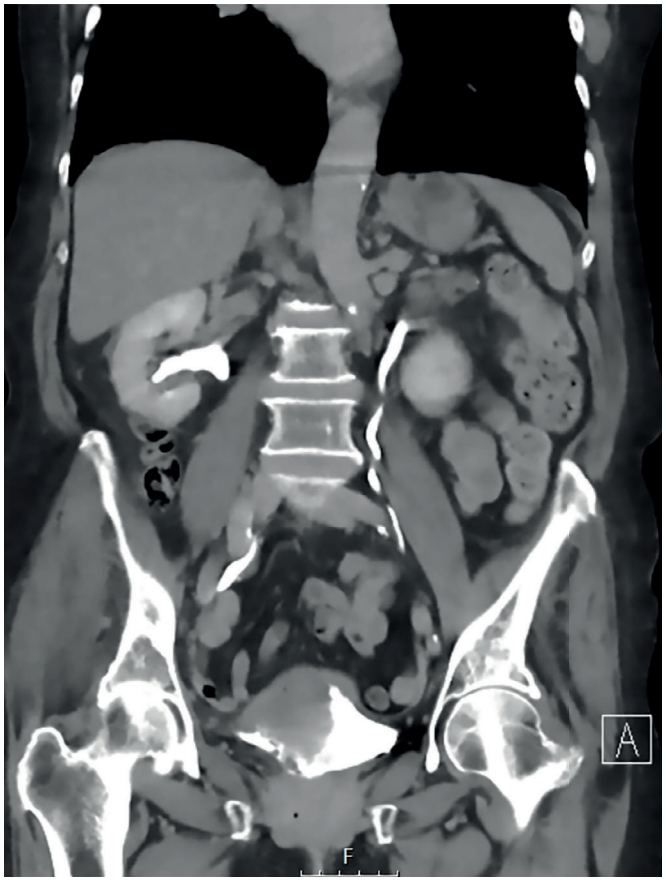

Figure 83.35 Computed tomography showing a large right-sided bladder tumour.

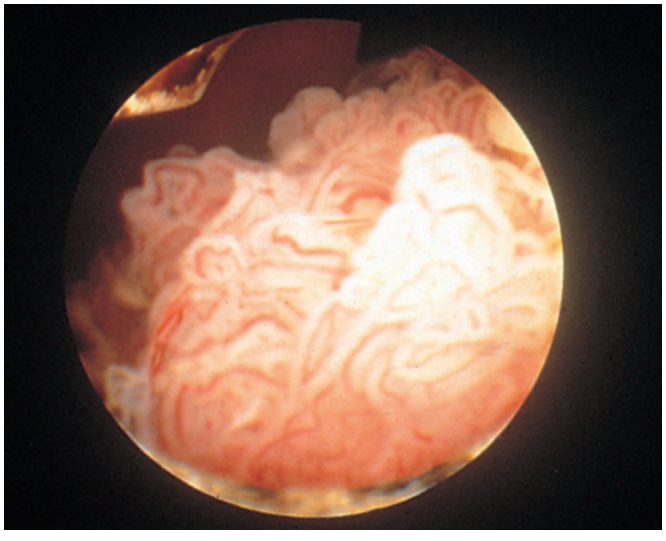

Figure 83.36 Cystoscopic appearance of a papillary bladder tumour.

Non-muscle-invasive bladder cancer

The aim of managing patients with NMIBC is to reduce the risk of tumour recurrence and progression to MIBC.

Transurethral resection

The initial management of bladder tumours consists of TURBT for accurate staging purposes. This is performed with a rigid cystoscope under general anaesthesia. A bimanual examination should be performed prior to resection to determine whether a mass is palpable and, if so, whether it is mobile or fixed. This should be repeated following resection. For large tumours, a standard fractionated resection of the entire tumour, including the tumour base with deep muscle, is performed. For smaller (<3 cm) solitary tumours, en bloc resection of the entire tumour can be performed and may reduce the risk of tumour recurrence by preventing the spread of tumour cells and subsequent implantation across the bladder. The following details should be recorded to enable accurate risk stratification: the size of the primary tumour, the number of tumours, the nodular or papillary features, concern for the presence of CIS and completeness of visual resection. Mapping biopsies from the trigone, bladder dome and the right, left, anterior and posterior bladder wall should be taken if CIS is suspected.

Postoperative mitomycin C instillation

Approximately 30% of patients with NMIBC will experience early recurrence following initial TURBT and so an immediate

post-TURBT dose of mitomycin C should be instilled into the bladder. This has been shown to reduce the risk of tumour recurrence by 12%.

Risk stratification

Based on the final histological grade and stage, the patient can be risk stratified. Those with multifocal high-grade T1 tumours with CIS are at highest risk of disease recurrence and progression to MIBC. For these patients, early radical cystectomy should be discussed as they are at high risk of tumour progression. An alternative is intravesical bacillus Calmette–Guérin (BCG) to reduce the risk of tumour progression. Those with solitary low-grade Ta tumours have the lowest risk of recurrence and progression and so the management of this group consists of regular cystoscopic surveillance alone. For intermediate-risk tumours, a 6-week course of intravesical mitomycin C can be considered to reduce the risk of recurrence.

Repeat TURBT

For those with high-grade or T1 tumours, a repeat TURBT 2–6 weeks after initial TURBT should be performed to identify any residual tumour. Upstaging to MIBC is found in up to 40%.

Intravesical BCG

For high-risk tumours, intravesical treatment with immunotherapy (BCG) has been shown to reduce the risk of progression to MIBC. The treatment is given weekly for 6 weeks, followed by a 3-weekly treatment every 6 months for 3 years. Side effects include transient fever, dysuria, rarely BCG sepsis and BCG cystitis necessitating cystectomy.

Muscle-invasive bladder cancer

The two primary radical treatment options for MIBC are radical cystectomy with urinary diversion or chemoradiotherapy. Whichever modality is employed, 5-year survival rates are approximately 60%. There is a move towards primary surgical treatment in most centres. The use of systemic chemotherapy given before (neoadjuvant) radical cystectomy has been shown to improve survival by about 5–7%. Newer immunotherapy approaches are being evaluated in the neoadjuvant and adjuvant setting; in particular, immune-checkpoint inhibitors with antibodies targeting the programmed cell death ligand 1 (PDL1) pathway are demonstrating promising results.

Radical cystectomy and ileal conduit urinary diversion

Those with poor bladder function, significant haematuria, upper tract obstruction, widespread CIS or factors that affect successful radiotherapy (e.g. bilateral hip replacements, inflammatory bowel disease) are more suitable for radical cystectomy and pelvic lymphadenectomy. This is major surgery with a perioperative morbidity rate of up to 50%, and so patients should undergo anaesthetic assessment to assess suitability for surgery.

Alternative drainage for urine is necessary after removal of the bladder. The standard procedure is to perform an ileal conduit diversion. Male patients should be counselled about the onset of erectile dysfunction and anejaculation after the operation, although in some cases the nerve supply for erectile function can be preserved through careful dissection; they should also be told about alternative forms of urinary diversion, which include continent urinary diversions and orthotopic bladder replacement.

Patients should be seen by a stoma care therapist, who will ensure that the correct stoma site is chosen, avoiding skin creases to prevent leakage from the ileostomy.

The abdomen is opened through a lower midline incision from the umbilicus to pubic symphysis. The liver and the retroperitoneum are checked for evidence of metastases and the operability of the bladder is assessed. A bilateral pelvic lymphadenectomy is performed, removing external iliac nodes, internal iliac nodes and the nodes in the obturator fossae. The vessels passing to the bladder from the side wall of the pelvis are ligated and divided; the ureters are then divided. The posterior ligaments extending from the pararectal area to the back of the bladder are ligated and divided, and the layer posterior to Denonvilliers' fascia is opened. The endopelvic fascia is then divided on each side and the puboprostatic ligaments are divided. The dorsal venous complex is divided, and the urethra is then mobilised and divided. The ligaments lateral to the prostate are divided and the bladder is removed. In women, the uterus and anterior vaginal wall need to be included. Women must be counselled about the loss of ovarian and uterine function. Laparoscopic and robotic cystectomy are increasingly becoming the standard of care with the aim of minimising perioperative morbidity, but evidence for superiority of these techniques over the traditional open approach is awaited.

An isolated loop of ileum is then prepared on its own mesentery, and continuity of the small bowel restored. The ureters are then implanted into the bowel either separately (Bricker) or as one plate (Wallace) and the ileostomy is created. Meticulous care must be taken to close all mesenteric windows, thus avoiding internal hernias (***Figure 83.37***).

Alternative techniques of urinary diversion

Alternative forms of diversion are most suitable for highly motivated patients with adequate renal and liver function who wish to avoid an external collection device.

Orthotopic bladder

An orthotopic bladder is the creation of a pouch (typically using small or large bowel) that is then anastomosed to the patient's urethra. Contraindications to an orthotopic bladder include widespread CIS and tumour in the prostatic urethra. Many different types of orthotopic bladder have been described but

Charles Pierre Denonvilliers, 1808–1872, Professor of Anatomy and later of Surgery, Paris, France. Denonvilliers' fascia is the fascial layer that separates the prostate and bladder from the rectum.
Eugene Bricker, 1908–2000, American surgeon, described the separate anastomosis of each ureter to the ileal segment.
David Mitchell Wallace, 1913–1992, urologist, St Peter's Hospital, London, UK, described the anastomosis of both ureters together followed by anastomosis to the ileal segment in one plate in 1966.

the Studer pouch is widely performed. The aim is to achieve a large-capacity, low-pressure reservoir. A pouch is made from 57 cm of detubularised ileum. The ureters are implanted into a proximal 'chimney' that acts as an antireflux mechanism, and the pouch is anastomosed to the urethra (***Figure 83.37***). Patients can void by relaxing the pelvic floor and straining, but CISC may be required to completely empty the pouch in 15–30%.

Continent cutaneous diversion (heterotopic bladder substitute)

For those who require urethrectomy, or in whom the urethra is non-functional, a continent cutaneous diversion can be performed. A Studer pouch can be made as described above. The appendix, or a separate section of ileum if the appendix is not available, is then anastomosed from the bladder to the umbilicus or right iliac fossa. The patient can then intermittently catheterise this channel to drain the pouch.

Ureterosigmoidostomy (Mainz II pouch)

This option is popular in developing countries as there is no requirement for an external appliance or catheters. Patients require good anal sphincteric function. The sigmoid colon is detubularised and refashioned into a pouch into which the ureters are inserted (***Figure 83.37***). However, high rates of ascending UTI and increased risk of malignancy (associated with mixing of faecal and urinary streams), bowel frequency and urge incontinence have limited its use.

Complications of urinary diversion

The ileal conduit urinary diversion has the lowest rate of complications of all forms of urinary diversion. Risks include ureteroileal leak or stricture (5%), stomal complications such as stenosis or hernia (20%), upper tract dilatation (30%), recurrent UTIs and rarely metabolic complications (hyperchloraemic metabolic acidosis).

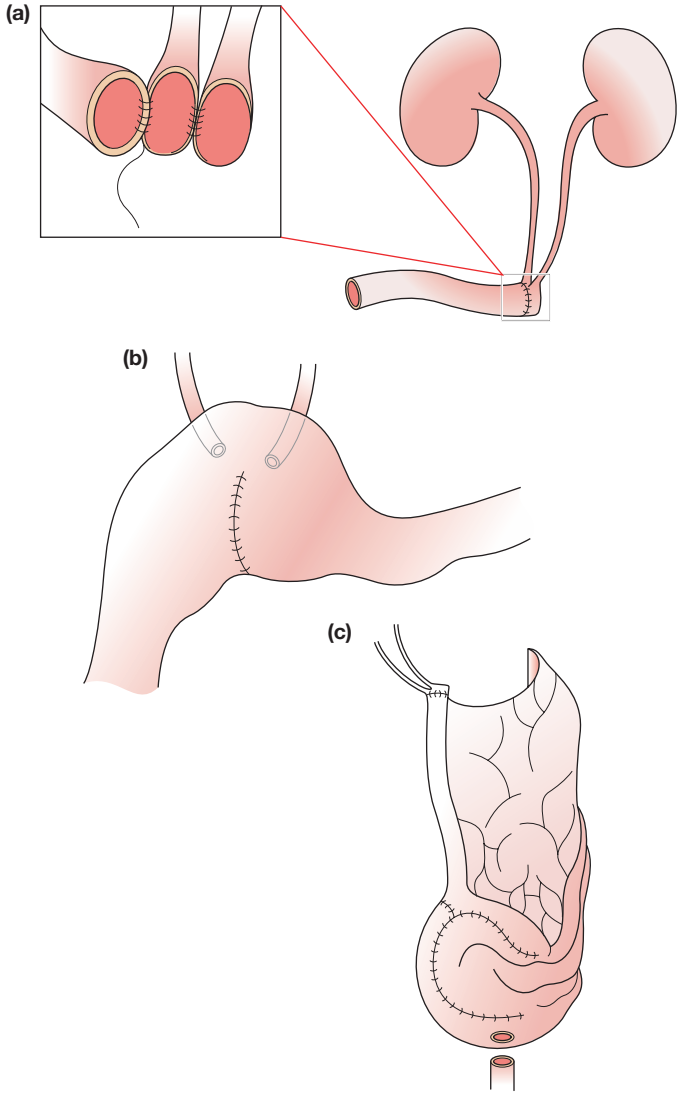

Figure 83.37 Techniques of urinary diversion of urine. **(a)** Ileal conduit; the ureters are spatulated and anastomosed to ileum; **(b)** ureterosigmoidostomy; **(c)** ileal neobladder with an antireflux long afferent limb.

Summary box 83.8

Bladder cancer

- The commonest presenting symptom of bladder cancer is haematuria
- Smoking and occupational exposure to certain chemicals are the commonest risk factors
- Bladder cancer can be non-muscle-invasive or muscle-invasive
- The management of NMIBC is TURBT, followed by intravesical mitomycin C or BCG depending on the risk stratification
- The management of MIBC is neoadjuvant chemotherapy followed by radical cystectomy
- Options for urinary diversion include ileal conduit, orthotopic bladder substitute, heterotopic bladder substitute or ureterosigmoidostomy
- The choice of diversion is dependent on patient factors, tumour factors and surgeon experience

Complications of orthotopic or continent pouches include ureteroileal leak or stricture, urinary leak from the pouch, stone formation, UTIs, metabolic complications (hyperchloraemic metabolic acidosis) and rarely adenocarcinoma (5%). Stenosis and incontinence are the main complications of appendicovesicostomy and up to 50% may require some form of revision surgery to the channel over a 5-year period.

Radical external beam radiotherapy

Radical radiotherapy is an option for very elderly or unfit patients who are unsuitable for radical cystectomy. Typically, treatment with 66 Gy is administered in 30 fractions over 6 weeks. However, long-term urinary and bowel side effects can impair quality of life and there is a risk of secondary malignancy and fistula.

Urs Studer, contemporary, Swiss urologist, described a neobladder pouch that is made of ileum.
The **Mainz II** pouch describes the formation of a low-pressure sigmoid colon pouch into which both ureters are anastomosed. It is named after the city where the inventors of this technique worked.

Bladder preservation with radical TURBT, neoadjuvant chemotherapy and then chemoradiotherapy is being studied as an option for those with very localised MIBC, but this remains an option for only a very select group.

BLADDER TRAUMA

Bladder trauma can be classified as iatrogenic or non-iatrogenic (blunt or penetrating). Of non-iatrogenic causes, abdominal trauma and pelvic fracture are the most common, with bladder injury reported in 10% of cases. Iatrogenic injury is most commonly the result of TURBT, anti-incontinence surgery or pelvic surgery (e.g. hysterectomy, caesarean section, colorectal surgery). Rarely, spontaneous rupture can occur after bladder augmentation without any history of trauma. This is due to overdistension in those with limited bladder sensation (e.g. SCI), and often presents with vague abdominal pain, fever or sepsis. A high index of suspicion of bladder rupture in patients with a history of bladder augmentation is required.

Classification

Bladder injuries can be either extraperitoneal (the peritoneum is intact and urine extravasates into the retropubic space but not into the peritoneal cavity), intraperitoneal (the peritoneum over the bladder is injured and urine extravasates into the peritoneal cavity) or mixed (***Table 83.18***). Intraperitoneal ruptures are associated with a risk of urinary peritonitis and ileus, and so are more significant than extraperitoneal ruptures.

Clinical features

If iatrogenic, the injury may be recognised at the time. If perforation during transurethral surgery is noted, the procedure should be stopped, haemostasis should be achieved and the patient should be catheterised. In cases of trauma, patients typically present with suprapubic pain, difficulty or inability to pass urine, haematuria and abdominal distension.

Investigation

Retrograde cystogram or CT cystogram confirms the diagnosis and identifies whether the injury is intraperitoneal or extraperitoneal (***Figure 83.38***). Postdrainage views should be obtained as a small amount of contrast extravasation may be missed with a full bladder. With intraperitoneal perforation, contrast is seen to outline loops of bowel.

Extraperitoneal injury

The management of extraperitoneal rupture consists of urethral catheterisation with free bladder drainage for 10–14 days, followed by a cystogram to ensure that the injury has healed prior to removal of the catheter. If the extraperitoneal injury is iatrogenic and recognised at the time of open or laparoscopic surgery, it can be repaired at the time in two layers with 2/0 Vicryl absorbable suture. If the bladder injury is associated with a pelvic fracture and the patient is undergoing surgery for open fixation, or repair of a rectal or vaginal perforation, the bladder should be repaired at the same time.

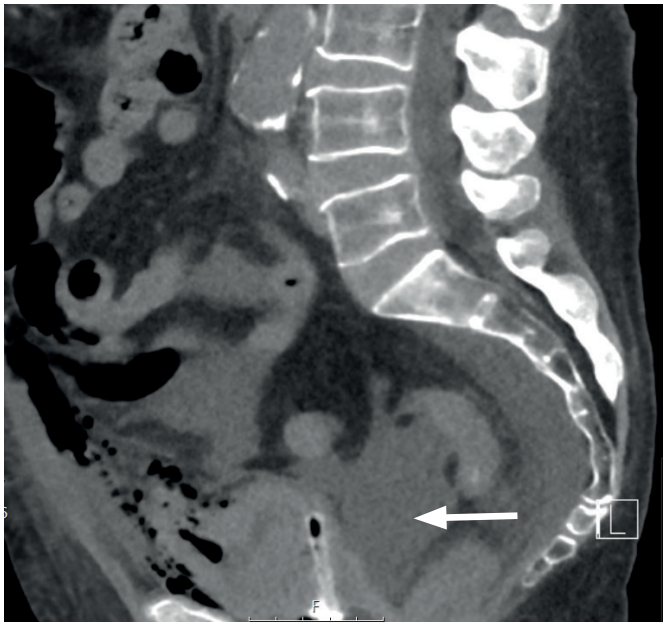

Figure 83.38 Computed tomography showing intraperitoneal bladder injury after transurethral resection of the bladder tumour (arrow pointing to intraperitoneal urinary extravasation).

TABLE 83.18 Grading of bladder trauma.

Grade	Injury	Description
I	Haematoma	Contusion, intramural haematoma
	Laceration	Partial thickness
II	Laceration	Extraperitoneal bladder wall laceration <2 cm
III	Laceration	Extraperitoneal ≥2 cm or intraperitoneal <2 cm bladder wall laceration
IV	Laceration	Intraperitoneal bladder wall laceration ≥2 cm
V	Laceration	Laceration extending into the bladder neck or ureteral orifice (trigone)

Intraperitoneal injury

Intraperitoneal injuries usually require open surgical repair to reduce the risks of urinary contamination of the peritoneal space. If the injury is small without significant fluid extravasation, a period of catheterisation can be attempted in clinically well patients, but close monitoring is required and a cystogram at 2 weeks should confirm complete healing prior to removal of the catheter. If it has not healed, open repair will be required.

Summary box 83.9

Bladder trauma

- Bladder trauma can be extraperitoneal or intraperitoneal
- Extraperitoneal injury can be managed with indwelling catheterisation for 10–14 days
- Intraperitoneal injury most often requires laparotomy and repair of the bladder defect

CHAPTER 84

The prostate and seminal vesicles

Learning objectives

To understand:

- The relationship of anatomical structure and biochemical function to the development and treatment of benign and malignant disease of the prostate
- The terminology used to describe lower urinary tract symptoms and to know their causes as well as the treatment options available
- Which investigations are appropriate for benign and malignant conditions of the prostate
- Clinical staging of carcinoma of the prostate and how staging contributes to the complex decision making

BENIGN PROSTATIC HYPERPLASIA

Aetiology

Hormones

Serum testosterone levels slowly but significantly decrease with advancing age; however, levels of oestrogenic steroids are not decreased equally. According to this theory, the prostate enlarges because of increased oestrogenic effects. It is likely that the secretion of intermediate peptide growth factors plays a part in the development of **benign prostatic hyperplasia** (BPH). Metabolic syndrome and hereditary factors have also been implicated in its development.

Summary box 84.1

Benign prostatic hyperplasia (BPH)

- Occurs in men over 50 years of age; by the age of 60 years, 50% of men have histological evidence of BPH
- It is a common cause of significant lower urinary tract symptoms (LUTS) in men and the most common cause of bladder outflow obstruction (BOO) in men >70 years of age

Pathology

BPH affects both glandular epithelium and connective tissue stroma to variable degrees. BPH typically affects the submucous group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the peripheral zone glands into a false capsule and causes the appearance of the typical 'lateral' lobes.

When BPH affects the central zone glands, a 'middle' lobe develops that projects up into the bladder within the internal sphincter (*Figure 84.1*).

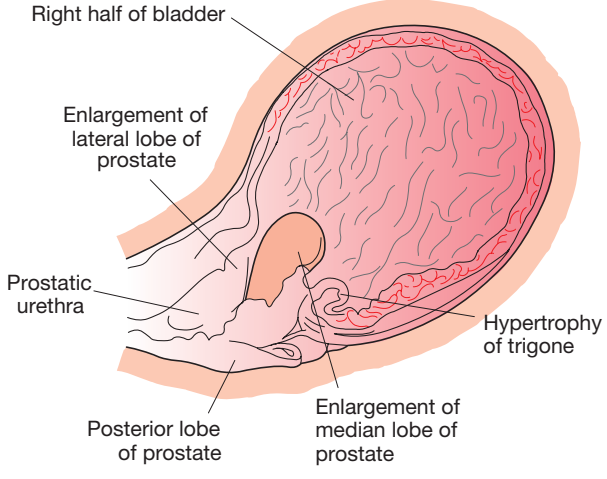

Figure 84.1 Diagram of late-stage bladder outflow obstruction showing enlargement of the prostate from benign prostatic hyperplasia, trabeculation of the bladder with smooth muscle hypertrophy and fibrosis.

Effects of benign prostatic hyperplasia

It is important to realise that the relationship between anatomical prostatic enlargement, LUTS and urodynamic evidence of BOO is complex (*Figure 84.2*).

Summary box 84.2

Consequences of BPH

- No symptoms, no BOO
- No symptoms, but urodynamic evidence of BOO
- LUTS, no evidence of BOO
- LUTS and BOO
- Others (acute/chronic retention, haematuria, urinary infection and stone formation)

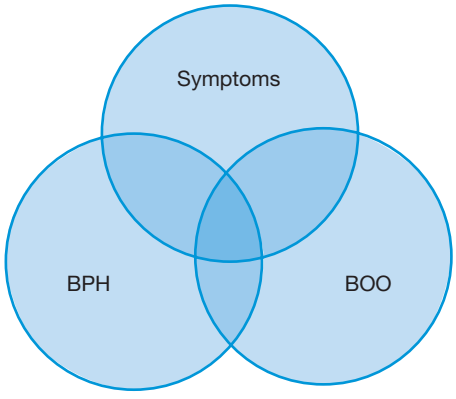

Figure 84.2 Diagrammatic representation of the relation between symptoms of prostatism, benign prostate hyperplasia (BPH) and urodynamically proven bladder outflow obstruction (BOO).

Anatomically, the effects are as follows:

- **Urethra**. The prostatic urethra is lengthened, sometimes to twice its normal length, but it is not narrowed anatomically. The normal posterior curve may be so exaggerated that it requires a curved catheter to negotiate it. When only one lateral lobe is enlarged, distortion of the prostatic urethra occurs.
- **Bladder**. If BPH causes BOO, the musculature of the bladder hypertrophies to overcome the obstruction and appears trabeculated (***Figure 84.3***). Significant BPH is associated with increased blood flow, and the resultant veins at the base of the bladder are apt to cause haematuria.

Lower urinary tract symptoms

In both sexes, non-specific symptoms of bladder dysfunction become more common with age, probably owing to impairment of smooth muscle function and neurovesical coordination. Not all symptoms of disturbed voiding in ageing men should therefore be attributed to BPH causing BOO. Urologists prefer the term LUTS and discourage the use of the descriptive term 'prostatism'.

The following conditions can coexist with BOO, leading to difficulty in diagnosis and in predicting the outcome of treatment:

- idiopathic detrusor overactivity (see ***Chapter 83***);
- neuropathic bladder dysfunction as a result of diabetes, stroke, Alzheimer's disease or Parkinson's disease (see ***Chapter 83***); degeneration of bladder smooth muscle giving rise to impaired voiding and detrusor instability;
- BOO due to BPH.

LUTS can be described as:

- Voiding:
  - hesitancy (worsened if the bladder is very full);
  - poor flow (unimproved by straining);
  - intermittent stream – stops and starts;
  - dribbling (including after micturition);
  - sensation of poor bladder emptying;
  - episodes of near retention.
- Storage:
  - frequency;
  - nocturia;
  - urgency;
  - urge incontinence;
  - nocturnal incontinence (enuresis).

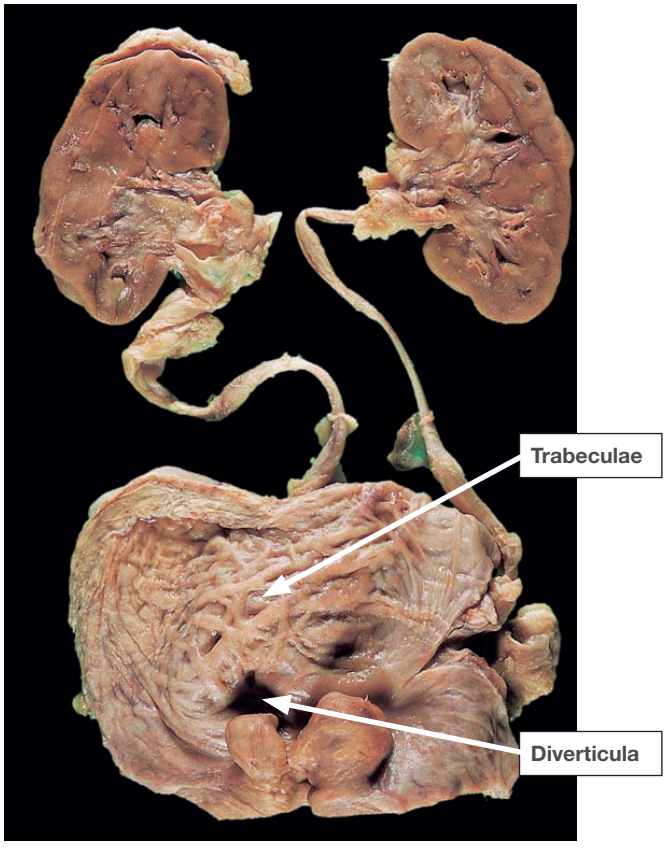

Figure 84.3 Pathological specimen of bladder and kidneys in a case of bladder outflow obstruction caused by benign prostatic hyperplasia. Bladder trabeculation, bilateral hydroureter and hydronephrosis can be seen.

LUTS are usually assessed by means of scoring systems, which give a semiobjective measure of severity and may be helpful in assessing the outcome of the therapy.

Severe irritative symptoms are usually associated with detrusor instability. Postmicturition dribbling is now known not to be a consequence of BOO and is not usually improved by prostatectomy. It is due to retained urine in the urethra.

Bladder outflow obstruction

This is a urodynamic concept based on the combination of low flow rates in the presence of high voiding pressures. It can

Alois Alzheimer, 1864–1915, neurologist, worked at Heidelberg and Munich before being appointed Professor of Psychiatry at Breslau, Germany (now Wrocław, Poland).

James Parkinson, 1755–1824, general practitioner of Shoreditch, London, UK, published *An essay on the shaking palsy* in 1817.

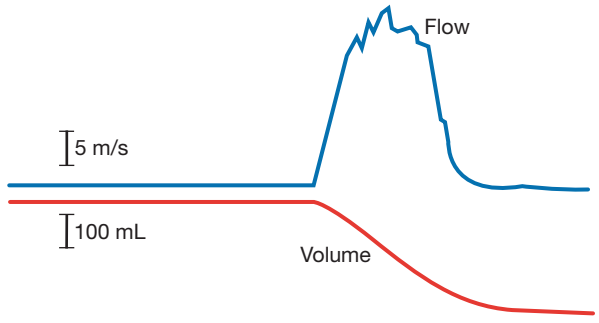

Figure 84.4 Normal flow rate. The voided volume is well in excess of 350 mL, and the maximum flow rate is in excess of 25 mL/s.

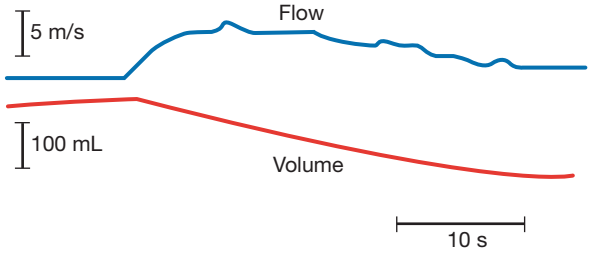

Figure 84.5 Diagram of a low flow rate showing a rather low voided volume of about 200 mL, but with a markedly decreased flow rate. Such a flow rate could be caused by a urethral stricture, bladder outflow obstruction or a weak detrusor.

be diagnosed definitively only by pressure–flow studies. This is because symptoms are relatively non-specific and can result from detrusor instability, neurological dysfunction and weak bladder contraction. Even low measured peak flow rates (<10–12 mL/s) are not absolutely diagnostic because, in addition to BOO, weak detrusor contractions or low voided volumes (owing to instability) can be the cause. Nonetheless, flow rates provide a useful guide for everyday clinical management.

Urodynamically proven BOO may result from:

- BPH;
- bladder neck stenosis;
- bladder neck dyssynergia or functional bladder neck obstruction;
- bladder neck hypertrophy;
- prostate cancer;
- urethral stricture;
- functional obstruction due to neuropathic conditions.

The primary effects of BOO on the bladder are as follows:

- **Urinary flow rates decrease**: for a voided volume >200 mL, a peak flow rate of >15 mL/s is normal (***Figure 84.4***); one of 10–15 mL/s is equivocal; and one <10 mL/s is low (***Figure 84.5***).
- **Voiding pressures increase**: pressures >80 cmH_2O are high (***Figure 84.6***); pressures between 60 and 80 cmH_2O are equivocal; and pressures <60 cmH_2O are normal.

The long-term effects of BOO are as follows:

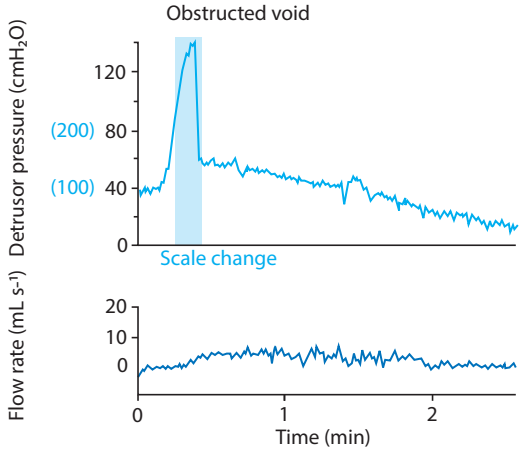

Figure 84.6 Conventional urodynamic trace showing detrusor pressure during voiding (voided volume 340 mL). There has been a change in scale because the pressure was so high; voiding pressures are increased with a low flow rate. This is diagnostic of bladder outflow obstruction.

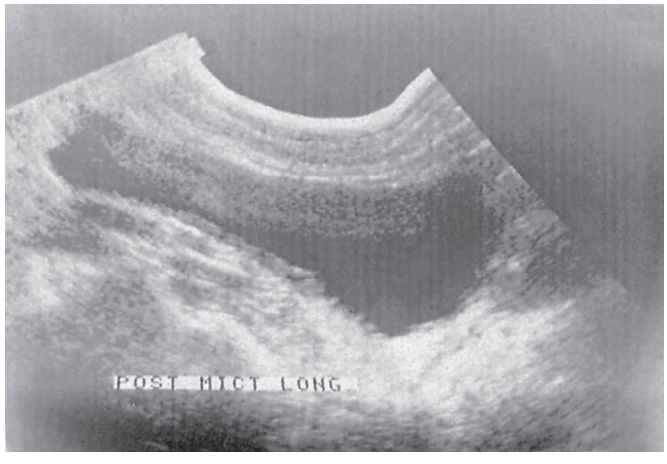

Figure 84.7 An ultrasonogram showing a large postvoid residual urine.

- The bladder may decompensate so that detrusor contraction becomes progressively less efficient and a residual urine develops, leading to chronic retention.
- The bladder may become more irritable during filling with a decrease in functional capacity partly caused by detrusor overactivity (see ***Chapter 83***), which may also be caused by neurological dysfunction or ageing, or may be idiopathic.

Aside from symptoms, the complications of BOO are as follows:

- Acute retention of urine is sometimes the first symptom of BOO.
- Chronic retention. In patients in whom the residual volume is >250 mL or so (***Figure 84.7***), the tension in the bladder wall increases owing to the combination of a large volume of residual urine and increased resting and filling bladder pressures (a condition known as high-pressure chronic retention). The increased intramural tension results in functional obstruction of the upper urinary

tract with the development of bilateral hydronephrosis (***Figures 84.8–84.10***). As a result, upper tract infection and renal impairment may develop. Such men may present with overflow incontinence, enuresis and renal insufficiency. These symptoms should alert the doctor to the presence of this condition.

- Impaired bladder emptying. If the bladder decompensates with the development of a large volume of residual urine, urinary infection and calculi are prone to develop.
- Development of storage bladder symptoms secondary to BOO that can be irreversible if BOO is not treated.
- Haematuria. This may be a complication of BPH. Other causes must be excluded by carrying out urine culture, cytology, computed tomography (CT) urography and cystoscopy.

ASSESSMENT OF THE PATIENT WITH LOWER URINARY TRACT SYMPTOMS

History

Symptom score sheets such as the International Prostate Symptom Score (IPSS) assign a score that gives information regarding the severity of symptoms at the outset and changes over time and following intervention. The IPSS assessment should include an assessment of quality of life, which is a reflection of the degree of 'bother' caused by a patient's symptoms. In addition to the IPSS, a frequency–volume diary completed by the patient before attending the clinic is invaluable in revealing fluid intake habits, diurnal variation in outputs and low-volume, frequent voiding.

Summary box 84.3

Investigations of men with LUTS

Essential investigations

- Urine analysis by dipstick for blood, leukocyte esterase, glucose and protein
- Urine culture for infection
- Serum creatinine
- Urinary flow rate and residual volume measurement

Additional investigations

- PSA if indicated
- Pressure–flow studies

Abdominal examination

Abdominal examination is usually normal. In patients with chronic retention, a distended bladder will be found on palpation, on percussion and sometimes on inspection with loss of the transverse suprapubic skin crease. General physical examination may demonstrate signs of chronic renal impairment with anaemia, pedal oedema and dehydration. The external urinary meatus should be examined to exclude stenosis and the epididymides are palpated for signs of inflammation.

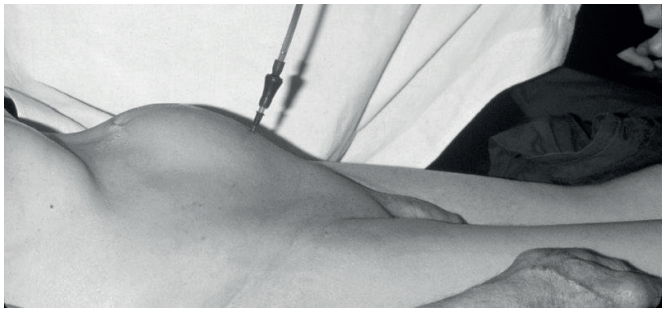

Figure 84.8 An abdomen with high-pressure urinary retention.

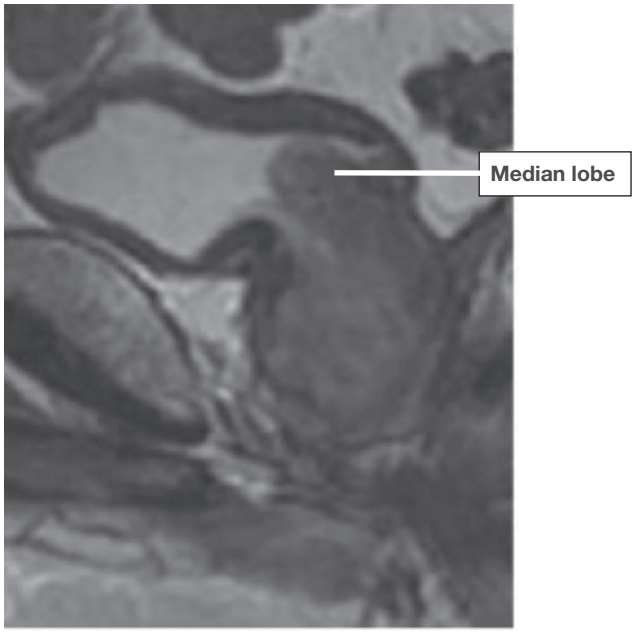

Figure 84.9 Magnetic resonance image showing an enlarged prostate and a median lobe projecting into the bladder and causing bladder outflow obstruction.

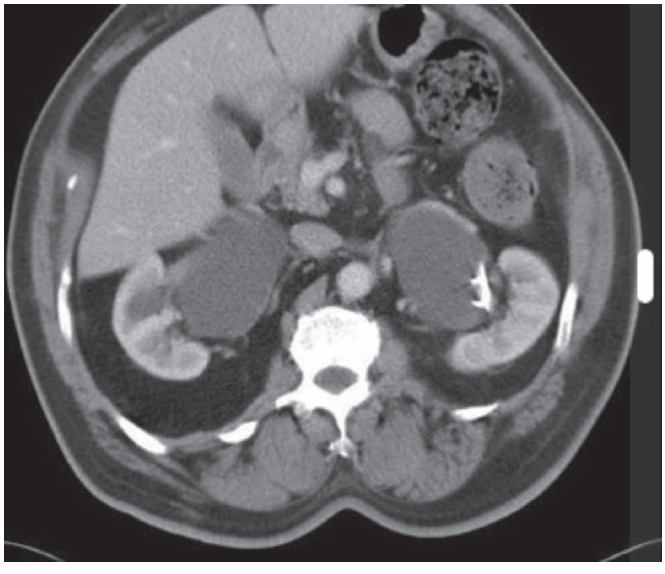

Figure 84.10 Computed tomography scan showing bilateral hydronephrosis as a result of bladder outflow obstruction.

Rectal examination

In benign enlargement, the posterior surface of the prostate is smooth, convex and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. It should be noted that, if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is. It is not always possible to examine the cranial extreme of the very large prostate per rectum. An inability to get to the prostate base implies a volume of at least 50 mL.

The nervous system

The nervous system is examined to eliminate a neurological lesion. Diabetes mellitus, tabes dorsalis, disseminated sclerosis, cervical spondylosis, Parkinson's disease and other neurological states may mimic prostatic obstruction. If these are suspected, then a pressure–flow urodynamic study should be carried out to diagnose BOO. Examination of perianal sensation and anal tone is useful in detection of an S2–4 cauda equina lesion.

Serum prostate-specific antigen

After suitable counselling, measurement of serum PSA may be helpful. Men in whom a diagnosis of early prostate cancer might influence treatment option (such as those under 70 years or those with a positive family history who might be offered radical treatment) should be offered a PSA measurement. If the PSA range is 4–10 ng/L, a free-to-total PSA ratio of less than 15% should be suspicious of malignancy. Multiparametric magnetic resonance imaging (mpMRI) should be done, which may show a suspicious index lesion. In this situation, transrectal ultrasound (TRUS)-guided or transperineal biopsies should be considered.

Flow rate measurement

For this to be meaningful, two or three voids should be recorded using a special flow meter, usually found in urology outpatient clinics; the voided volume should be in excess of 150–200 mL. A typical history and a flow rate <10 mL/s (for a voided volume of >200 mL; ***Figure 84.5***) will be sufficient for most urologists to recommend treatment. Usually, a flow rate measurement will be coupled with ultrasound measurement of postvoid residual urine.

There are pitfalls in the measurement of flow rates. The machine must be accurately calibrated. The patient must void volumes in excess of 150 mL and two or three recordings are needed to obtain a representative measurement. Decreased flow rates and LUTS may be seen in:

- BOO;
- low voided volumes (characteristically in men with detrusor instability);
- men with weak bladder contractions (low pressure–flow voiding), also known as underactive detrusor.

Pressure-flow urodynamic studies

Details of these studies are outlined in ***Chapter 81***. They should be performed on the following patients:

- men with suspected neuropathy (Parkinson's disease, dementia, longstanding diabetes, previous strokes, multiple sclerosis);
- men with a dominant history of irritative symptoms and men with lifelong urgency and frequency;
- men with a doubtful history and those with flow rates in the near normal range (~ or >15 mL/s);
- men with invalid flow rate measurements (because of low voided volumes);
- high residual/chronic retention;
- men with recurrence of LUTS after previous BPH surgery (in the absence of urethral or bladder pathology);
- young men (<50 years) and older men (>80 years) with LUTS.

Blood tests

Serum creatinine, electrolytes and haemoglobin should be measured.

Examination of urine

The urine is examined for glucose, leukocyte esterase and blood; a midstream specimen should be sent for bacteriological examination and cytological examination may be carried out if carcinoma *in situ* is thought possible.

Upper tract imaging

Most urologists no longer carry out imaging of the upper tract in men with straightforward symptoms. Obviously, if infection or haematuria is present, then the upper tract should be imaged by means of intravenous urogram/CT urography or ultrasound scan.

Cystourethroscopy

Inspection of the urethra, the prostate and the urothelium of the bladder should be done immediately prior to prostatectomy to exclude a urethral stricture, a bladder carcinoma and the occasional non-opaque vesical calculus. This should be based on the patient's symptoms, signs and investigations. Direct inspection of the prostate is not used as an indicator to establish the presence of BOO and the need for surgery.

MANAGEMENT OF MEN WITH BENIGN PROSTATIC HYPERPLASIA OR BLADDER OUTFLOW OBSTRUCTION

Strong indications for treatment (usually prostatectomy) include:

- **Acute retention** (see ***Chapter 83***) in fit men with no other cause for retention (drugs, constipation, recent operation, etc.) (accounts for 25% of prostatectomies).

- **Chronic retention and renal impairment**: a residual urine of 200 mL or more, hydroureter or hydronephrosis demonstrated on ultrasound, uraemic manifestations and abnormal renal function (accounts for 15% of prostatectomies).
- **Complications of BOO**: stone, infection and diverticulum formation.
- **Haemorrhage**: these patients present with recurrent haematuria with no obvious cause and a very vascular prostate can be seen on cystoscopy.
- **Elective prostatectomy for severe symptoms**: this accounts for about 60% of prostatectomies. Frequency alone is not a strong indication for prostatectomy. The natural progression of outflow obstruction is variable and rarely gets worse after 10 years. Severe symptoms not responding to drug therapy, a low maximum flow rate (<10 mL/s) and an increased residual volume of urine (100–250 mL) are relatively strong indications for operative treatment.

Summary box 84.4

Options for treatment of LUTS secondary to BPH

- Conservative measures include watchful waiting in conjunction with fluid manipulation (avoid fluid binge and late night intake) and a reduction in caffeinated and alcoholic drinks
- Drug therapy is with α-blockers or, in men with a large prostate, a 5α-reductase inhibitor, or both; combination therapy has a better outcome in glands bigger than 35 g
- Interventional measures include transurethral resection of the prostate (TURP), which remains the gold standard; consider HOLEP (holmium laser enucleation of the prostate), open/robotic simple prostatectomy for large glands; new minimally invasive treatment options that are available to patients include prostate artery embolisation (PAE), water vapour prostate treatment (Rezūm), prostatic urethral lift (Urolift) and water jet treatment (Aquablation)

Acute retention

The management of retention is discussed in detail in ***Chapter 83***. Once the bladder has been drained by means of a catheter, the patient's fitness for treatment is determined. If retention was not caused by drugs or constipation, then prostatectomy would usually be the correct management. Unfit men or those with dementia may be treated by means of an indwelling urethral or suprapubic catheter. The role of α-adrenergic drugs followed by a trial of a catheter has been tested and found to be successful in certain groups with a short history and a low residual volume of urine, but the recurrence rate becomes cumulatively high. 5α-reductase is given to prevent progression of symptoms in men with large (>35–40 mL) prostates. Combination therapy (α-blocker and 5α-reductase) is better for the larger gland. Patients who develop renal impairment and/or hydronephrosis after urinary retention will need to keep the catheter until definitive surgical treatment is provided, usually not less than 6 weeks afterwards to allow renal function recovery.

Special problems in the management of chronic retention

Men with chronic retention who have relatively low volumes of residual urine and who do not have symptoms suggestive of coexisting infection and with good renal function do not necessarily require catheterisation before proceeding to prostatectomy on the next available list. For those who are uraemic, urgent catheterisation is mandatory to allow renal function to recover and stabilise. Haematuria often occurs following catheterisation owing to collapse of the distended bladder and upper tract, but settles within a couple of days.

Uraemic patients with chronic retention are often dehydrated at the time of admission. Owing to the chronic back pressure on the distal tubules within the kidney, there is loss of the ability to reabsorb salts and water. The result, following release of this pressure, may be an enormous outflow of salts and water, which is known as postobstructive diuresis. It is for this reason that a careful fluid chart, daily measurements of the patient's weight and serial estimations of creatinine and electrolytes are essential. Intravenous fluid replacement is required if the patient is unable to keep up with this fluid loss. These patients are often anaemic and may require a blood transfusion once fluid balance is stabilised (if haemoglobin is <9 g/L).

Considerations for elective treatment in men with LUTS secondary to BPH

The following questions should be answered before considering a surgical treatment:

- Have they failed a preliminary trial of medical therapy? Commonly, men will have been treated with α-blockers or 5α-reductase inhibitors and will have failed treatment.
- Is BOO present? In many cases, the findings of significant symptoms (assessed by symptom scoring) and a benign enlarged prostate supplemented by the finding of a low maximum flow rate (<10–12 mL/s for a good voided volume [>150–200 mL]) – will suffice to make a reasonable working diagnosis of BOO.
- How severe are the symptoms and what are the risks of doing nothing? Severe symptoms and a large residual volume of urine will usually require treatment. Men with mild symptoms, good flow rates (>15 mL/s) and good bladder emptying (residual urine <100 mL) may be safely managed by reassurance and review; such patients rarely develop severe complications such as retention in the long term.
- Is the man fit for operative treatment?
- What treatments are available, what are the outcomes and do the side effects justify treatment?

Treatment

Men with symptoms attending for elective treatment (excluding acute and chronic retention)

Conservative treatment

It is in men with relatively mild symptoms, reasonable flow rates (>10–15 mL/s) and good bladder emptying (residual urine <100 mL) that careful discussion over the merits and side effects of operative treatment is warranted. Waiting for a period of 6 months after careful discussion of the diagnosis is indicated. After this, a repeat assessment of symptoms and flow rates and an ultrasound scan are helpful; many men with stable symptoms will elect to leave matters be.

Drugs

In men who are very concerned about the development of sexual dysfunction after TURP, the use of drugs may be helpful. Two classes of drug have been used in the treatment of men with BOO. α-adrenergic blocking agents inhibit the contraction of smooth muscle that is found in the prostate. The other class of drug is the 5α-reductase inhibitors, which inhibit the conversion of testosterone to 1,5-dihydrotestosterone (DHT), the most active form of androgen. These drugs, when taken for a year, result in a 25% reduction in the size of the prostate gland. Both groups of drugs are effective; however, α-blockers work more quickly and although the 5α-reductase inhibitors have fewer side effects they need to be taken for at least 6 months and their effect is greatest in patients with large (>40 g) glands. Drug therapy results in improvements in maximum flow rates by about 2 mL/s more than placebo and results in a mild (20%) improvement in symptom scores. Another drug class that has improved patients' symptom scores but not their maximum flow rate are the phosphodiesterase 5 inhibitors, which reduce smooth muscle tone and possibly the inflammation in the prostate gland. These drugs are particularly useful if patients have concomitant erectile dysfunction. TURP, however, results in improvements in maximum flow rates from 9 to 18 mL/s and a 75% improvement in symptom scores. These drugs are expensive in comparison with their effectiveness, and a significant proportion of men who try these drugs will subsequently undergo surgical treatment.

Operative treatment

Apart from the strong indications for operative treatment mentioned above, the most common reason for TURP is a combination of severe symptoms and a low flow rate of <12 mL/s. The key is to assess the symptoms carefully and to counsel men about side effects and likely outcome before advising operative treatment.

Counselling men undergoing prostatectomy

Men undergoing prostatectomy need to be advised about the following:

- **Retrograde ejaculation or anejaculation**. This occurs in about 65–85% of men after prostatectomy.

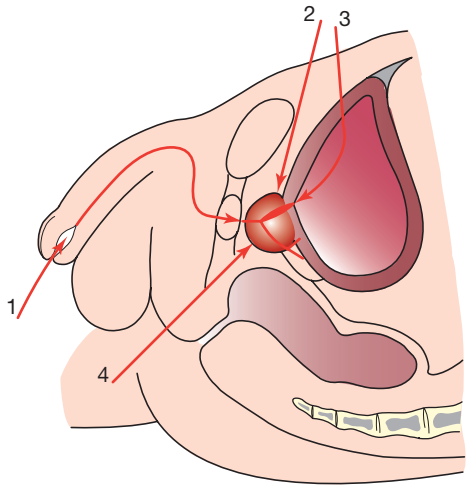

Figure 84.11 The surgical approaches to the prostate. (For key see text.)

- **Erectile dysfunction**. This occurs in about 5–10% of men, usually in those whose potency is waning.
- **Success rate**. On the whole, men with acute and chronic retention do well from the symptomatic point of view. Ninety per cent of men undergoing elective operation for severe symptoms and urodynamically proven BOO do well in terms of symptoms and flow rates. Only about 65% of those with mild symptoms or those with weak bladder contraction as the cause of their symptoms do well. Men who are unobstructed and have detrusor instability do not respond well to TURP; in fact, their storage symptoms could accentuate postoperatively. Patients who have concomitant BOO and secondary detrusor overactivity may need an anticholinergic drug for a few months if they have persistent irritative symptoms.
- **Risk of reoperation**. After TURP, this is about 15% after 8–10 years.
- **Morbidity rate**. Death after TURP is infrequent (<0.5%); severe sepsis is found in about 6%; and severe haematuria requiring transfusion of more than 2 units of blood occurs in about 3%. After discharge, about 15–20% of men subsequently require antibiotic treatment for symptoms of urinary infection.
- **Incontinence**. Although the risk is rare and is about 1%, the risk is higher in older patients and those with a very large prostate.

Methods of performing prostatectomy

The prostate can be approached (1) transurethrally (TURP); (2) retropubically (RPP); (3) through the bladder (transvesically; TVP); or (4) from the perineum (***Figure 84.11***).

Transurethral prostate surgery

Transurethral resection of the prostate

TURP remains the most commonly performed procedure for the surgical correction of BOO. Perhaps the greatest advance in the history of transurethral surgery was marked by the development of the rigid lens system of Professor Harold

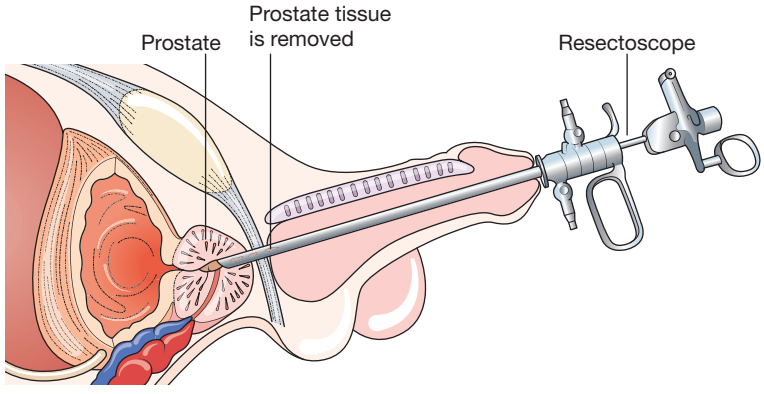

Figure 84.12 For transurethral resection of the prostate the resectoscope is inserted transurethrally. Electric current is passed through a diathermy loop at the end of the instrument. The surgeon moves this back and forth to create a cavity using diathermy to cauterise as they go. The resultant chips are washed out of the bladder intermittently throughout the procedure. A visual image of the operative field is transmitted through lenses running in the middle of the resectoscope. Around this lens, irrigating fluid is instilled and flows out, washing blood away from the operative field. The procedure is complete when an adequate channel has been created through the prostate.

Hopkins. His lenses, illuminated by a fibreoptic light source, permit unparalleled visualisation of the working field. Men with indwelling catheters, those with recent urinary infection, those with chronic retention or those with prosthetic material or heart valves benefit from prophylactic antibiotics in addition to the standard for clean surgery at induction of anaesthesia.

Strips of tissue are cut from the bladder neck down to the level of the verumontanum (***Figure 84.12***). Cutting is performed by a high-frequency diathermy current, which is applied across a loop mounted on the hand-held trigger of the resectoscope. Coagulation of bleeding points can be accurately achieved. The 'chips' of prostate are then removed from the bladder using an Ellik evacuator. Resection proceeds at 1 g/minute in experienced hands. The duration of resection for monopolar TURP is limited to 1 hour due to the risk of resorption of water if 1% glycine is used as an irrigant. The advent of bipolar TURP where normal saline is used as an irrigant permits resection of larger prostates. Following TURP, careful haemostasis is performed, and a three-way, self-retaining catheter irrigated with isotonic saline is introduced into the bladder to prevent any further bleeding from forming blood clots. Irrigation is continued until the outflow is pale pink, and the catheter is usually removed on the second or third postoperative day. In men with small prostates or bladder neck dyssynergia or stenosis, it is better to divide the bladder neck and prostatic urethra with a Collins knife or laser.

Laser prostatectomy

Laser can be used to ablate or vaporise (e.g. green light laser) or enucleate (e.g. HOLEP) the prostate. Photoselective vaporisation of the prostate or green light laser has the advantage that vaporisation is haemostatic and this procedure can be performed even while patients are anticoagulated; however, it is unsuitable for a very large gland. In holmium laser enucleation of the prostate (HOLEP), laser is used to cut all the attachments of the adenoma to the false capsule and simultaneously coagulate any of the small vessels crossing the relatively avascular plane between the peripheral and transitional zones of the prostate while the tip of the cystoscope is used, much like the surgeon's finger in Millin's prostatectomy, to enucleate the transitional zone adenoma. The enucleated adenoma is pushed into the bladder, where it is morcellated and extracted via the cystoscope. Damage to the external sphincter is avoided provided the verumontanum is used as a guide to the most distal point of the resection/vaporisation/enucleation.

Complications of prostatectomy

Local

Haemorrhage is a major risk following prostatectomy whatever the surgical approach. Care should be taken in applying diathermy to arterial bleeding points after TURP, and to any bleeding vessels at the bladder neck; they are often better seen when the rate of inflow of fluid is decreased. Some of the venous bleeding due to deep resection can only be stopped by gentle traction via a Foley catheter balloon inflated to 30–40 mL and kept in the bladder. Sustained traction is applied by taping the catheter to the anterior abdominal wall or thigh for 12–24 hours. This causes compression of the prostatic tissue and veins and thus stops the bleeding. In the recovery room, one should check that the bladder is draining adequately; if it is not, this may indicate that a clot is blocking the eye of the catheter. The bladder should be promptly washed out using a strict aseptic technique. The catheter should be changed by the surgeon. Only rarely is it necessary to return the patient to the operating room.

Secondary haemorrhage tends to occur several days after the patient has been discharged. All men should be warned about this possibility and given appropriate advice to rest and to have a high fluid intake. It is usually minor in degree but if

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, University of Reading, Reading, UK, invented the rigid rod endoscope (Hopkins' rod, 1954) and contributed to the development of the fibres for flexible endoscopes.
Milo Ellik, 1905–1975, American urologist, developed the Ellik evacuator in 1937.
Terence John Millin, 1903–1980, surgeon, Westminster Hospital, London, UK, and honorary surgeon, All Saints' Hospital for Genitourinary Diseases, London, UK, described the operation of retropubic prostatectomy in 1945. He was regarded as 'the greatest of Irish urologists' and 'the pioneer of the retropubic space'. To facilitate his operation, he devised a self-retaining retractor that goes by his name and the 'boomerang' needle to close the prostatic capsule. He used to be invited all over the world to operate on VIPs. He was a former President of the Royal College of Surgeons in Ireland. He gave up operating at the age of 57 to enjoy his farm in County Wicklow, where he died of laryngeal carcinoma. He played international rugby for Ireland.
Frederic Eugene Basil Foley, 1891–1966, urologist, Ancker Hospital, St Paul, MN, USA.

clot retention occurs the patient will need to be readmitted, a catheter passed and the bladder washed out.

Perforation of the bladder or the prostatic capsule can occur at the time of transurethral surgery. This usually occurs from a combination of inexperience in association with a large prostate or heavy blood loss. If the field of vision becomes obscured by heavy blood loss, it is often prudent to achieve adequate haemostasis and abandon the operation, swallowing one's pride on the understanding that a second attempt may be necessary. A large perforation with marked extravasation may require the insertion of a small suprapubic drain. Rectal perforation should be extremely rare.

Sepsis

Bacteraemia is common even in men with sterile urine and occurs in over 50% of men with infected urine, prolonged catheterisation or chronic retention. Sepsis can occur in these patients shortly after operation or when the catheter is removed. Routine use of prophylactic antibiotics is recommended based on local antimicrobial sensitivity profiles. The most worrying aspect of infection is the early rigor following surgery. If left undetected and untreated, this may progress to septic shock with profound hypotension. A blood culture should be taken and antibiotics given parenterally (e.g. amoxicillin plus cefuroxime, or gentamicin).

Incontinence

Incontinence is rare after BPH surgery; however, it is inevitable if the external sphincter mechanism is damaged. The bladder neck is rendered incompetent by any prostatectomy and, therefore, an intact distal sphincter mechanism is essential for continence. The verumontanum marks the proximal margin of the external sphincter. In some patients, detrusor instability contributes to the incontinence. The use of anticholinergic agents such as mirabegron/solifenacin/tolterodine may help. Mild degrees of stress incontinence usually recover in a few days to a few weeks. If physiotherapy is ineffective, then full assessment with cystoscopy and pressure studies including video urodynamics should be carried out before proceeding with offering the patient the insertion of an artificial urinary sphincter or a sling to increase the resistance of the urethra. One should usually wait for 6 months to 1 year before any sling or sphincter is implanted.

Retrograde ejaculation and erectile dysfunction

Men with prior good sexual function are less likely to have erectile dysfunction following BPH surgery, but retrograde ejaculation occurs commonly (>75%) because of disruption to the bladder neck mechanism; occasionally, anejaculation can occur as a result of disruption of the ejaculatory ducts. This should be discussed with all men before the surgery.

Urethral stricture

This may be secondary to prolonged catheterisation, the use of an unnecessarily large catheter, clumsy instrumentation or the presence of the resectoscope in the urethra for too long a period. These strictures arise either just inside the meatus or in the bulbar urethra. An early stricture can usually be managed by simple dilatation or urethrotomy if dense fibrosis is present. If the stricture recurs then urethroplasty is considered. The use of an Otis urethrotomy in the tight urethra prior to TURP can reduce the incidence of postoperative stricture.

Bladder neck contracture

Occasionally, a dense fibrotic stenosis of the bladder neck occurs following overaggressive resection of a small prostate. It may be due to the overuse of coagulating diathermy. This usually happens in the early postoperative period. Transurethral incision of the scar tissue is necessary using laser or diathermy.

General complications

Death occurs in about 0.2–0.3% of men undergoing elective prostatectomy. In very elderly men, in men with prostate cancer admitted as an emergency with acute or chronic retention or in those with very large prostates, the 30-day death rate may be of the order of 1%.

Cardiovascular

Pulmonary atelectasis, pneumonia, myocardial infarction, congestive cardiac failure and deep venous thrombosis are all potentially life-threatening conditions that can affect this elderly and often frail group of men.

Water intoxication

Absorption of water into the circulation at the time of transurethral resection can give rise to congestive cardiac failure, hyponatraemia and haemolysis. Accompanying this, there is frequently confusion and other cerebral events often mimicking a stroke. The incidence of this condition has been reduced since the introduction of isotonic glycine for irrigating during resection, and further still with the development of bipolar TURP where saline is used as an irrigant. The treatment consists of fluid restriction.

BLADDER OUTFLOW OBSTRUCTION CAUSED BY THE BLADDER NECK

Aetiology

This condition usually occurs in men but can rarely affect children of both sexes and women. It may be due to muscular hypertrophy or fibrosis of the tissues at the bladder neck following TURP.

Clinical syndromes

Owing to muscle hypertrophy or dyssynergia

Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum or hydro-

Fessenden Nott Otis, 1825–1900, nineteenth century American urologist.
Jean Baptiste Camile Marion, 1869–1932, Professor of Urology, The Faculty of Medicine, Paris, France.

nephrosis (Marion's disease or 'prostatism sans prostate'). It is thought that dyssynergic contraction of the smooth muscle of the bladder neck (bladder neck dyssynergia) may account for some cases of BOO. It is also known as functional bladder neck obstruction.

Owing to fibrosis

The symptoms are similar to those of prostatic enlargement but are a consequence of scarring after TURP or radical prostatectomy (usually compounded by external beam radiotherapy [EBRT]).

Treatment

The management of these patients depends on achieving an accurate diagnosis. For this, urodynamic investigation is often necessary, which should demonstrate raised voiding pressures and diminished flow rate.

Drugs

The presence of α-adrenergic receptors in the region of the bladder neck and prostatic urethra allows pharmacological manipulation of the outflow to the bladder.

α-blocking drugs

Alfuzosin (10 mg once daily), tamsulosin (0.4 mg once daily), doxazosin (1 mg at night, up to a maximum of 8 mg/day), indoramin (20 mg twice daily, increased to a total maximum of 100 mg/day in divided doses), prazosin (2.5 mg twice daily, maintenance up to 2 mg/day) terazosin (1 mg at night, to a total maximum of 10 mg/day) and Silodosin (4 to 8 mg once a day) can be very useful, causing relaxation of the bladder neck. These drugs are not target specific, and patients must be warned of the possibility of postural hypotension, which is usually limited to the first few doses.

Transurethral incision

Transurethral incision of the bladder neck is the operation of choice. Sometimes symptoms recur, but this is usually due to inadequate division of the fibres of the bladder neck.

Congenital valves of the prostatic urethra

See ***Chapter 85***.

PROSTATIC CALCULI

Prostatic calculi are of two varieties: endogenous, which are common, and exogenous, which are comparatively rare. An exogenous prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. Endogenous prostatic calculi are usually composed of calcium phosphate combined with about 20% organic material.

Clinical features

Prostatic calculi are usually symptomless, being discovered on TRUS, on radiography of the pelvis, during prostatectomy or associated with carcinoma of the prostate or chronic prostatitis. In cases associated with severe chronic prostatic infection, the associated fibrosis and nodularity are difficult to differentiate from carcinoma. On radiographs or ultrasound scans, these stones are often seen to form a horseshoe (***Figure 84.13***) or a circle. It is postulated that they are associated with BOO.

Figure 84.13 Endogenous prostatic calculi.

Treatment of prostatic calculi

Prostatic calculi usually require no treatment.

Conservative measures

Associated chronic prostatic infection may be treated by means of ciprofloxacin or trimethoprim.

Transurethral resection

Transurethral resection will often release small calculi as the strips of prostatic tissue are excised. Others are passed through the urethra at a later date. Any associated benign prostatic enlargement is treated in the same sitting with TURP.

Corpora amylaceae

Corpora amylaceae are tiny calcified lamellated bodies found in the glandular alveoli of the prostates of elderly men and apes, but not in the prostates of animals lower in the phylogenetic scale than anthropoids. Corpora amylaceae are probably the forerunners of endogenous prostatic calculi.

CARCINOMA OF THE PROSTATE

Carcinoma of the prostate is the most common malignant tumour in men over the age of 65 years. In the UK in 2017, more than 48 000 men were diagnosed with, and more than

11 800 died from, prostate carcinoma; the corresponding figures in the USA were 190 000 and 33 000, respectively. If histological section of prostates at autopsy is performed, increasingly frequent foci of microscopic prostate cancers are found with increasing age. These foci of prostate cancer have variable potential for progressing clinically to metastatic disease. About 10–15% of younger men who develop prostate cancer have a positive family history of the disease, but the aetiology is unclear. Throughout the world, rates of microscopic foci of prostate cancer are constant, but rates of clinically evident disease are low in men in Japan, China and India. Carcinoma of the prostate usually originates in the peripheral zone of the prostate, so 'prostatectomy' for benign enlargement of the gland confers no protection from subsequent carcinoma.

Pathology

Serial sections of prostates obtained at routine necropsy demonstrate prostate carcinoma in 25% of men between 50 and 65 years of age. The incidence in men over 80 years is in the region of 70%. Most of these neoplasms are tiny and (if life had continued) might have remained latent for years. Most men die with the prostate cancer rather than because of cancer.

The following types of prostate cancer occur:

- microscopic latent cancer found on autopsy or at cystoprostatectomy;
- tumours found incidentally during TURP (T1a and T1b) or following screening by PSA measurement (T1c);
- early, localised prostate cancer (T2);
- locally advanced and high-risk prostate cancer (T3 and T4);
- metastatic disease, which may arise from a clinically evident tumour (T2, T3 or T4) or from an apparently benign gland (T0, T1) (i.e. occult prostate cancer).

It should be noted that only the last two groups cause symptoms, and such tumours are not curable. Only screening or the treatment of incidentally found tumours or early prostate cancer (T1 and T2) can result in cure of the disease. The problem is that many such tumours would never progress during the patient's lifetime and only a few will grow and metastasise; herein lies the problem with prostate cancer.

Screening for prostate cancer

Prostate cancer screening with PSA is controversial and the test does not fulfil the World Health Organization's (WHO) criteria for an adequate screening programme. Screening trials are limited by contamination of patients who have already had prior PSA tests, and most include mainly white men. Most screening trials do not include high-risk groups of men (family history of prostate cancer, Africans) and screening can lead to overdiagnosis of insignificant disease. The four largest randomised trials include in total around 700 000 patients; they have shown that screening did not improve overall mortality, but there is a small improvement in prostate cancer-specific mortality. However, screening increased prostate cancer detection in 18 men per 1000 men screened, increased complications from prostate biopsies and can lead to overdiagnosis.

Summary box 84.5

Screening for prostate cancer

The results of several large-scale randomised clinical trials evaluating the role of PSA screening for prostate cancer suggest that, at present, screening the entire population with serum PSA is not cost-effective as a large number of men must be screened, biopsied and treated in order to prevent each death from prostate cancer

Local spread

Locally advanced tumours tend to grow upwards to involve the seminal vesicles, the bladder neck and trigone and, later, the tumours tend to spread distally to involve the distal sphincter mechanism. Further upward extension obstructs the lower end of one or both ureters, with obstruction of both resulting in anuria. The rectum may become stenosed by tumour infiltrating around it, but direct involvement is rare.

Spread by the bloodstream

Spread by the bloodstream occurs particularly to bone; indeed, the prostate is the most common site of origin for skeletal metastases, followed in turn by the breast, the kidney, the bronchus and the thyroid gland. The bones involved most frequently by carcinoma of the prostate are the pelvic bones and the lower lumbar vertebrae. The femoral head, ribcage and skull are other common sites.

Lymphatic spread

Lymphatic spread may occur via (i) lymphatic vessels passing to the obturator fossa or along the sides of the rectum to the lymph nodes beside the internal iliac vein and in the hollow of the sacrum and (ii) lymphatics that pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From retroperitoneal lymph nodes, the mediastinal nodes and occasionally the supraclavicular nodes may become implicated.

Staging using the tumour-node-metastasis (TNM) system

The TNM staging system for prostate cancer is shown in *Figure 84.14*.

- **T1a, T1b and T1c**. These are incidentally found tumours in a clinically benign gland after histological examination of a prostatectomy specimen. T1a is a tumour involving less than 5% of the resected specimen; these tumours are usually well or moderately well differentiated. T1b is a tumour involving >5% of the resected specimen. T1c tumours are impalpable tumours found following investigation of a raised PSA.
- **T2a** disease presents as a suspicious nodule (*Figure 84.15*) on rectal examination that is confined within the prostate capsule and involves one lobe.

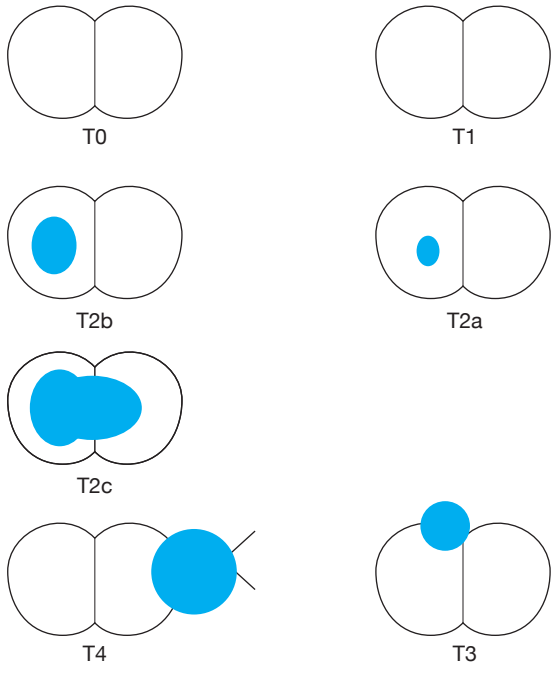

Figure 84.14 Tumour–node–metastasis staging system for prostate cancer.

- **T2b** means that the cancer is in more than half of one side of the prostate gland, but not both sides.
- **T2c** means that the cancer is in both sides but is still inside the prostate gland.
- **T3** tumour extends through the capsule:
  - T3a, uni- or bilateral extension;
  - T3b, seminal vesical extension.
- **T4** is a tumour that is fixed or invading adjacent structures other than seminal vesicles – levator muscles, external sphincter, rectum or pelvic side wall.

Summary box 84.6

The natural history of prostate cancer

This depends on the stage and grade of disease:

- T1 and T2
  - The progression rate of well-differentiated T1a prostate cancer is very low: 10–14% after 8 years. For moderately differentiated tumours, the rate is about 20%. For T1b and T2 tumours, the rate is in excess of 35%
- T3 and T4 (M0)
  - About 50% progress to bony metastases after 3–5 years
- M1
  - The median survival of men with metastatic disease is about 3 years

Clinical features

Only advanced disease gives rise to symptoms, but even advanced disease may be asymptomatic. Symptoms of advanced disease include:

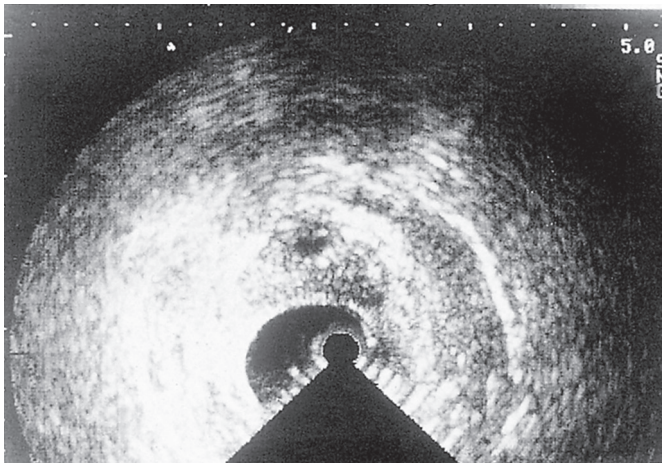

Figure 84.15 Transrectal ultrasound scan of a T2 nodule in the prostate.

- BOO;
- pelvic pain and haematuria;
- bone pain, malaise, 'arthritis', anaemia or pancytopenia;
- renal failure;
- locally advanced disease or even asymptomatic metastases, which may be found incidentally on investigation of other symptoms.

Early prostate cancer is asymptomatic and may be found:

- incidentally following TURP for clinically benign disease (T1a and b);
- T1c – because of serum PSA screening;
- as a nodule (T2) on rectal examination.

Summary box 84.7

The presentation of men with prostate cancer

- Often men are asymptomatic and detection is by opportunistic PSA testing
- Cancer is detected in men describing LUTS or may present with symptoms of metastatic disease

Rectal examination

Rectal examination can detect nodules within the prostate and advanced disease. Irregular induration, characteristically stony hard in part or in the whole of the gland (with obliteration of the median sulcus), suggests carcinoma. Extension beyond the capsule up into the bladder base and vesicles (***Figure 84.16***) is diagnostic, as is local extension through the capsule (***Figure 84.17***).

Multiparametric magnetic resonance imaging

mpMRI is an investigation to diagnose an early prostate cancer that might reduce overdiagnosis of insignificant prostate cancer. Here dynamic contrast is given and should have four sequences: T1-weighted imaging, T2-weighted imaging,

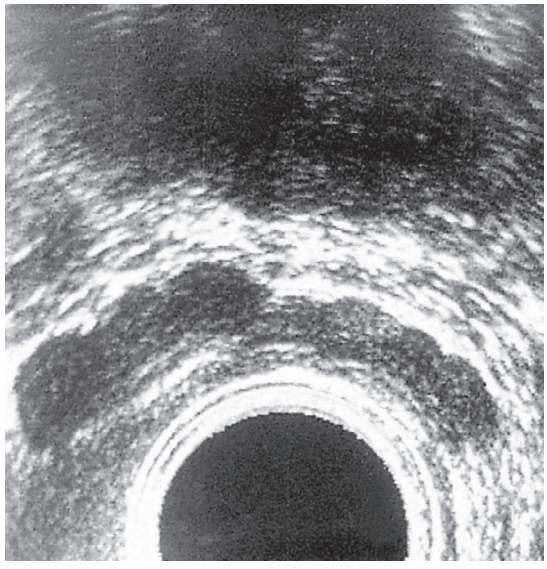

Figure 84.16 Transrectal ultrasound scan showing normal seminal vesicles.

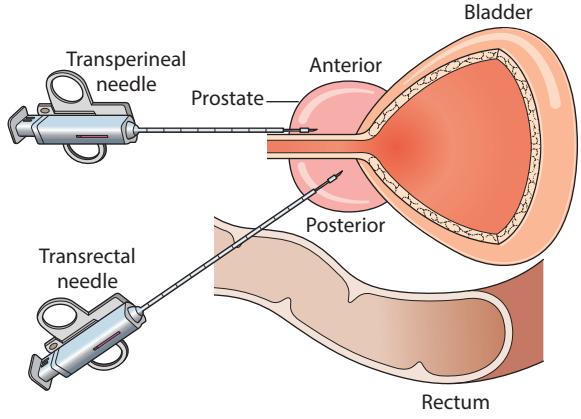

Figure 84.18 The prostate is commonly biopsied by two routes. The biopsy needle can be inserted through the skin between the scrotum and anus (perineum) or through the rectum. In both cases the passage of the needle is usually guided to the correct place with transrectal ultrasound. Transrectal ultrasound is not good for sampling the anterior prostate, particularly when the prostate is large. Transperineal biopsy is gaining popularity as an alternative to conventional transrectal biopsy.

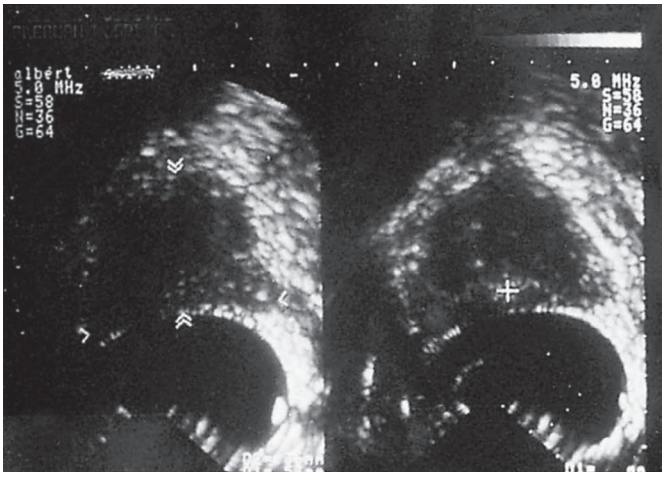

Figure 84.17 Transrectal ultrasound scan showing local extension of a T3 prostate cancer.

diffusion-weighted imaging and dynamic contrast-enhanced imaging and spectroscopic imaging. The accuracy of mpMRI in localising and staging prostate cancer shows a high degree of variation between reporting radiologists. Interpretation and reporting of mpMRI must be carried out following standardised scoring systems (such as Prostate Imaging Reporting and Data System [PI-RADS] v.2). A score of 3 or above is indicative of malignancy.

Prostatic biopsy

If there is suspicion of prostate cancer, because of local findings, a raised PSA or metastatic disease, then a prostate biopsy using an automated gun under TRUS guidance is recommended (*Figure 84.18*). This is usually performed transrectally, although increasingly the transperineal approach is being used. Broad-spectrum antibiotic cover is given to all patients to reduce the incidence of sepsis, which is greater with transrectal than with transperineal biopsy. Transperineal biopsy usually involves sedation or general anaesthetic while transrectal biopsy can be performed under local anaesthetic. Increasingly, areas appearing suspicious for prostate cancer on mpMRI can be targeted for biopsy to increase the diagnostic yield. Nowadays, fusion biopsy is becoming popular; this is where mpMRI and TRUS images are fused with the help of software and a biopsy is taken very accurately from the index lesion.

Histological appearances

The prostate is a glandular structure consisting of ducts and acini; thus, the histological pattern is one of an adenocarcinoma. The prostatic glands are surrounded by a layer of myoepithelial cells. The first change associated with carcinoma is the loss of the basement membrane, with glands appearing to be in confluence. As the cell type becomes less differentiated, more solid sheets of carcinoma cells are seen. A classification of the histological pattern based on the degree of glandular dedifferentiation and its relation to stroma has been devised by Gleason. Prostate cancers exhibit heterogeneity within tissue, and so two histological areas of prostate are each scored between 3 and 5. Grades 1 and 2 are now not reported as their outcome is similar to grade 3. Grade 3 cancers almost never metastasise. The scores are added to give an overall Gleason score of between 6 and 10; this (and the volume of the cancer) appears to correlate well with the likelihood of spread and the prognosis. The International Society of Urological Pathology (ISUP) and WHO have recommended a simplified grading system composed of five prognostic grade groups. Each group

Donald F Gleason, 1920–2008, pathologist, University of Minnesota, Minneapolis, MN, USA, published the Gleason System in 1966. He spent his last 20 years sailing, baking bread and playing bridge.

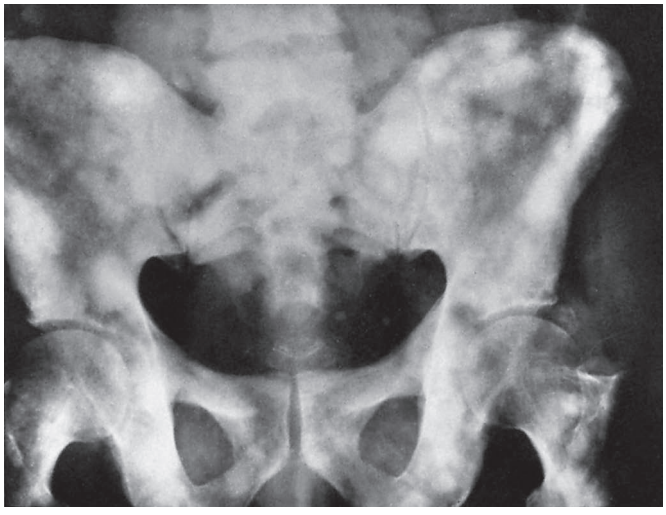

Figure 84.19 Osseous metastases of the pelvic bones in carcinoma of the prostate (courtesy of LN Pyrah, Leeds, UK).

has prognostic significance and a higher grade group has a poorer prognosis.

Grade groups are as follows:

- 1 = Gleason score 3 + 3 = 6
- 2 = Gleason score 3 + 4 = 7
- 3 = Gleason score 4 + 3 = 7
- 4 = Gleason score 8 (4 + 4 = 8, 3 + 5 = 8, 5 + 3 = 8)
- 5 = Gleason score ≥9 (4 + 5 = 9, 5 + 4 = 9, 5 + 5 = 10)

General blood tests

These are normal in early disease but, in metastatic disease, there may be leukoerythroblastic anaemia secondary to extensive marrow invasion, or anaemia may be secondary to renal failure. There may be thrombocytopenia and evidence of disseminated intravascular coagulopathy with increased fibrinogen degradation products.

Liver function tests

These will be abnormal if there is extensive metastatic invasion of the liver. Alkaline phosphatase may be raised from either hepatic involvement or secondaries in the bone. These can be distinguished by measurement of isoenzymes or gamma-glutamyltransferase.

Prostate-specific antigen

This is discussed earlier in this chapter. It is good at following the course of advanced disease; however, it is lacking in sensitivity and specificity in the diagnosis of early localised prostate cancer. Nevertheless, the finding of a PSA >10 ng/mL is suggestive of cancer and >35 ng/mL is almost diagnostic of advanced prostate cancer, in the absence of active urinary tract infection. A decrease in PSA to the normal range following hormonal ablation is a good prognostic sign. Following radical prostatectomy the serum PSA should fall to undetectable levels (the limit for detection for modern supersensitive assays is <0.03 ng/mL).

Radiological examination

Radiographs of the chest may reveal metastases in either the lung fields or the ribs. An abdominal radiograph may show the characteristic sclerotic metastases in lumbar vertebrae and pelvic bones (***Figure 84.19***). The bone appears dense and coarse, and it is sometimes difficult to distinguish the change from that in Paget's disease of bone. Nevertheless, osteolytic metastases are very common in prostate cancer and may coexist with sclerotic ones.

Cross-sectional imaging with magnetic resonance imaging and transrectal ultrasound

MRI with a high-tesla magnet (1.5–3 T) is the most accurate method of staging local disease. mpMRI is used preoperatively to assess pelvic lymph nodes as well as local stage, although the sensitivity of mpMRI to detect small areas of capsular spread is limited, even in the best hands. As well as preoperative staging, mpMRI plays an important role in active surveillance and localisation of recurrent prostate cancer after surgery. Low-grade tumours are frequently not seen on MRI and are often clinically insignificant.

TRUS scanning can also be used to stage prostate cancer. Locally extensive disease (T2) can be diagnosed with increased sensitivity by TRUS (***Figure 84.15***) compared with rectal examination, but many tumours will still be missed. This problem remains a real one in screening for early prostate cancer; in comparison with breast cancer, with mammography detecting 70–80% of tumours, TRUS plus rectal examination and measurement of PSA will detect only 30–50% of cancers that are known to be present on autopsy studies (although it may detect the larger, more significant cancers).

Bone scan

Once the diagnosis has been established, if metastatic spread is suspected (on the basis of a high PSA [>10 ng/mL], locally advanced disease or presence of Gleason 7 or higher) a bone scan should be carried out. If, however, the PSA is <10 ng/mL, then a bone scan would be performed only on clinical indications. The bone scan is performed by the injection of technetium-99m, which is then monitored using a gamma camera. It is more sensitive in the diagnosis of metastases (***Figure 84.20***) than a skeletal survey, but false positives occur in areas of arthritis, osteomyelitis or a healing fracture.

Positron emission tomography scan

In prostate cancer gallium-labelled prostate-specific membrane antigen (PSMA) has been increasingly used in positron

Sir James Paget, 1814–1899, English surgeon and pathologist, best known for his description of Paget's disease of the bone.

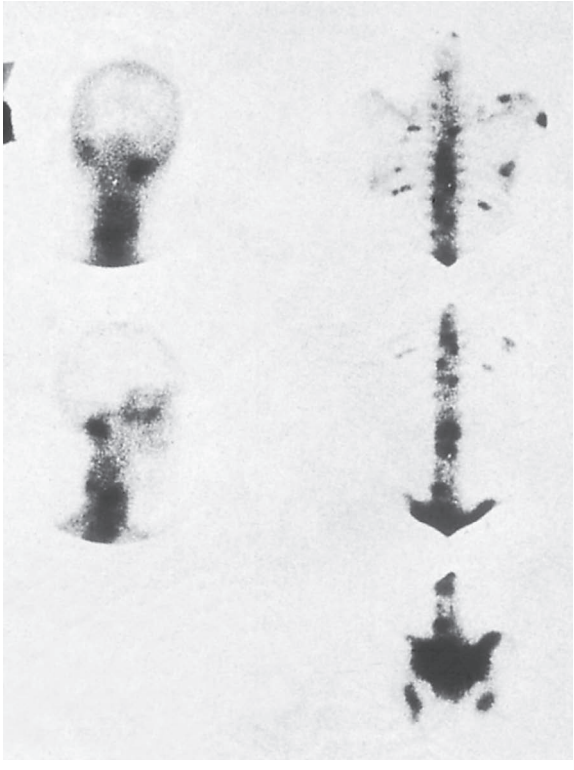

Figure 84.20 Bone scan showing multiple hot spots suggestive of metastatic disease in a man with prostate cancer.

emission tomography (PET) scans. It is sensitive in detecting lymph node metastasis and may be superior to MRI; however, smaller lymph nodes can be missed on PSMA-PET. If available, this test offers an additional and highly sensitive modality for detecting metastasis prior to offering treatment. It also has an increasing role in restaging after treatment relapse.

Treatment

Patients are counselled on their treatment options based on an estimated risk of a localised cancer spreading and causing death. The patient's life expectancy and comorbidities should be taken into consideration. The strongest risk factors for metastasis are PSA level, Gleason grade and clinical stage. Tables and nomograms are available using these three parameters to predict lymph node involvement and risk of metastasis.

Early disease

Curative treatment can only be offered to patients with early disease. Low-risk prostate cancer (low PSA, small foci of Gleason 6 disease) can be managed by active surveillance. Here, with 3-to 6-monthly digital rectal examination (DRE) and PSA measurement, mpMRI yearly or 2-yearly and repeated prostate biopsy, a proportion can safely avoid the toxicity of radical treatment. However, one-third of patients embarking on this approach will require radical treatment within a few years. The options available for T1, T2 or some T3 disease need to take into account the patient's age, performance status and lifestyle preferences. The treatment of patients with advanced disease (T4 or any nodal or distant metastases) is only palliative.

Summary box 84.8

Treatment and stage

- Treatment options for prostate cancer depend on stage of disease, life expectancy of the patient and patient preference
- PSA, DRE and biopsy Gleason grade are used to predict pathological stage
- Localised cancers can be treated by radical prostatectomy, radiation therapy and active monitoring (surveillance)
- Treatment of advanced disease is palliative, and hormone ablation remains the first-line therapy; once it starts failing, chemotherapy is used with short-term success

Summary of treatment for carcinoma of the prostate

- **Low-risk disease**. For men in their seventies, conservative treatment would usually be the correct approach. Radical surgical treatment might be considered in younger (<70 years) men with this form of the disease and/or with a family history, although, even in this group, some men will elect to pursue a conservative course (active surveillance) when counselled about risks versus benefits (impotence/incontinence).
- **Intermediate-risk disease**. In younger (<70 years), fitter men, this may be treated by radical prostatectomy or radical radiotherapy. Active monitoring remains an option, particularly for more elderly patients towards the lower end of the risk spectrum. In elderly patients with outflow obstruction, transurethral resection with or without hormone therapy is indicated. The benefit of radical treatment over a conservative approach is likely to be about 25%, given that progression to metastatic disease is of this order of magnitude after 10 years.
- **High-risk disease**. These patients are at significant risk of disease progression. They need multimodal therapy. Early androgen ablation is favoured if close follow-up is not possible. For the sexually active, a careful conservative approach with the adoption of androgen ablation when symptoms arise is reasonable. Androgen ablation coupled with radiotherapy, perhaps with surgery (radical prostatectomy plus salvage radiotherapy) as part of a multimodal approach, is standard treatment for younger men with T3 disease.
- **Metastatic disease**. Once metastases have developed, the outlook is poor. For patients with symptoms, there is no dilemma; androgen ablation will provide symptomatic relief in over two-thirds of patients. For patients with asymptomatic metastases, the timing of treatment is less clear. Systemic chemotherapy with docetaxel should be considered in younger, fitter men.

PROSTATITIS

In both acute and chronic prostatitis, the seminal vesicles and posterior urethra are usually also involved.

Acute prostatitis

Aetiology

Acute prostatitis is common, but underdiagnosed. The usual organism responsible is *Escherichia coli*, but *Staphylococcus aureus*, *Staphylococcus albus*, *Streptococcus faecalis*, *Neisseria gonorrhoeae* or *Chlamydia* may be responsible. The infection may be haematogenous from a distant focus or it may be secondary to acute urinary infection.

Clinical features

General manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has 'aches' all over, especially in the back, and may easily be diagnosed as having influenza. The temperature may be up to 39°C. Pain on micturition is usual, but not invariable. The urine contains threads in the initial voided sample, which should be cultured. Perineal heaviness, rectal irritation and pain on defecation can occur; a urethral discharge is rare. Frequency occurs when the infection involves the bladder. Rectal examination reveals a tender prostate; one lobe may be swollen more than the other, and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

Treatment

Treatment must be rigorous and prolonged or the infection will not be eradicated and recurrent attacks may ensue. Spread of infection to the epididymides and testes may occur. Prolonged treatment with an antibiotic that penetrates the prostate wall is indicated (trimethoprim, ciprofloxacin or aminoglycoside).

Prostatic abscess

In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply with rigors. Antibiotics disguise these features. Severe, unremitting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an anorectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender and perhaps fluctuant. TRUS or MRI may aid diagnosis. Retention of urine is likely to occur and, in such men, suprapubic catheterisation is best.

Treatment

The abscess should be drained without delay by transurethral resection (unroofing the whole cavity) or using a needle via the transrectal or perineal route. Injectable antibiotics such as aminoglycoside or a third-generation cephalosporin is often required for a week.

Chronic prostatitis

Many urologists find the diagnosis of chronic prostatitis and 'prostatodynia' very difficult as many men present with perigenital pain, testicular pain, prostatic pain exacerbated by sexual intercourse or pain that apparently renders sexual intercourse out of the question. Psychosexual dysfunction in such patients may be the underlying problem. The diagnosis of chronic prostatitis has to be based on:

- persistent threads in voided urine;
- prostatic massage showing pus cells with or without bacteria in the absence of urinary infection.

Aetiology

This is thought to be the sequela of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, the responsible organism is often difficult to find. Other organisms such as *Chlamydia* species may be responsible for chronic abacterial prostatitis.

Clinical features

The clinical features are extremely varied. Only men with symptoms of posterior urethritis, prostatic pain and perigenital pain accompanied by intermittent fever and pus cells or bacteria in the postprostatic massage specimen should be diagnosed as having chronic prostatitis.

Diagnosis

The three-glass urine test is valuable. If the first glass with the initial voided sample is clear and the second and third glasses show urine containing prostatic threads and leukocytes, prostatitis is present. Rectal examination of the prostate may be normal or may show a soft, boggy and tender prostate. Examination of the prostatic fluid obtained by prostatic massage should show pus cells and bacteria. Urethroscopy may reveal inflammation of the prostatic urethra, and pus may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and oedematous. In many men with the symptoms described above, all investigations are normal.

Treatment

Antibiotic therapy should be administered only in accordance with bacteriological sensitivity tests. Trimethoprim or ciprofloxacin penetrate well into the prostate. If *Trichomonas* or anaerobes are the responsible agent, a rapid response is obtained from administration of metronidazole (200 mg three times daily for 7 days to both partners). If *Chlamydia* is suspected, doxycycline is the antibiotic treatment of choice. α-blockers and anti-inflammatory drugs have been used with some success. There is little evidence that prostatic massage helps in eradicating the infection.

Prostatodynia

This diagnosis is made by the presence of perigenital pain in the absence of any objective evidence of prostatic inflammation. Whether the syndrome has any relationship with the prostate is unclear. The syndrome is part of the chronic pelvic pain syndrome spectrum and often has psychological and stress components.

PART 12 | Genitourinary

CHAPTER 85

The urethra and penis

Learning objectives

To recognise and understand:

- The common congenital anomalies of the urethra
- The diagnosis and treatment of urethral trauma
- The diagnosis and treatment of urethral stricture
- The diagnosis and treatment of phimosis
- The diagnosis and treatment of erectile dysfunction
- The common diseases of the penis and urethra and the principles of their surgical management

THE MALE URETHRA

Anatomy

The male urethra is a fibromuscular tube that extends from the bladder neck to the meatus. Functionally the urethra allows transport of urine from the bladder and semen from the ejaculatory ducts through the penis. The male urethra is subdivided into the following parts. The meatus is a vertical slit-like opening at the tip of the glans penis. The glandular part of the urethra is called the fossa navicularis. The penile urethra extends from the meatus to the penoscrotal junction. The bulbar urethra extends from the penoscrotal junction to the bulbomembranous junction. The penile urethra and bulbar urethra are surrounded by corpora spongiosa. The membranous urethra extends from the bulbomembranous junction to the verumontanum. It is surrounded by the voluntary external sphincter, which consists of both the smooth muscle external sphincter and the striated rhabdosphincter. It is innervated by the pudendal nerve, originating from spinal segments S2–4. The prostatic urethra extends from the bladder neck to the verumontanum and is surrounded by the prostate. The bladder neck contributes to the maintenance of continence in the male. Its main role is to act as a genital sphincter that closes at the time of ejaculation. The bladder neck and external sphincter can independently maintain continence in men. The urethral lining changes from transitional cell epithelium proximally to stratified squamous cell epithelium distally.

Congenital anomalies

Posterior urethral valves

The incidence of posterior urethral valves is around 1 in 8000 live male births. The valves are membranes that have a small posterior slit within them. They typically lie just distal to the verumontanum and cause obstruction to the urethra. They function as flap valves; although they are obstructive to antegrade urinary flow, a urethral catheter can be passed retrogradely without any difficulty. Posterior urethral valves need to be detected and treated as early as possible to minimise the degree of renal failure.

Diagnosis

Antenatal ultrasound shows a distended bladder, dilated prostatic urethra and hydroureteronephrosis. The presentation varies according to the severity of the obstruction. The more severe the obstruction, the earlier the presentation. If the diagnosis is not made antenatally, babies typically are presented by parents because of voiding complaints and urinary tract infection (UTI). Rarely the valves are incomplete, and the patient may present in adolescence or adulthood.

Impaired renal function is assessed by ultrasound to check renal cortical thickness and by nuclear renography to check for differential renal function. Investigations include a voiding cystourethrogram (VCUG), which shows a dilated posterior (prostatic) urethra (***Figure 85.1***). The bladder is hypertrophied and often shows diverticula. Typically, there may be vesicoureteral reflux.

Figure 85.1 A voiding cystourethrogram showing a dilated bladder with a dilated prostatic urethra above an obstruction at the level of the posterior urethral valves (courtesy of Dr Shashank Shrotriya, Pune, India).

Treatment

Initial treatment is by catheterisation to drain the urine and decompress the bladder and upper urinary tracts. The valves themselves can be difficult to see on urethroscopy because the flow of irrigant sweeps them into the open position.

Definitive treatment is by endoscopic ablation of the valves. Long-term follow-up is required in view of the associated vesicoureteral reflux, bladder dysfunction and renal impairment.

Summary box 85.1

Posterior urethral valves

- Posterior urethral valves are congenital membranes that cause obstruction to the urinary tract in the male
- Antenatal ultrasound typically shows a distended bladder, dilated prostatic urethra and hydroureteronephrosis
- Treatment is by endoscopic valve ablation
- Patients need long-term follow-up in view of recurrent UTI, bladder dysfunction and renal impairment

Hypospadias

The incidence of hypospadias is around 1 in 300 male live births. It is the most common congenital abnormality of the urethra. Diagnosis is made on physical examination. There are three characteristic features, including an ectopic ventrally located urethral meatus; usually a ventral penile curvature (chordee); and an incomplete dorsal hood prepuce.

Hypospadias is classified according to the position of the meatus (***Figure 85.2a–d***).

- Glanular hypospadias: the ectopic meatus is placed on the glans penis, but proximal to the normal site of the external meatus, which is marked by a blind pit.
- Coronal hypospadias: the meatus is placed at the level of the coronal sulcus.
- Penile hypospadias: the meatus is on the underside of the penile shaft.
- Penoscrotal hypospadias: the meatus is at the level of the penoscrotal junction.
- Perineal hypospadias: this is a rare and severe abnormality. The scrotum is bifid, and the urethra opens between

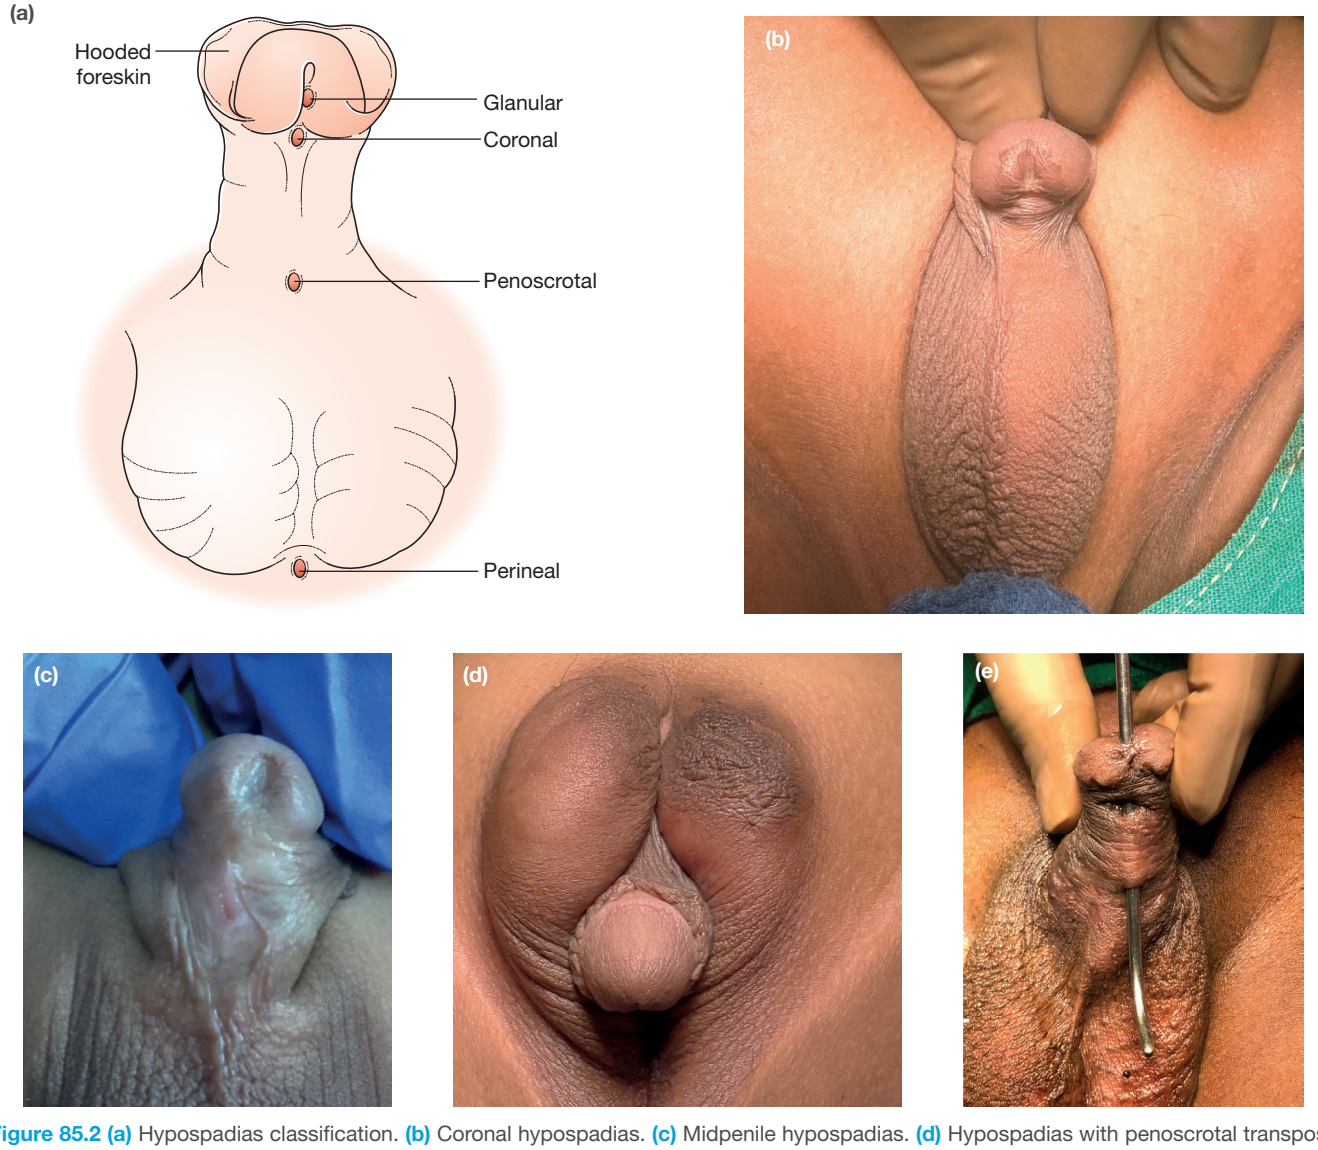

Figure 85.2 (a) Hypospadias classification. **(b)** Coronal hypospadias. **(c)** Midpenile hypospadias. **(d)** Hypospadias with penoscrotal transposition in which the scrotum is placed superior and anterior to the penis. **(e)** Urethrocutaneous fistula seen in multiple failed hypospadias surgeries.

its two halves. In children with severe hypospadias it is important to consider disorders of sexual development, which are usually associated with undescended testes, hernia and micropenis.

Treatment

Surgery for distal hypospadias is often for cosmetic reasons. This is usually treated by a tubularised incised plate urethroplasty. Proximal hypospadias with chordee needs surgical correction and may involve a two-stage repair. The first stage corrects the penile curvature and the second stage repairs the urethra. Circumcision should be avoided as preputial skin may be required for future repairs or revisions. Surgery for hypospadias is best performed by experts in hypospadias surgery and is typically undertaken before the age of 18 months. Failed hypospadias repair can present as urethrocutaneous fistula (***Figure 85.2e***).

Epispadias

Epispadias is very rare. In penile epispadias, the urethral opening is on the dorsum of the penis and is associated with an upward curvature of the erect penis (***Figure 85.3***). Epispadias often coexists with bladder exstrophy and other severe developmental defects.

Summary box 85.2

Hypospadias

- Hypospadias is diagnosed clinically by a ventrally placed urethral meatus, a hooded foreskin and penile curvature
- In severe cases with coexisting testicular maldescent and micropenis, consider disorders of sexual development as a diagnosis
- Avoid circumcision as the prepuce may be used in procedures to correct the abnormality
- Surgical treatment should be undertaken by experts

Urethral diverticulum

Congenital urethral diverticulum is rare. It is commonly seen post urethroplasty where genital skin is used for augmentation (***Figure 85.4***). Typically, patients present with postmicturition dribble. Diagnosis is made by urethrography and the diverticulum is repaired by surgery.

Injuries to the male urethra

Bulbar urethral trauma

The patient usually gives a history of a falling-astride injury, leading to blunt trauma of the perineum. Other common causes include falling from a tree, cycling, skating and industrial accidents. The bulbar urethra is crushed upwards onto the pubic bone, typically with significant bruising.

Clinical features

The signs of a ruptured bulbar urethra are perineal bruising and haematoma, typically with a butterfly distribution. There is usually bleeding from the urethral meatus and retention of urine.

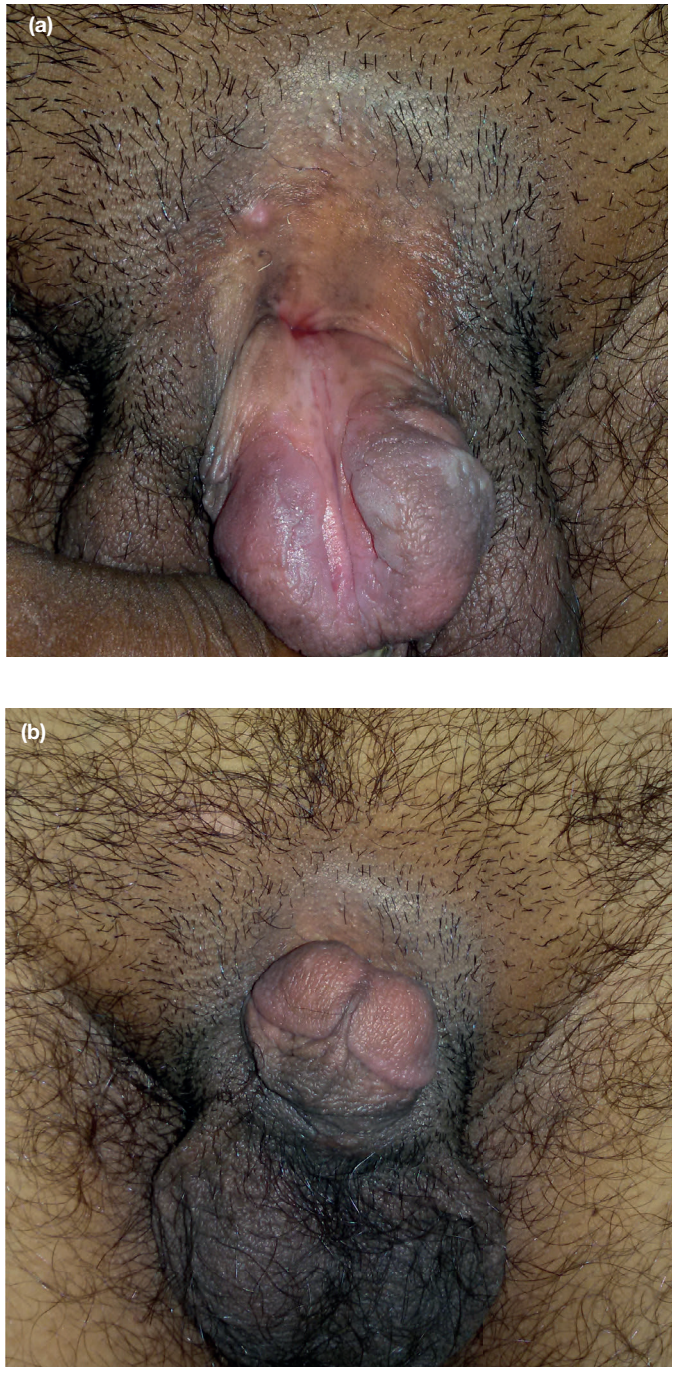

Figure 85.3 (a) Epispadias in an adult showing a dorsal urethral plate that is open and the meatus opened at the penopubic junction. **(b)** Dorsal chordee in a patient with epispadias (courtesy of Dr GV Datar, Pune, India).

Management

Investigations include a retrograde urethrogram (RGU). A gentle attempt at catheterisation may be made. If the catheter fails to drain urine, a suprapubic cystostomy is performed (***Figure 85.5***).

Delayed anastomotic urethroplasty is performed after 3 months with excellent success rates.

Figure 85.4 Urethrogram showing a urethral diverticulum in the penile urethra.

Summary box 85.3

Bulbar urethral trauma

- The aetiology is usually blunt injury to the perineum
- Diagnosis is made by urethrography
- If a catheter fails to drain, suprapubic cystostomy is performed
- Delayed urethroplasty is the surgical treatment of choice

Pelvic fractures and urethral injuries

The incidence of posterior urethral injury in pelvic fracture is approximately 10%. These are crush injuries. They are most commonly seen after road traffic accidents.

The site of injury is usually the bulbomembranous junction. The bladder with the prostate and membranous urethra is disrupted from the bulbar urethra. The displacement can be both posterior and superior (***Figure 85.6***). The injury can be partial or complete. Occasionally the injury is complex with bladder neck disruption and rectourethral fistula.

Clinical features

Initial treatment includes resuscitation and haemodynamic stabilisation of the patient.

Clinical features include blood at the meatus and urinary retention. The injury is usually diagnosed on the ultrasound or computed tomography (CT) scan done as part of trauma management (Focused Assessment with Sonography in Trauma [FAST]). To confirm the diagnosis an RGU is performed (***Figure 85.6***). If the tear is partial a gentle attempt at catheterisation is made. If urine does not drain, a suprapubic cystostomy (percutaneous or open) is performed. Complex patients may need evaluation with a three-dimensional CT or magnetic resonance imaging (MRI) scan of the pelvis. Emergency laparotomy is required for bladder rupture and bladder neck injuries. A diverting colostomy is performed in associated rectal injuries.

Treatment

In some centres, early endoscopic realignment is attempted. Once the patient is stable, endoscopy is performed from a suprapubic cystostomy. A guidewire is passed from the urethral

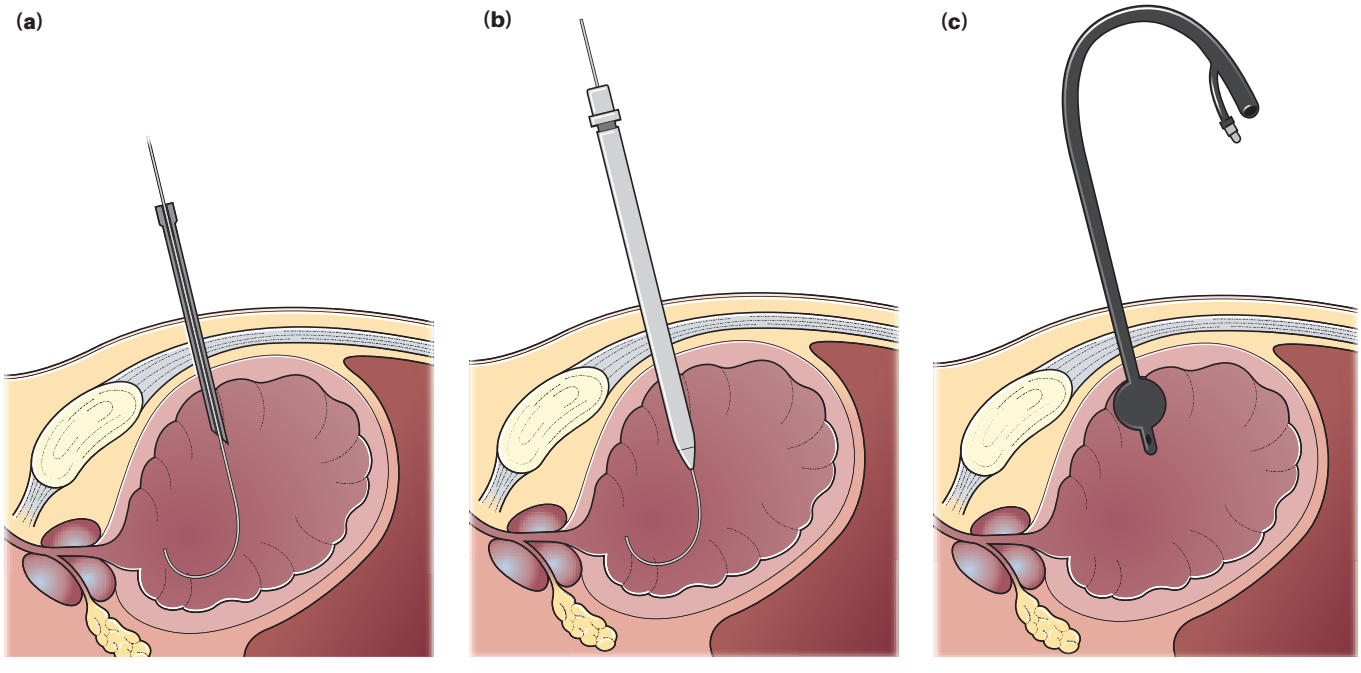

Figure 85.5 (a) Percutaneous puncture of the bladder with passage of a guidewire into the bladder followed by dilatation of the track over the guidewire **(b)**, thereby allowing placement of a catheter into the bladder **(c)**.

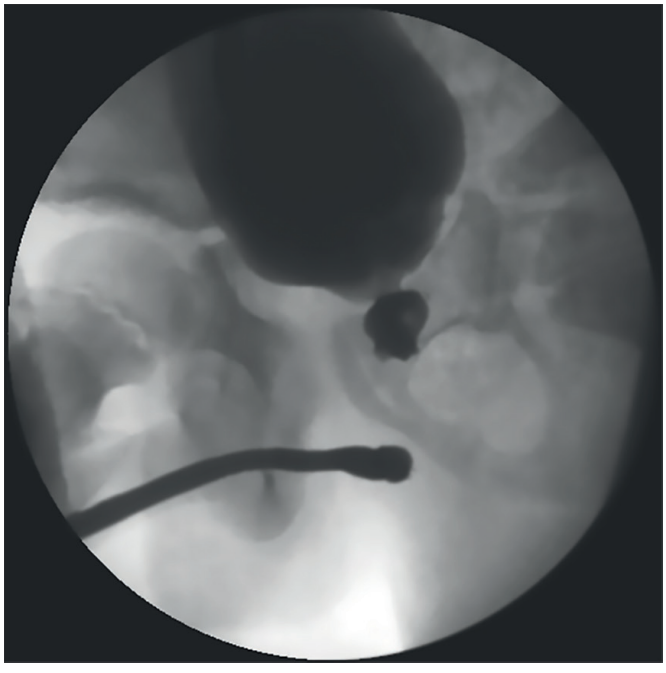

Figure 85.6 A retrograde urethrogram and voiding cystourethrogram in a patient with a pelvic fracture urethral injury showing the gap. The bladder along with the prostate is displaced upwards and there is a gap between the bulbar urethra and membranous urethra.

meatus and pulled up into the bladder through the haematoma. A Foley catheter is passed over the guidewire. This procedure is challenging and is not always successful. There is an increased risk of infection of the haematoma. If endoscopic realignment is successful, some patients may not need further surgery. Even if it fails, the gap may become shorter and easier to manage with urethroplasty. Delayed anastomotic urethroplasty is the treatment of choice and is performed after 3–6 months. It is a highly challenging procedure and should be undertaken at specialist centres where the surgery has higher success rates.

Complications

Erectile dysfunction (ED). This is common after pelvic fracture with urethral injury. It can be vasculogenic (damage to dorsal arteries) or neurogenic (damage to cavernosal nerves). The erectile function is evaluated by penile Doppler ultrasound. Usually, an intracavernosal injection of a vasoactive agent (papaverine) is given prior to Doppler evaluation. Penile Doppler ultrasound is used to evaluate the velocity of blood flow in the cavernosal and dorsal penile arteries. Patients often recover from ED over a period of time (up to 1 year). Those who fail may require further treatment with oral agents such as sildenafil. If this fails they are treated with self-intracavernosal injection of vasoactive agents, a vacuum device or a penile implant.

Urinary incontinence. Incontinence is rare. In complex cases, the injury may affect the prostate–membranous urethra with a bladder neck tear. These patients have a higher risk of incontinence.

Orthopaedic injuries. Stabilisation of the fractured pelvis may be performed by the orthopaedic team by either external or internal fixation.

Summary box 85.4

Pelvic fractures and urethral injury

- Suspect a pelvic fracture and associated urethral injury if there is retention of urine or blood at the meatus
- Diagnostic RGU is performed
- Partial tears can be treated with a single gentle attempt at catheterisation
- Initial management is insertion of a suprapubic catheter
- Delayed anastomotic urethroplasty has a high success rate in specialised centres

Penile and bulbar urethral stricture

Aetiology

The common causes of urethral stricture are:

- lichen sclerosus (LS);
- iatrogenic (post catheter and/or instrumentation);
- sexually transmitted diseases (gonorrhoea);
- post radiation;
- traumatic;
- idiopathic;
- congenital.

Pathophysiology

Postinflammatory strictures are less common since the introduction of effective antibiotic treatment of gonorrhoea. The stricture is commonly seen in the bulbar urethra. There is infection in the periurethral glands, which persists after inadequately treated gonorrhoea. The infection spreads to cause a periurethritis, which heals by fibrosis. Most strictures appear within 1 year of infection but may not cause difficulty in micturition until later.

LS (previously known as balanitis xerotica obliterans [BXO]) is a condition characterised by fibrosis of the foreskin, resulting in phimosis. The glans may be involved and it presents as white patches. There can be a meatal stenosis and penile urethral stricture. The cause of the condition is unknown. The majority of studies suggest that it is an autoimmune condition or caused by infection. LS is usually diagnosed by visual inspection but a biopsy will confirm the diagnosis. It is seen in two forms: active and burnt out. Patients usually present with poor flow. A uroflowmetry study followed by RGU and VCUG can help in making the diagnosis of stricture.

The strictures produced are typically long and difficult to treat. Common sites of stricture in LS are penile or panurethral. However, isolated bulbar urethral strictures are also seen in LS.

Frederic Eugene Basil Foley, 1891–1966, urologist, Ancker Hospital, St Paul, MN, USA.
Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

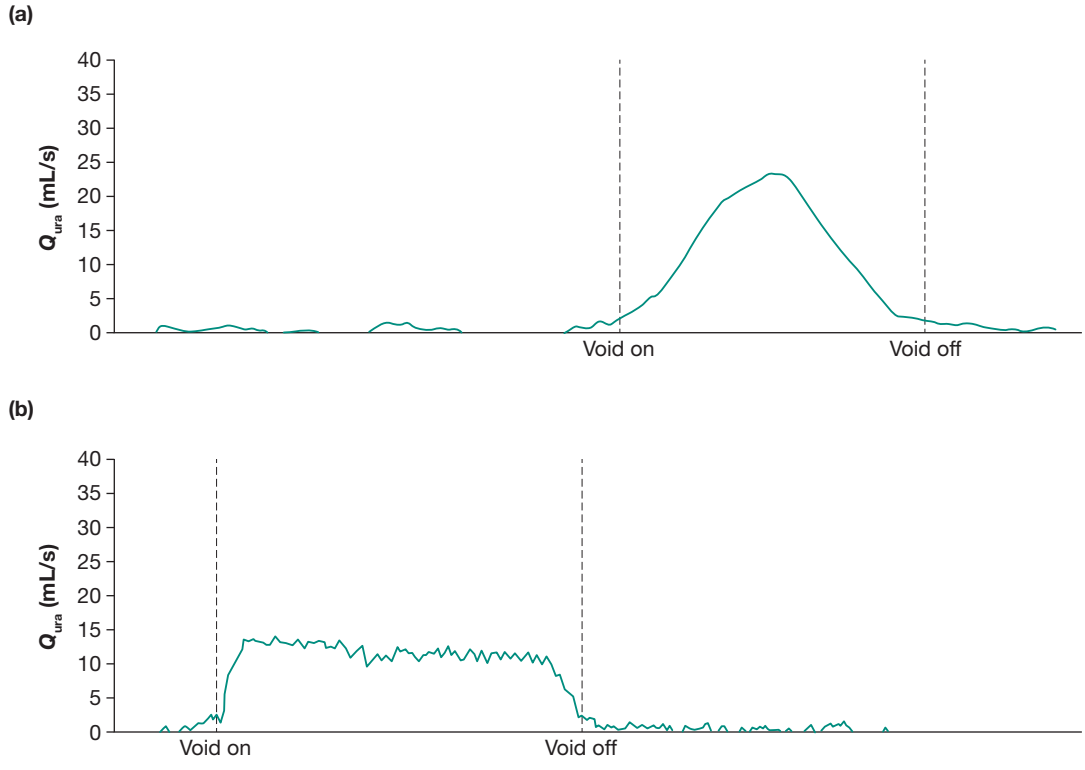

Figure 85.7 (a) A normal uroflow pattern. Normal flow is a bell-shaped curve with a maximum flow rate of more than 15 mL/s. **(b)** A urinary flow rate trace from a patient with a urethral stricture. Note the prolonged flow with the typical box pattern (the vertical lines depict the start and end of micturition).

Postinstrumentation strictures following an endoscopy or catheterisation may affect any part of the urethra. Post-transurethral resection of prostate (TURP) strictures are seen in the submeatal area, the bulbar urethra or penoscrotal junction. Bladder neck stenosis can occur following TURP and following radical prostatectomy for the treatment of prostate cancer.

Clinical features

Symptoms are usually hesitancy, poor flow and prolonged voiding time. The patients may complain of recurrent UTIs. Occasionally patients present with urinary retention. Investigations include uroflowmetry, urethroscopy, urethrography and ultrasound scanning to assess bladder emptying and to detect any upper tract dilatation. The urinary flow rate is typically prolonged and shows a box pattern (***Figure 85.7***). RGU and VCUG using a water-soluble contrast medium are performed (***Figures 85.8 and 85.9***). Urethroscopy is used to assess the stricture intraoperatively (***Figure 85.10***).

Complications

These include recurrent UTI, retention of urine, upper tract dilatation, bladder stones and periurethral abscess.

Treatment

The management of urethral strictures has changed considerably over the past 25 years. Urethral dilatation is one of the oldest surgical procedures and has been performed for 5000 years. In the past, serial metal dilators were used under local anaesthesia. The complications include pain, fever, bleeding and false passage creation. Nowadays, dilatation is performed over a guidewire using serial plastic dilators. Dilatation is particularly effective for soft and short strictures. It is also indicated for unfit patients, patients refusing urethroplasty or those with multiple failed urethroplasties. Urethral dilatation rarely cures stricture and most patients require repeated dilations.

Direct visual internal urethrotomy (DVIU). DVIU is performed using an optical urethrotome. The stricture is incised under visual control using a cold knife passed through the sheath of a rigid urethrotome.

Alternatively, a laser fibre (holmium/thulium) can be used. DVIU is indicated for short, non-traumatic bulbar strictures but should not be used in the penile urethra or the sphincter active membranous urethra.

Self-dilatation/clean intermittent catheterisation. In self-dilatation, the patient inserts a small-calibre (12/14Fr), usually disposable catheter into the urethra at regular intervals. Thus, the patient dilates his own stricture, but this is not a curative option. Patients who are not willing to undergo urethroplasty may choose the option of self-dilatation.

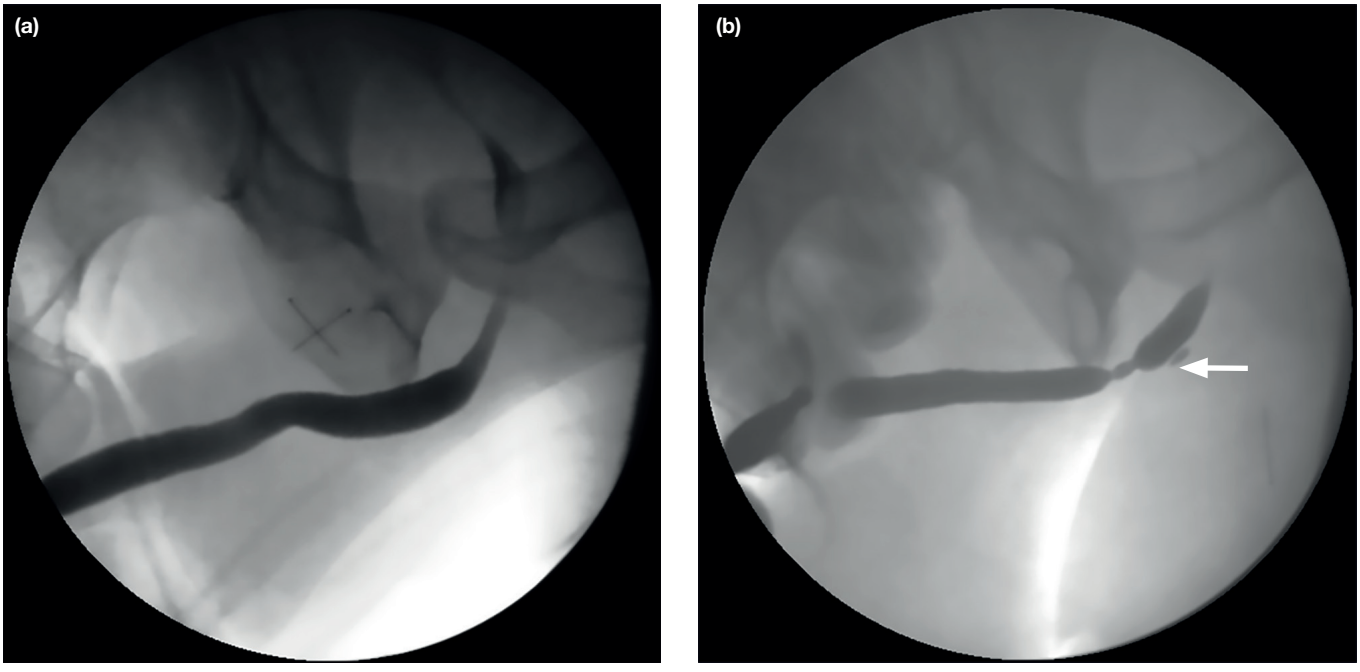

Figure 85.8 (a) A normal urethrogram. **(b)** An ascending urethrogram showing urethral stricture of the bulbar urethra (arrow).

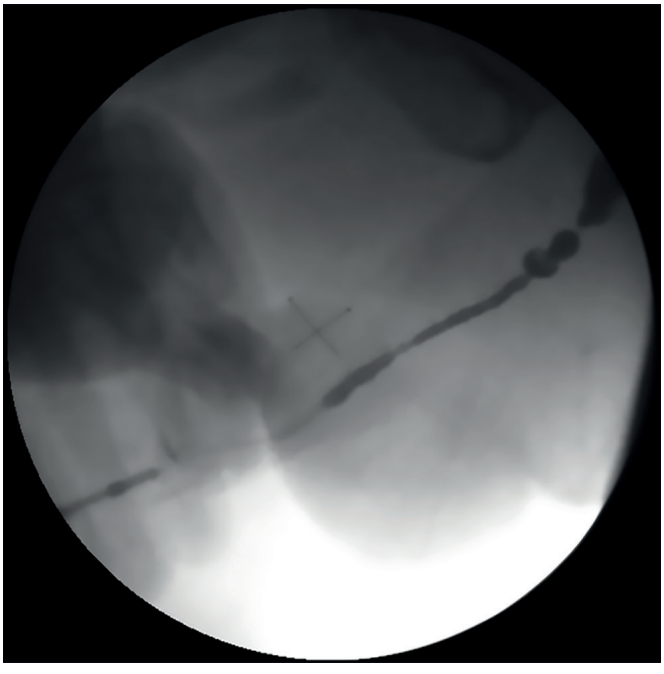

Figure 85.9 Panurethral stricture.

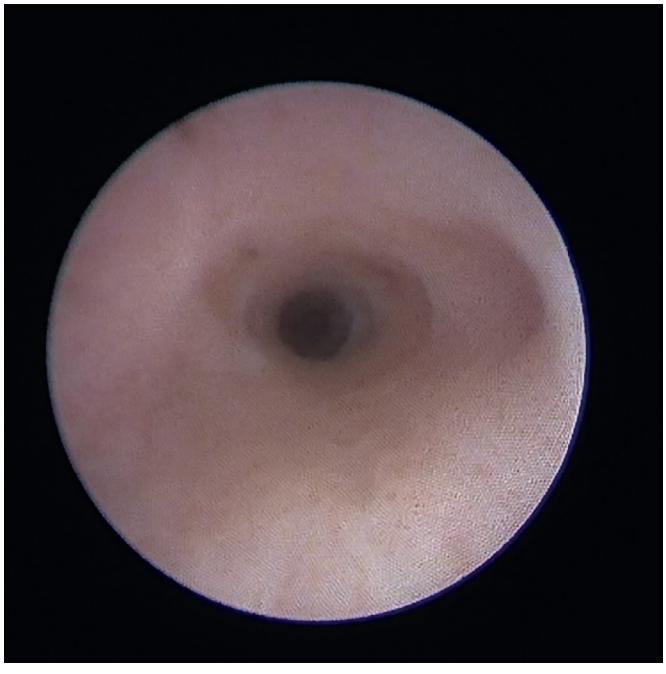

Figure 85.10 Endoscopic appearance of a urethral stricture with a fibreoptic endoscope.

Urethroplasty. There are two types of urethroplasty: anastomotic and augmentation. Anastomotic urethroplasty is performed for bulbar urethral traumatic strictures where there is a gap in the urethra. This involves dissection of the two ends of the urethra, spatulation and anastomosis. Augmentation urethroplasty is performed for non-traumatic and long strictures. In this type of urethroplasty the structured segment of urethra is incised and augmented with a patch (graft). The usual choice of patch material for augmentation urethroplasty is buccal mucosa. If required, lingual grafts can be harvested from the undersurface of the tongue. The techniques include dorsal onlay augmentation, dorsal inlay or ventral onlay.

Panurethral stricture

This is a long urethral stricture (***Figure 85.9***). The aetiology includes LS and iatrogenic causes. The treatment is by

urethroplasty. A perineal incision is made and the penis is invaginated. The urethra is dissected along the full length on one side and a dorsal onlay buccal mucosa urethroplasty is performed.

Use of flaps

Preputial and penile fasciocutaneous flaps with their own vascular pedicle can be utilised for complex posterior urethroplasty to bridge long gaps in the urethra and postradiation strictures.

Summary box 85.5

Treatment of urethral strictures

- A newly diagnosed short bulbar stricture is best treated initially by DVIU
- Traumatic strictures need anastomotic urethroplasty
- Long non-traumatic strictures are treated by augmentation urethroplasty
- Anastomotic urethroplasty has a success rate of around 90%, while augmentation urethroplasty has a success rate of 85% over 10 years. Long-term follow-up is required

Other conditions of the urethra

Urethral fistula

This is seen after failed hypospadias surgery (***Figure 85.2e***). Tight strictures with periurethral abscess can present as multiple fistulae (watering-can perineum).

Urethral calculi

Urethral calculi can arise primarily behind a stricture or in an infected urethral diverticulum. More commonly, the stone is a renal calculus that has migrated to the urethra via the bladder.

Clinical features

Urethral calculi present as episodes of retention, pain or haematuria.

Treatment

A stone lodged within the prostatic urethra should be displaced back into the bladder and treated by laser or pneumatic fragmentation. Calculi in more distal parts of the urethra are fragmented *in situ* by a holmium/thulium laser. Open removal is indicated in large or multiple calculi inside a urethral diverticulum.

Neoplasms

Bloody urethral discharge without infection should raise suspicion that the patient has a urethral tumour, although such tumours are rare. Multifocal transitional cell cancer of the bladder is sometimes associated with tumours in the prostatic urethra and occasionally more distally. They can be treated by local laser ablation but are associated with a tendency to distant spread. Squamous carcinoma may develop in an area of squamous metaplasia in patients with LS. It is treated by radical surgery and carries a poor prognosis.

THE FEMALE URETHRA

Anatomy

The female urethra is around 4 cm long, extending from the bladder neck to the meatus. The entire length of female urethra is sphincter active. There is extra support from the surrounding pelvic floor musculature.

Abnormalities of the female urethra include:

- caruncle;
- stricture;
- diverticulum;
- papillomas;
- carcinoma.

Caruncle

This is seen in elderly women. It presents as a soft, raspberry-like mass about the size of a pea. It is actually the prolapsed urethral mucosa at the 6 o'clock position (***Figure 85.11***). Occasionally, there is bleeding. If required it is treated by excision and diathermy coagulation of the base of the stalk.

Stricture

Urethral stricture is uncommon in women. The aetiology includes urethritis, trauma associated with a prolonged or difficult labour or instrumentation. Urinary retention is an occasional consequence and is usually chronic. The stricture is initially managed by urethral dilatation. Urethroplasty with buccal mucosa augmentation is advocated for recurrent strictures.

Diverticulum

A female urethral diverticulum may be congenital or caused by rupture of a distended and infected paraurethral gland or by injury of the urethra during childbirth. Urine within the diverticulum becomes infected, causing local pain and repeated bouts of cystitis. Purulent urine is discharged if the urethra is compressed with a finger placed in the vagina. Diagnosis is by MRI or by transvaginal ultrasound. Excision of

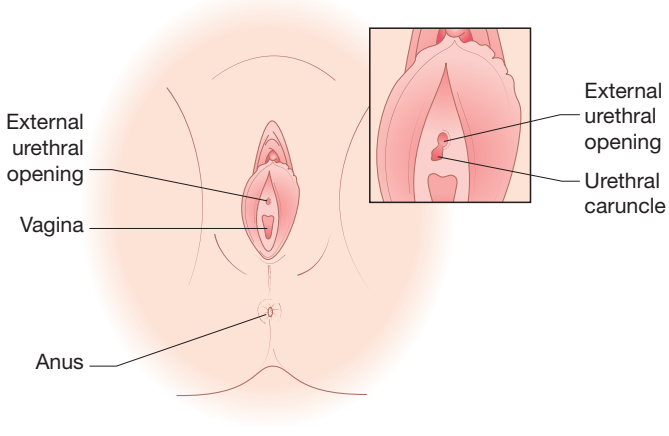

Figure 85.11 A urethral caruncle.

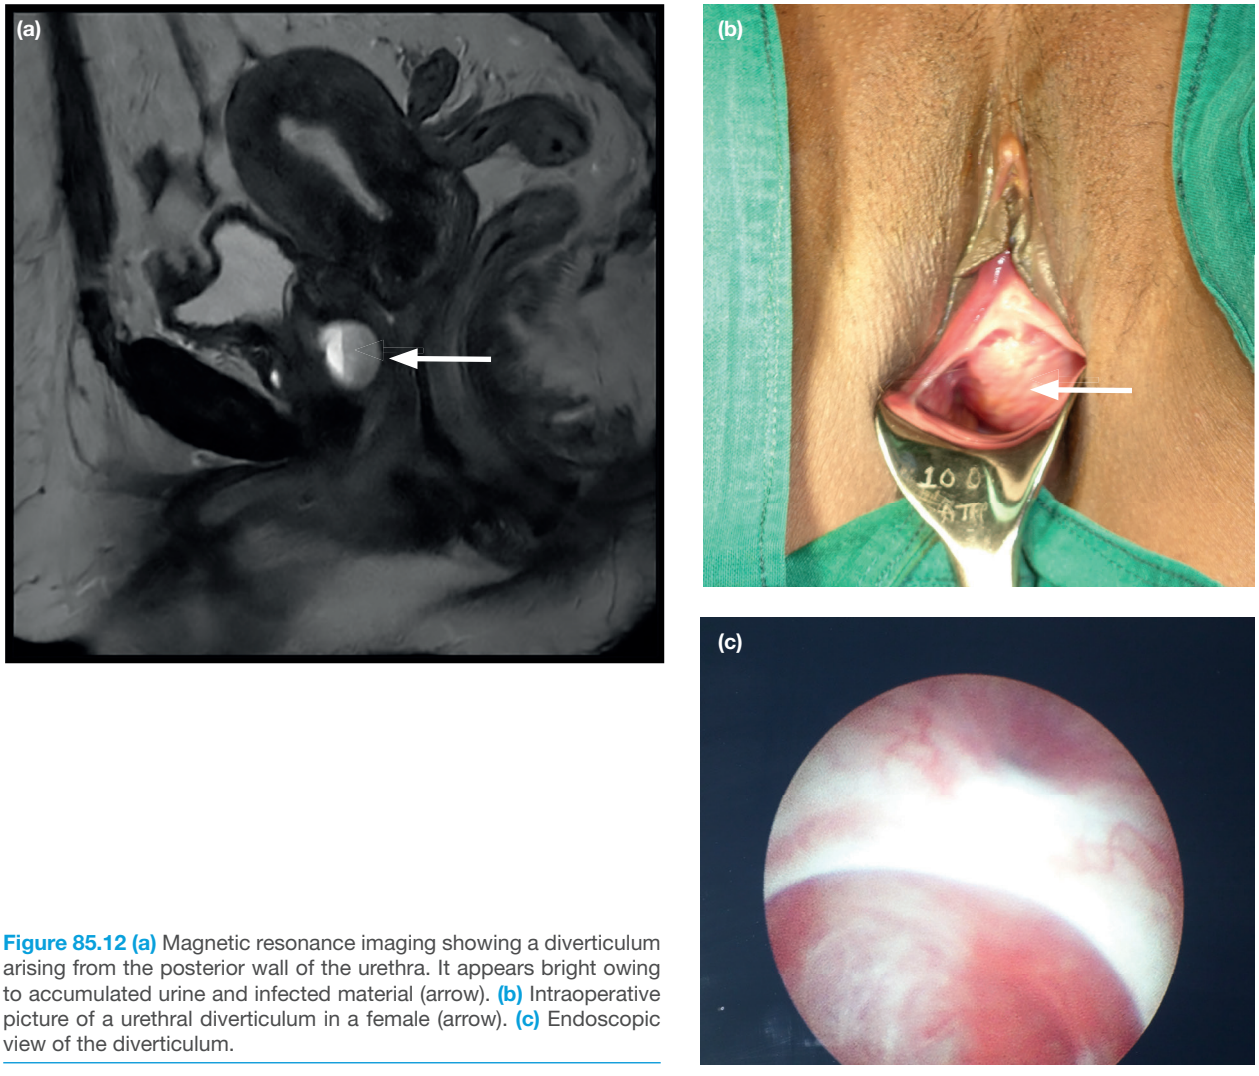

Figure 85.12 (a) Magnetic resonance imaging showing a diverticulum arising from the posterior wall of the urethra. It appears bright owing to accumulated urine and infected material (arrow). **(b)** Intraoperative picture of a urethral diverticulum in a female (arrow). **(c)** Endoscopic view of the diverticulum.

the diverticulum through the anterior vaginal wall is effective, but care must be taken not to damage the urethral sphincter (***Figure 85.12***).

Papillomas/condyloma acuminata

Condyloma acuminata (also known as anogenital warts) are a common sexually transmitted disease caused by human papillomavirus (HPV) types 6 and 11. Warts are small, skin-coloured or pink growths and may be smooth and flat or raised with a rough texture. They are usually located on the labia, at the opening of the vagina or around or inside the anus. Most women with warts do not have any symptoms at all. Less commonly, there may be itching, burning or tenderness in the genital area.

The treatment options vary depending on the size. They include local application of podophyllotoxin or imiquimod; surgical treatments include cryotherapy, electrocautery, excision and laser therapy.

Carcinoma of the urethra

This occurs twice as often in women as in men. Whether a caruncle can become malignant is disputed, but caruncles and tumours often occur close together. Malignant swellings of the urethra feel harder than benign ones. Treatment is by radiotherapy or radical surgery. The overall prognosis is poor.

THE PENIS

Anatomy

The penis is a sexual organ and composed of three tubular structures. The two dorsal structures, the corpora cavernosa, provide erectile function and are anchored posteriorly onto the pubic rami. The ventral tubular structure is the corpus spongiosum, which surrounds the urethra. It expands distally to form the glans penis.

The corpora cavernosa have an outer tough covering of tunica albuginea. There is a septum between them. The tunica albuginea encloses the erectile tissue, which has a trabecular structure with a network of sinusoidal spaces lined by endothelium within which blood pools during erection. The central arterial blood supply (cavernosal artery) is a branch of the internal pudendal artery. Sacral parasympathetic nerves are responsible for erection. They cause smooth muscle relaxation

Figure 85.13 Phimosis in a child with inability to retract the prepuce.

with increased arterial inflow, dilatation of the sinusoids and blood accumulation within the trabecular spaces. Simultaneously there is venous outflow occlusion by the coverings of the corpora cavernosa.

DISEASES OF THE FORESKIN

Phimosis

There are physiological adhesions between the foreskin and the glans penis at birth. They begin to disappear around the age of 2 years and may persist until 6 years of age or later, giving the false impression that the prepuce will not retract. This condition (sometimes known as physiological phimosis) should not be confused with true phimosis in young boys.

Phimosis in boys

In true phimosis the prepuce does not retract (***Figure 85.13***). This may result in ballooning of the foreskin during micturition and may also result in infection (balanoposthitis).

Phimosis in adults

Scarring in adults occurs as a result of balanitis (inflammation of the glans penis), posthitis (inflammation of the foreskin) or LS. In LS (***Figures 85.14 and 85.15***) the normal pliant foreskin becomes thickened, typically whitish in appearance and forms a constricting band that prevents retraction. As a consequence, it is difficult to keep the penis clean and there may be recurrent attacks of balanitis.

Treatment

In physiological phimosis, no treatment is necessary or appropriate. True phimosis causing symptoms requires circumcision. In emergency situations, such as when catheterisation is required, a dorsal slit under local anaesthesia may be required.

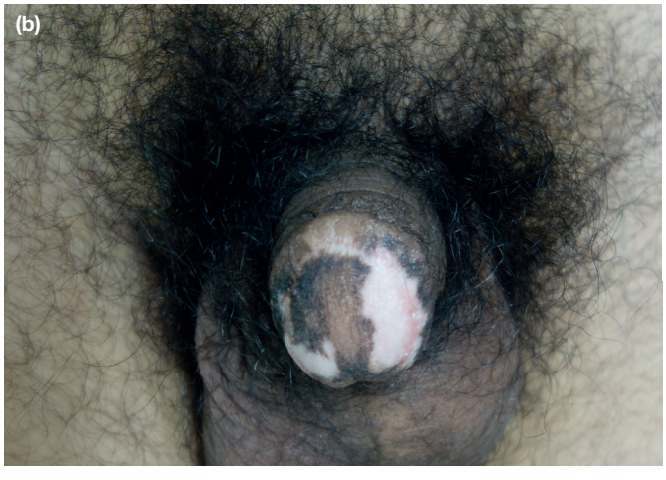

Figure 85.14 (a) Active phase of lichen sclerosus (LS). **(b)** Burnt-out phase of LS.

Circumcision

Circumcision has been practised since as early as 4000 BCE. Circumcision should not be performed in the presence of hypospadias, penile curvature or buried penis.

Indications. In infants and young boys, circumcision is usually performed at the request of the parents for social or religious reasons. Medical indications for circumcision in boys include true phimosis, LS (rare under the age of 5 years), recurrent

Figure 85.15 Lichen sclerosus is a genital skin disease and can involve the skin of the genitalia.

attacks of balanoposthitis and recurrent UTIs with abnormalities such as high-grade vesicoureteral reflux.

In adults, circumcision is indicated when there is inability to retract the foreskin for intercourse, for splitting of an abnormally tight frenulum or for recurrent balanitis.

Recently, evidence has emerged that circumcision protects against the spread of human immunodeficiency virus (HIV). The virus dies quickly on a dry penis. A large-scale programme of adolescent circumcision under the auspices of the World Health Organization is ongoing in some African countries.

Technique. Under anaesthesia the prepuce is held in artery forceps and put on a gentle stretch. A circumferential incision in the penile skin is made at the level of the corona using a knife. The prepuce is then slit dorsally in the midline to within 1 cm of the corona. (An alternative technique slits the prepuce first.) This converts the foreskin into two flaps.

When the undersurface of the prepuce has been separated from the glans, the inner layer of each flap is again marked with a pen and then incised with a second circumferential incision, leaving about 0.5 cm of the inner layer of the preputial skin. Cutting the remaining connective tissue completes the excision (***Figure 85.16***). Vessels should be preferably secured with bipolar diathermy or with absorbable sutures. The cut edges of the skin are approximated using interrupted sutures, making certain that the frenular vessels are ligated.

In LS, the separation of prepuce from foreskin is at times difficult. The excised skin should be sent for histology.

Summary box 85.6

Circumcision

- Commonly performed for religious and cultural reasons
- Physiological phimosis does not need circumcision
- Symptomatic phimosis is treated by circumcision

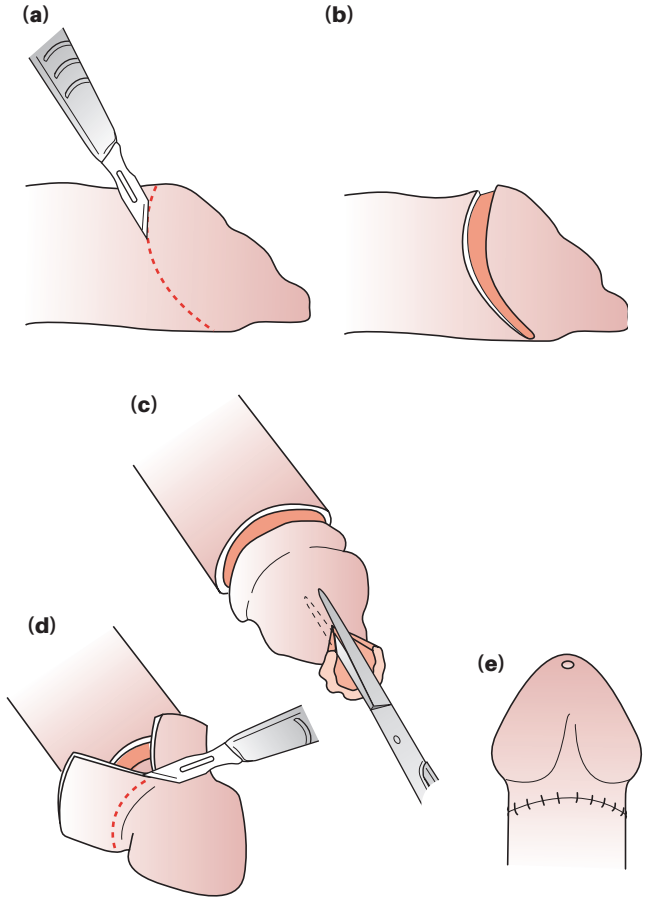

Figure 85.16 (a–e) Stages in circumcision.

Short frenulum

Phimosis should not be confused with the condition where the frenulum is short. It causes pain when the foreskin is retracted. Another possible presentation is tearing of the frenulum during sexual activity. Treatment is by frenuloplasty, which utilises the Heineke–Mikulicz principle to lengthen the frenulum.

Paraphimosis

A tight foreskin once retracted may be difficult to return and a paraphimosis results. In this condition, the venous and lymphatic return from the glans and distal foreskin is obstructed and these structures become oedematous, causing even more pressure within the obstructing ring of prepuce (***Figure 85.17***). Gentle manual compression and injection of a solution of hyaluronidase in normal saline may help to reduce the swelling. A dorsal slit of the prepuce under local anaesthesia may be enough in an emergency. These patients can be treated by circumcision if careful manipulation fails.

Walter Hermann von Heineke, 1834–1901, surgeon and Professor of Surgery in Erlangen, Germany.
Jan Mikulicz-Radecki, 1850–1905, surgeon and Director of Surgery in Krakow and Wrocław, Poland.

Figure 85.17 Paraphimosis.

Figure 85.18 Balanoposthitis.

Balanoposthitis

Inflammation of the prepuce is known as posthitis; inflammation of the glans is balanitis. The opposing surfaces of the two structures are often involved, hence the term balanoposthitis (***Figure 85.18***). In mild cases, the only symptoms are itching and some discharge. In more severe inflammation, the glans and foreskin are red-raw and pus exudes. Treatment is by broad-spectrum antibiotics and local hygiene measures. Balanoposthitis is common in patients with diabetes. Recurrent balanoposthitis requires circumcision.

INJURIES OF THE PENIS

Avulsion of the skin of the penis

Entanglement of clothing in rotating machinery and zip injuries are the usual causes. Partial injury to the penile skin can be repaired. Complete avulsion is treated by a two-stage procedure. Burying the penis in the scrotum is the first stage and lifting it is the second stage. The scrotal skin now forms the covering of the penis. An alternative approach is initial debridement with skin grafting later.

Figure 85.19 Penile fracture. Note the extensive bruising of the penis and scrotum.

Fracture of the penis

Fracture of the penis usually occurs when the erect penis is bent suddenly. It leads to rupture of the tunica albuginea with extravasation of blood from within the penis. Usually the patient feels a cracking or popping sound. It is associated with pain and detumescence. Clinically there is bruising and penile haematoma (***Figure 85.19***). There may occasionally be an associated urethral injury.

Investigations include ultrasound and MRI. Surgical management involves early exploration of the penis with surgical repair of the ruptured tunica albuginea.

Strangulation of the penis

Strangulation of the penis is caused by rings placed on the penis, usually for sexual pleasure. It can cause venous engorgement, which prevents their removal. The ring must be cut off with a ring cutter.

Other abnormalities of the penis

Erectile dysfunction

ED is failure to attain or maintain an erection. It can arise as a consequence of psychological issues, but the commonest cause is vascular disease affecting the penile arterial blood flow; as such, ED is associated with diabetes, hypertension, dyslipidaemia and smoking. Other rarer causes include endocrine disease (hypogonadism and prolactin-secreting pituitary tumours), neurological disease (multiple sclerosis, spinal cord injury and prolapsed intervertebral disc), iatrogenic damage to the cavernosal nerves owing to radical pelvic surgery (e.g. radical prostatectomy, abdominoperineal excision of the rectum and radical cystectomy), neuropathy secondary to pelvic radiotherapy and drug-induced causes (including antihypertensive agents, antidepressants and antipsychotics). ED may be a marker of cardiovascular disease.

Physical examination of the genitalia, measurement of the blood pressure and assessment of the secondary sexual

characteristics is required; biochemical assessment of the blood sugar, the serum lipid profile and the serum testosterone is necessary in all cases. Penile Doppler ultrasound is performed with the use of intracavernosal vasoactive agents such as papaverine. Initially the ED is treated with phosphodiesterase type 5 inhibitors (such as sildenafil).

A few patients need treatment with self-intracavernosal injection of vasoactive agents. Vacuum erection devices are a non-invasive alternative. Penile implants are broadly of two types: semirigid and inflatable. Their use is becoming increasingly popular.

Summary box 85.7

Erectile dysfunction

- Appropriate investigation involves identification of vascular risk factors
- Phosphodiesterase inhibitors are the first-line treatment
- Penile implants are becoming popular for management of ED

Peyronie's disease

Peyronie's disease (PD) is characterised by penile deformity (***Figure 85.20***), palpable penile plaques inside the penis, ED and pain on erection. The cause is unknown, but probably involves minor injury to the erect penis with secondary microhaemorrhage beneath the tunica albuginea and fibrosis. The latter results in the palpable plaques that can be identified on examination. The plaques may rarely be calcified (***Figure 85.21***). The presence of these relatively inelastic plaques causes the erect penis to bend towards the side of the plaque. The deformity is commonly dorsal (towards the abdomen) and the deformity may prevent penetrative sexual intercourse.

While the aetiology is uncertain, there is an association with Dupuytren's contracture. The natural history of the condition is that it typically progresses for 18–24 months before stabilising. During this active phase of the disease, surgery is not indicated; a variety of medical treatments have been tried, although none with any good evidence of benefit.

The diagnosis is usually made on clinical examination but MRI may be helpful.

Newer treatments include intralesional injections of collagenase clostridium histolyticum (Xiaflex).

Surgical correction can be performed in two ways. If the penis is of adequate length, it is possible to plicate the tunica albuginea on the side opposite to the maximum curvature. The plication can be done by Nesbit's technique or a 16-dot technique. The second option involves incision of the plaque and a bovine pericardial patch.

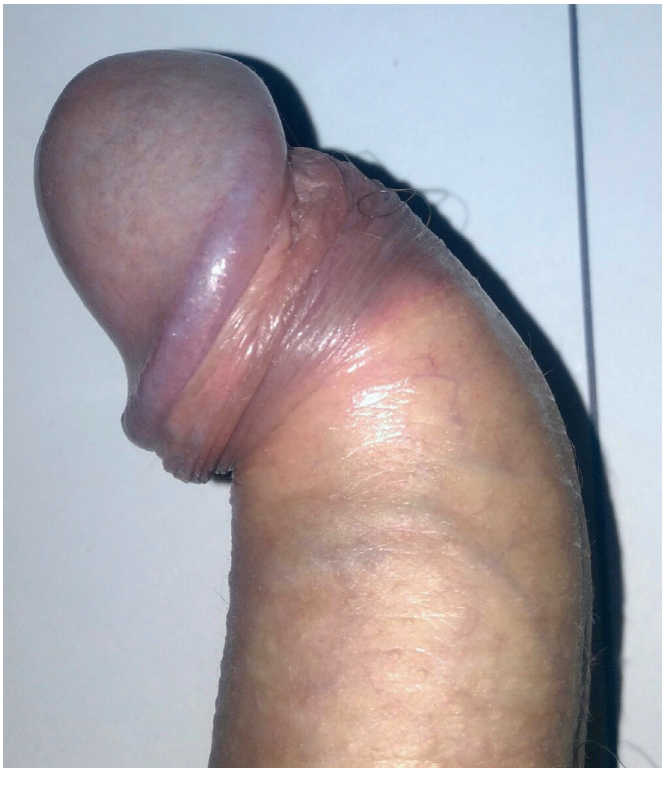

Figure 85.20 Dorsal deformity of the erect penis that is typical of Peyronie's disease.

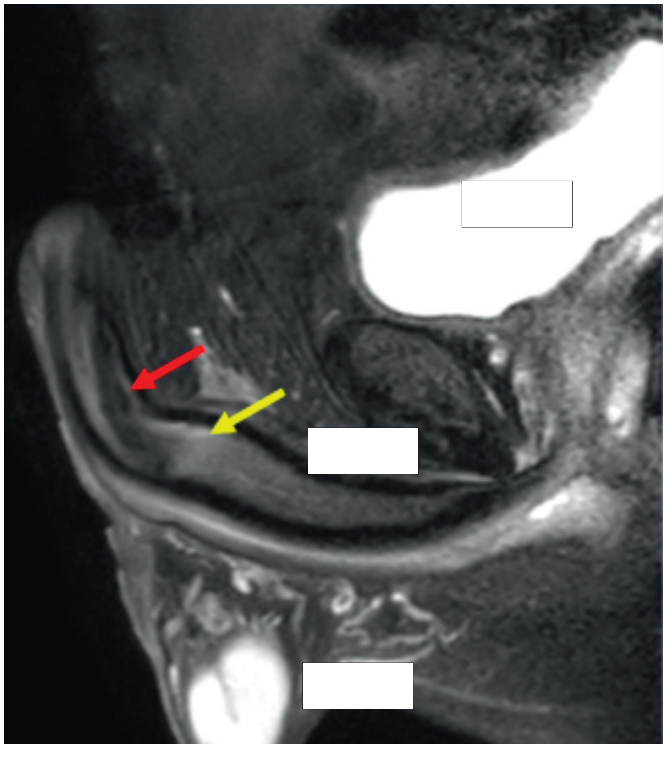

Figure 85.21 Magnetic resonance imaging in Peyronie's disease showing plaque. The yellow arrow shows calcified plaque; the red arrow shows active disease on the dorsal wall of the penis.

Francois de la Peyronie, 1678–1747, surgeon to King Louis XIV of France and founder of the Royal Academy of Surgery, Paris, France.
Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.
Reed Miller Nesbit, 1898–1979, urologist, University of Michigan Medical School, Ann Arbor, MI, USA. Nesbit was a pioneer of transurethral resection of the prostate.

Summary box 85.8

Peyronie's disease

- The disease has two phases: an initial active phase and a later stable phase
- There is no effective treatment in the active phase
- Surgery may be indicated in the chronic phase to correct deformity that interferes with sexual activity

Congenital curvature of the penis

This penile deformity is similar and analogous to Peyronie's disease and is occasionally seen in young men (***Figure 85.22***). In congenital curvature of the penis, the urethral length is normal and it typically results in a ventral deformity of the erect penis. If the deformity interferes with sexual activity, then surgery, usually a Nesbit procedure, will straighten the erect penis.

Priapism

Priapism means a persistent erection lasting longer than 4 hours; it is a surgical emergency. There are two main types of priapism: ischaemic and non-ischaemic.

Ischaemic priapism

Ischaemic or veno-occlusive priapism is the more common. It is due to venous congestion, with consequent thrombosis and ischaemia. The penis remains erect and becomes painful. This is a pathological erection and the glans penis and corpus spongiosum are not involved. The condition is most commonly seen as a side effect of medication, most notably antipsychotic medication and intracavernosal injections. It can also arise as a complication of hypercoagulable blood disorders such as sickle cell disease or leukaemia. A small proportion of cases are caused by malignant disease in the corpora cavernosa or the pelvis.

Blood taken from the penis shows hypoxia, hypercapnia and acidosis, while Doppler scanning shows an absence of blood flow within the penis.

An underlying cause should be excluded and the patient should be referred for specialist urological care. The condition is an emergency since delay beyond 6 hours results in progressive, irreversible damage to the corpora cavernosa tissue with subsequent fibrosis and ED. Aspiration of the sludged blood in the corpora cavernosa is the first-line therapy; if this fails, intracavernosal injection of phenylephrine (an α-adrenoceptor agonist) is the next line of therapy. If that proves ineffective, it may be necessary to decompress the penis by creating a shunt between the corpus cavernosum and either the glans penis or the corpus spongiosum. Treatment initiated after 24–36 hours rarely restores normal erectile function. Recurrent ischaemic (stuttering) priapism is seen in sickle cell disease.

Non-ischaemic priapism

This rarer form of priapism arises as a consequence of traumatic damage to the central penile artery, usually as a consequence of blunt perineal trauma. A fistula develops between the artery and the sinusoidal space, which results in a persistent erection that is painless, in contrast to ischaemic priapism. This is a high-flow priapism. Blood gas analysis shows the characteristics of arterial blood and Doppler scanning and selective arteriography will demonstrate the fistula. Treatment involves androgen ablation therapy. If medical therapy fails, selective arterial embolisation is performed.

Figure 85.22 Congenital curvature of the penis.

Summary box 85.9

Ischaemic priapism

- The characteristic clinical features are a painful erection not involving the glans penis
- Blood gas analysis from the penis shows hypoxia, hypercapnia and acidosis
- Detumescence should be ideally achieved within 6 hours to avoid long-term ED

CARCINOMA OF THE PENIS

Aetiology

Circumcision soon after birth confers immunity against carcinoma of the penis. Later circumcision does not seem to have the same benefit, with the assumption that smegma is in some way carcinogenic. Infection with HPV types 16 and 18 is a risk factor, as are LS (***Figure 85.23***) and smoking. Phimosis and chronic balanoposthitis are known to be contributory factors and there are definite *precancerous* states including leukoplakia of the glans, which is similar to the condition seen on the tongue, and penile intraepithelial neoplasia (PeIN).

Figure 85.23 Early penile cancer seen in a patient with lichen sclerosus.

Investigations

A biopsy should be performed. MRI is performed for local staging. Assessment of locoregional lymph node status is essential.

Penile intraepithelial neoplasia (carcinoma *in situ* of the penis, Bowen's disease, erythroplasia of Queyrat)

PeIN is typically seen as a red cutaneous patch on the penis. When it occurs on the glans penis, it is known as erythroplasia of Queyrat; when it occurs on the shaft of the penis, it is called Bowen's disease. There are several other benign causes of red patches on the penis; when there is clinical doubt as to the underlying diagnosis a biopsy is indicated. When the diagnosis of carcinoma *in situ* is confirmed, treatment is by means of topical 5-fluorouracil cream, CO_2 laser ablation or surgical excision.

Figure 85.24 A squamous cell cancer of the penis.

Pathology

Carcinoma of the penis is most typically a squamous cell carcinoma arising in the skin of the glans penis or the prepuce. It may be flat and infiltrating or warty in appearance. The former often starts as leukoplakia or PeIN; the latter results from an existing papilloma. Local growth continues for months or years. T1 tumours are confined to the skin, with T2 tumours invading the corpus spongiosum or the corpus cavernosum. T3 tumours invade the urethra and T4 tumours invade adjacent structures. The earliest lymphatic spread is to the inguinal nodes (N1 and N2 disease) and then to the iliac nodes (N3 disease). Distant metastatic deposits are infrequent.

Clinical features

Many patients present late as a fungating/ulcerative growth (***Figure 85.24***), either because of embarrassment or because of misdiagnosis. About 10% of patients are under 40 years of age. By the time the patient presents, the growth is often large and secondary infection causes a foul, bloody discharge. There is typically little or no pain.

Around 50% have inguinal lymph node enlargement at presentation but the nodal enlargement often reflects infection. In many, the prepuce is non-retractile and must be split to view the lesion. A biopsy should be performed to make the diagnosis. Untreated, the whole glans may be replaced by a fungating offensive mass. Later, the inguinal nodes can erode the skin of the groin and, in rare cases, death of the patient can result from erosion of the femoral or external iliac vessels.

Treatment

Management is divided into treatment of the primary tumour and treatment of the inguinal nodes. Patients with small lesions

John Templeton Bowen, 1857–1940, American dermatologist, described this condition in 1912.
Louis Auguste Queyrat, 1856–1933, French dermatologist, described this condition in 1911.

of low grade and low stage are treated with organ-preserving surgery, such as limited excision, Mohs' surgery or laser ablation. Mohs' micrographic surgery is based on sequential tissue excision under repeat microscopic control. This helps in accurately identifying the tumour margin and maximally preserves the uninvolved tissues. For most primary tumours surgical excision is the mainstay of treatment, with the traditional view that a 2-cm margin of normal tissue be removed being superseded by a more recent, more conservative view, such that penis-preserving surgery with excision of much lower margins of normal tissue is now accepted. Tumours affecting the glans penis require glansectomy, with more advanced tumours requiring partial penectomy. In advanced cases, total penectomy is required with the formation of a perineal urethrostomy. These techniques are indicated even in advanced metastatic disease for reasons of local control.

Treatment of any associated enlarged inguinal lymph nodes should be delayed until at least 3 weeks after local treatment of the primary lesion. Enlargement caused by infection will usually show signs of subsiding with antibiotic treatment. For palpable nodes, ultrasound-guided fine-needle aspiration will confirm the diagnosis and a block dissection of both groins should be undertaken. The management of patients where the nodes are not palpable involves the use of sentinel lymph node biopsy (SLNB) followed by inguinal node dissection if the SLNB is positive.

Management of the pelvic nodes is controversial. When they are involved on CT scanning, surgery probably has little role; however, when the iliac nodes are not enlarged in the presence of N2 disease, the options are observation, pelvic lymphadenectomy or radiotherapy. Chemotherapy is relatively ineffective and currently is reserved for palliation in those with metastatic disease. The prognosis for tumours confined to the penis is good with 5-year survival rates in excess of 80%. With nodal involvement the 5-year survival rate falls to around 40%.

Summary box 85.10

Carcinoma of the penis

- Enlargement of superficial inguinal lymph nodes may be caused by infection or metastatic spread
- Surgery is the mainstay of treatment
- Nodal involvement indicates a poor prognosis

Buschke–Löwenstein tumour

The Buschke–Löwenstein tumour is uncommon. It has the histological pattern of a verrucous carcinoma. It is locally destructive and invasive but appears not to spread to lymph nodes or to metastasise. Treatment is by surgical excision.

Figure 85.25 Fournier's gangrene.

Malignant melanoma of the penis

This is an uncommon tumour with the principles of management being the same as for squamous cell carcinoma. Bloodborne metastatic disease is, however, more common.

INFECTION AND INFLAMMATION OF THE PENIS AND URETHRA

Fournier's gangrene

This is progressive infection of the genitalia and perineum (***Figure 85.25***). It is usually caused by mixed bacterial flora (*Escherichia coli*, *Bacteroides* spp., *Streptococcus pyogenes*, *Staphylococcus aureus*). It may be associated with diabetes, cancer, malnutrition, recent urogenital or colorectal instrumentation or trauma. The hallmark is rapid progression from symptoms and signs of cellulitis. There is erythema, swelling, pain and blister formation with ultimately foul-smelling necrotic lesions. It is a surgical emergency. Progression from genitalia to perineum to

Frederic E Mohs, 1910–2002, twentieth century American physician and general surgeon, University of Wisconsin, Madison, WI, USA, developed the Mohs' micrographic surgical technique in 1938 for cutaneous malignant lesions.
Abraham Buschke, 1868–1943, dermatologist, Berlin, Germany.
Ludwig Löwenstein, 1885–1959, dermatologist, Berlin, Germany.
Jean Alfred Fournier, 1832–1915, French syphilologist and founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

abdominal wall occurs extremely rapidly. There is an increased risk of bacterial septicaemia. It will lead to death if untreated.

Treatment involves a combination of broad-spectrum antibiotics and extensive surgical debridement.

Urethral discharge

The commonest cause of urethral discharge in men is urethritis; the two commonest causes of urethritis are non-specific urethritis (NSU) and gonococcal urethritis. Other related symptoms include dysuria and urethral pruritus while epididymitis can also be present. A sexual history should be sought, particularly a history of unprotected intercourse, oral sex and anal intercourse. A routine investigative screen includes a Gram stain of the discharge, dipstick testing and culture of a urine specimen as well as nucleic acid amplification testing (NAAT) of either a urine specimen or a urethral swab. If relevant, the same techniques can be used for vaginal, endocervical, anal and pharyngeal swabs. NAAT is a sensitive way of identifying both gonococcal and chlamydial urethritis. As with all sexually transmitted infections (STIs) the possibility of other infections (such as HIV) should always be borne in mind and, where appropriate, tested for.

Non-specific urethritis (synonym: non-gonococcal urethritis)

NSU is an STI that is the commonest cause of urethritis in the western world. In around 40% of cases it is due to *Chlamydia trachomatis*, with other cases being caused by *Ureaplasma urealyticum*, *Trichomonas vaginalis* or *Mycoplasma genitalium*. The causative agent in up to 50% of cases is unknown.

NSU can affect both men and women and asymptomatic infection is common in both. In men, dysuria and a white mucopurulent urethral discharge appear up to 6 weeks after sexual intercourse. Dysuria is usual. The urine appears to be clear but may contain 'threads' or pus cells. Epididymitis is common and urethral stricture is a potential late complication. In women, the condition is usually asymptomatic, although it can present as vaginal discharge or as a form of urethrotrigonitis. It may result in cervicitis or pelvic inflammatory disease.

Exclusion of gonorrhoeal infection is important. The diagnostic test of choice is NAAT: in men either a first-catch urine specimen or a urethral swab can be used; in women urine, endocervical or vaginal swabs can be used. If testing is positive, then partners should be screened.

The standard treatment regimens are azithromycin as a single dose (1 g) or doxycycline (100 mg orally twice daily) for 7 days. Treatment is usually effective, although relapse is common, especially in men, in whom the prostate may act as a reservoir of infection. It is important to treat both partners as reinfection is probable if this is not done; retesting of both partners at 3 months is recommended.

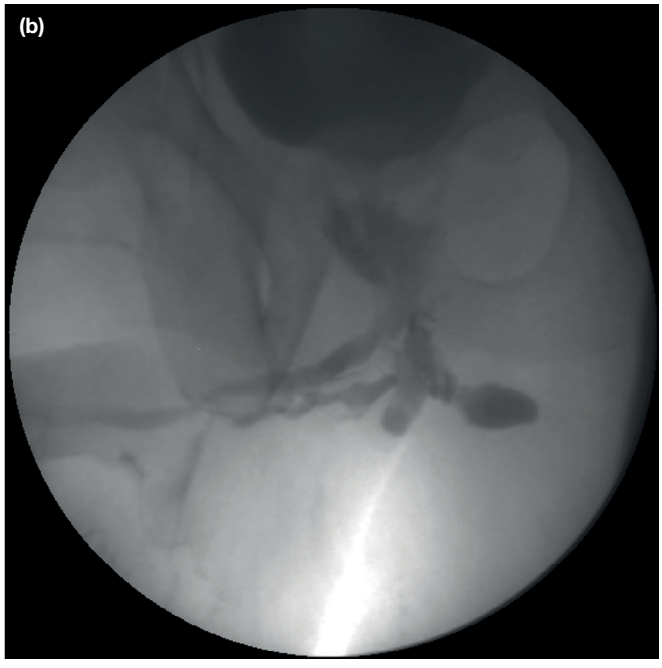
Gonorrhoeal urethritis

Gonorrhoea is a sexually transmitted disease caused by *Neisseria gonorrhoeae* (gonococcus), a Gram-negative kidney-shaped diplococcus that infects the anterior urethra in men, the urethra and cervix in women and the oropharynx, rectum and anal canal in both sexes, but especially men. It is transmitted by unprotected sexual intercourse and is the second commonest cause of urethritis in western countries.

Most men have symptoms of urethral discomfort and urethral discharge within a few days of infection. There is often scalding dysuria. In women it is often asymptomatic. There can be mild dysuria or slight urethral discharge, which can go unnoticed by the patient. Cervicitis can occur with about 10% suffering from pelvic inflammatory disease (salpingitis), which, if bilateral, may lead to infertility. A mother may transmit gonorrhoea to her newborn during childbirth, with the risk that blindness of the child can result. In addition, in both men and women exposed orally or anally, gonococcal infections can cause a predominantly asymptomatic pharyngitis or proctitis.

Traditionally, the diagnosis was made by identification of pus and gonococci in a Gram-stained urethral smear with subsequent culture. However, more recently, NAAT, which is more sensitive, has become the norm.

Complications are prevented by effective early treatment. In men complications include posterior urethritis, prostatitis (acute or chronic), acute epididymo-orchitis, periurethral abscess and urethral stricture. Gonococcal arthritis, iridocyclitis, septicaemia and endocarditis are unusual.



Treatment is with antibiotics. Ceftriaxone (250 mg intramuscularly) and azithromycin (1 g orally) are currently the treatment of choice. There is increasing antibiotic resistance to more traditional antibiotics such as ciprofloxacin or penicillin. Contact tracing is important in controlling the spread of the disease and management is usually by a genitourinary physician. Failure to respond to first-line treatment should raise the possibility of antibiotic resistance or co-infection with *Chlamydia*.

Reiter's disease (synonym: sexually acquired reactive arthritis)

Reiter's disease is an autoimmune disease characterised by the triad of urethritis, conjunctivitis and polyarthritis. Common triggers include chlamydial urethritis, less commonly gonococcal urethritis and diarrhoea secondary to *Salmonella*, *Shigella* or *Campylobacter*. It is an HLA-B27-associated condition. The conjunctivitis (present in around 50%) and arthritis typically occur 1–3 weeks after the primary infection. Diagnosis is made on clinical grounds and treatment is largely symptomatic, although antibiotic treatment of the precipitating infection is important. The urethritis and conjunctivitis frequently subside

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.
Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wrocław, Poland).
Hans Conrad Julius Reiter, 1881–1969, President of the Health Service and Honorary Professor of Hygiene, Berlin, Germany, described this condition in 1916. He was subsequently convicted of war crimes as a consequence of his involvement in the death of hundreds of inmates in Buchenwald.
Daniel Elmer Salmon, 1850–1914, veterinary pathologist, Chief of the Bureau of Animal Industry, Washington, DC, USA.

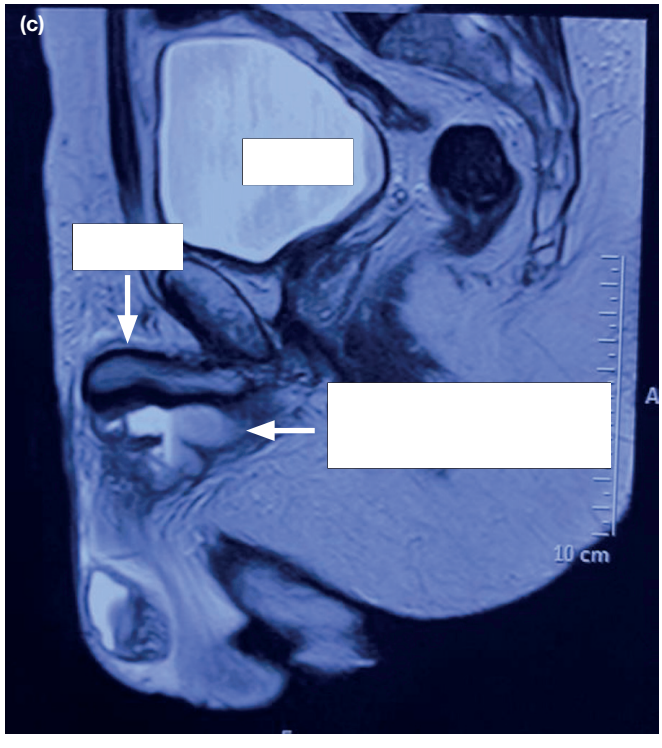


Figure 85.26 (a) Periurethral abscess with pinpointing at the penoscrotal junction. **(b)** Retrograde urethrogram of a periurethral abscess. **(c)** Magnetic resonance imaging (MRI) in a patient with a periurethral abscess.

after a few weeks, but the arthritis may persist for months. Severe anterior uveitis and frequently recurrent attacks suggest a poor outlook.

Periurethral abscess

Periurethral abscesses were once common with high morbidity but are now rare. Clinical presentation is varied but may include fever, dysuria, urethral discharge and swelling of the penis or scrotum. In untreated cases urethral fistulation and occasionally extensive cellulitis or necrotising fasciitis can occur.

A penile periurethral abscess arises following a gonococcal or chlamydial infection of one of the glands of Littre. There can be a coexisting urethral stricture. There is usually penile swelling with tender induration felt on the underside of the penis, which, if left untreated, may discharge externally, often leaving a fistula. Diagnosis can be helped by ultrasound of the urethra. Treatment should include both antibiotic treatment, as for urethritis, and surgical drainage into the urethra.

A periurethral abscess in relation to the bulbar urethra is even more uncommon. It may be associated with a urethral stricture, urethral trauma or, rarely, a urethral cancer. The infecting organisms are varied and can include both streptococci and anaerobic organisms. Extravasation of urine is not unusual. There is perineal pain with pyrexia, rigors and tachycardia. Tenderness and swelling rapidly spread from the perineum to the penis and the anterior abdominal wall. Ultrasound scanning and MRI are useful diagnostic aids and treatment with antibiotics is essential. Collections of pus should be drained and the urine should be diverted by a suprapubic urinary catheter.

A chronic periurethral abscess sometimes results from a longstanding urethral stricture (***Figure 85.26***). The multiple loculi of pus should be drained and the stricture treated. Urethral fistula occurs either spontaneously or as a result of incision of the abscess.

Alexis Littre, 1658–1726, surgeon and lecturer in anatomy, Paris, France.

Genital ulcers

The commonest cause of a genital ulcer is genital herpes. Other less common causes include syphilis and chancroid. As with all STIs, the possibility of other infections (such as HIV) should always be borne in mind and, where appropriate, tested for.

Genital herpes

Genital herpes is caused by sexual transmission of the herpes simplex virus (usually HSV-2, occasionally HSV-1). Infection is lifelong with recurrent symptomatic attacks occurring in 50% or more of cases. Pain along the distribution of the sensory nerve, usually the genitofemoral nerve, precedes the eruption by 2 days and may be particularly severe around the anus. A group of tiny vesicles rapidly erodes to form shallow ulcers, which are painful (***Figure 85.27a***). The first attack occurs around 4 days after exposure and is typically accompanied by fever, myalgia and inguinal lymphadenopathy. In female patients, the ulcers often spread onto the thighs during the attack. Involvement of the urethra may cause retention of urine, which may persist for up to 14 days if there is radiculitis of the S2 and S3 nerve roots.

Diagnosis is made clinically or, when there is doubt, by either cell culture or polymerase chain reaction (PCR)-based techniques. All primary infections should be treated by oral antiviral agents such as aciclovir (400 mg three times a day for 7–10 days), valaciclovir (1 g orally twice a day for 7–10 days) or famciclovir (250 mg three times a day for 7–10 days).

A child born to a mother with active infection is susceptible to a fatal generalised herpes infection in the neonatal period. Caesarean section should be considered in these circumstances. There is an increased risk of carcinoma of the cervix and annual cytology for life is recommended.

Syphilis

Syphilitic ulcers are typically painless, rubbery and indurated. Caused by the spirochaete *Treponema pallidum*, diagnosis was traditionally achieved by dark-field microscopy, but modern serological techniques are nowadays more appropriate. The incidence of syphilis is increasing since the advent of the retroviral drugs used to treat HIV in the mid-1990s. Treatment is with long-acting penicillin.

Tropical sexually transmitted infections

Lymphogranuloma venereum

Lymphogranuloma venereum is a sexually transmitted disease caused by *C. trachomatis* (chlamydia A) types L1–L3 and is primarily an infection of the lymphatics and lymph nodes. It can affect both sexes. While it was considered rare in resource-rich countries, some recent outbreaks in Europe have occurred, usually in conjunction with HIV.

The primary lesion is a fleeting, painless, genital papule or ulcer that develops 1–4 weeks after infection and is often unnoticed by the patient. The inguinal glands become enlarged and painful around 2–6 weeks after the primary lesion. The masses

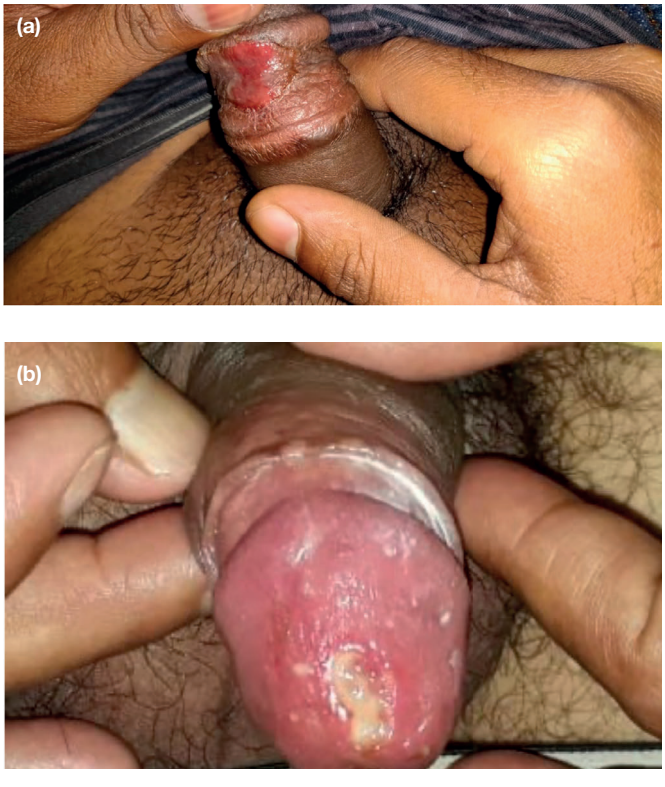

Figure 85.27 (a) Genital herpes. **(b)** Ulcer seen in chancroid. **(c)** Genital warts affecting the prepuce and glans (courtesy of Dr Narendra Patwardhan, dermatologist, Pune, India).

of nodes mat together above and below the inguinal ligament to give the 'sign of the groove'. The overlying skin reddens, there may be fluctuance and the mass occasionally ruptures. There may be a proctitis, which can go on to produce a rectal stricture if untreated. Lymphatic obstruction leads to lymphoedema in the perineum and, occasionally, the lower limbs. Urethritis and urethral stricture occur in men.

Diagnosis is confirmed clinically and by the detection of antibodies against the organism. Culture, direct immunofluorescence and NAAT can be performed. Treatment is by a combination of antibiotics, which may include doxycycline, azithromycin, erythromycin and ciprofloxacin. The multilocular lymphatic masses should not be incised, although aspiration is permissible to reduce discomfort.

Lymphogranuloma inguinale

This is a chronic and slowly progressive ulcerative tropical disease affecting the genitals and surrounding tissue, but occasionally occurring elsewhere in the body. It is usually sexually transmitted and is caused by *Klebsiella granulomatis*; it is most commonly seen among socially deprived people. The incubation period varies greatly but is typically between 7 and 30 days.

A painless vesicle or indurated papule, usually on the external genitals but occasionally elsewhere on the skin, gradually erodes into a slowly extending ulcer with a beefy-red, granulomatous base. More chronic lesions may become greyish, especially at the edges, where, after months or years, malignant change may develop. The ulcerated area may bleed if touched but is usually surprisingly painless. Without treatment healing is only partial and keloid is common.

Diagnosis is by microscopy of material from the edges of the ulcer, which shows the presence of short Gram-negative rods within the cytoplasm of the large mononuclear cells. Treatment is with azithromycin, although doxycycline, erythromycin, trimethoprim–sulfamethoxazole and gentamicin are alternatives.

Chancroid

Chancroid is a sexually transmitted, acute, ulcerative disease caused by *Haemophilus ducreyi*, a Gram-negative facultative anaerobe. Following an incubation period of 3–10 days, a soft painful penile ulcer (***Figure 85.27b***) appears and is commonly followed by the development of inguinal lymphadenopathy. Diagnosis is by bacterial culture or PCR techniques. Antibiotic treatment with ceftriaxone or azithromycin is usually effective therapy.

Condylomata acuminata (synonym: genital warts)

Genital warts are caused by infection with HPV and are sexually transmitted. Infection is very common, with only a small proportion of infected patients actually having visible warts.

Most commonly due to HPV types 6 and 11, these viruses do not cause cervical cancer. Ordinary skin warts can occur on the genitals by direct contact with a finger lesion, but they are less moist and soft and less often pedunculated than the genital variety. The lesions most commonly occur under the prepuce in the coronal sulcus but may be found elsewhere, including inside the urinary meatus and on the outer prepuce (***Figure 85.27c***). In women, genital warts are most commonly found on the vulva, but they may line the vagina and occur on the cervix. Perianal warts are common.

Other associated sexually transmitted diseases should be excluded: in women mainly candidiasis and *Trichomonas* infection and in men syphilis or gonorrhoea. Genital warts may complicate HIV infection.

Treatment is by chemical or physical means. Podophyllin is often effective as a topical application. It is applied to the wart, taking great care to avoid the surrounding skin, and washed off after 6 hours or so. An alternative agent is imiquimod. If chemical methods fail, the warts can be excised or they can be ablated with cryosurgery, electrosurgery or laser. Circumcision is sometimes advised if there are florid lesions under the foreskin.

CHAPTER 86

The testis and scrotum

Learning objectives

To diagnose and manage:

- Testicular maldescent
- Testicular torsion
- Common scrotal swellings (varicocele, hydrocele and epididymal cysts)
- Testicular and scrotal infections
- Testicular tumours
- Male factor infertility
- Testicular trauma

INCOMPLETE DESCENT OF THE TESTIS

Definition

Incomplete descent of the testis, also known as cryptorchidism, occurs when one or both testes are arrested at some point in the normal path to the scrotum. An ectopic testis is a testis that is abnormally placed outside this path (*Figure 86.1*).

Incidence

About 3% of full-term and 30% of premature male infants are born with one or both testes undescended. About two-thirds of these reach the scrotum during the first 3 months of life, but full descent after that is uncommon. The incidence of testicular maldescent at the age of 1 year is around 1%. The condition is sometimes missed in the neonatal period and only discovered later in life. The presence of a hernia, testicular pain or acute torsion may direct attention to the abnormality. Cryptorchidism occurs in approximately 1.5–4% of fathers and 6% of brothers of individuals with cryptorchidism.

Pathology

The condition is more common on the right and is bilateral in 20% of cases. In adults, secondary sexual characteristics are typically normal.

The testis may be:

- intra-abdominal; usually extraperitoneal just inside the internal inguinal ring;
- within the inguinal canal; it may not be palpable (*Figure 86.2*);
- extracanalicular; usually at the scrotal neck (high scrotal);

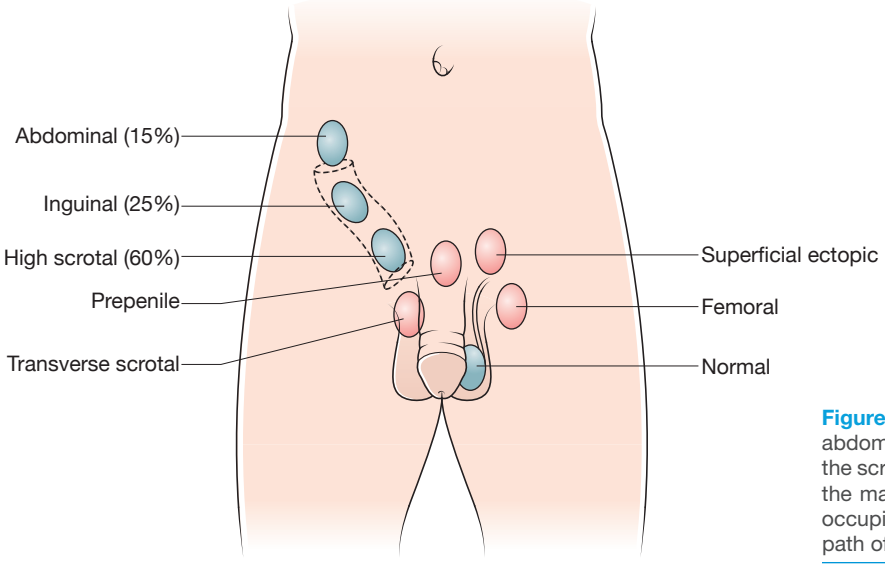

Figure 86.1 The path of descent of the testis from the abdomen (retroperitoneal) down the inguinal canal to the scrotum. Descent can be arrested at any stage with the majority in the high scrotal area. Rarely, the testis occupies a more ectopic position outside the normal path of descent (courtesy of Dr Mohan Gundeti).

Figure 86.2 Undescended testes in a boy aged 12 years. Note the bilateral undescended testes with the underdeveloped scrotum. In cases of retractile testis, the scrotum is relatively well developed.

- ectopic; an ectopic testis is one that has ended up away from the normal path of descent. The commonest site is the superficial inguinal pouch, just inferior and medial to the superficial inguinal ring. Other rarer ectopic sites include the femoral triangle, root of the penis and perineum.

Incompletely descended testes are often macroscopically normal in early childhood, but by puberty the testis is typically smaller than its intrascrotal counterpart. Microscopic changes are apparent from 1–2 years, including loss of Leydig cells, degeneration of Sertoli cells and decreased spermatogenesis. The higher the testis, the greater the degree of histological change.

Consequences

Infertility

Men with undescended testes may have reduced fertility, even after orchidopexy.

- The infertility rate for unilateral cases is not believed to be very different from the general population.
- The fertility reduction after orchidopexy for bilateral cryptorchidism is about 38%.
- Patients with bilateral undescended testes who receive orchidopexies as adults are almost always infertile and azoospermic; but there are reports of pregnancies achieved through sperm retrieval and assisted reproduction in this group.
- The recommendation for early surgery is due to degeneration of spermatogenic tissue and reduced spermatogonia counts after the second year of life in patients with untreated undescended testes.

Malignancy

Overall, the risk of testicular cancer if orchidopexy is done before puberty is around two to three times that of the general population. It is five to six times higher when orchidopexy is done after puberty. The risk of cancer does not seem to be different when orchidopexy is done early in infancy compared with later in childhood.

- The most common type of testicular cancer in untreated undescended testes is seminoma.
- The peak age range for this tumour is 15–45 years.
- In contrast, after orchidopexy, seminomas represent only 30% of testicular tumours in previously undescended testes.
- It is treatable if caught early, so boys who had an orchidopexy as infants should be taught testicular self-examination.

Hernia

Around 90% of boys with an undescended testis have a patent processus vaginalis although the incidence of a clinically apparent hernia is much lower.

Testicular torsion

The undescended testis is more prone to testicular torsion, largely as a consequence of a developmental abnormality between the testis and its mesentery.

Summary box 86.1

Undescended testis

- Testes that are absent from the scrotum after 3 months of age are unlikely to descend
- Histological changes in the testis can be seen from 1 year of age
- An incompletely descended testis tends to atrophy as puberty approaches
- Boys with undescended testes are at greater risk of infertility, testicular malignancy, hernia and torsion

Clinical features

When assessing a child with suspected testicular maldescent, it is helpful to have the boy as relaxed as possible in a warm room, usually in a supine position. The important differential diagnosis is the so-called 'retractile testis'. During childhood the testes are mobile and the cremasteric reflex is active, so that, in some boys, any stimulation of the skin of the scrotum or thigh causes the testis to ascend and to temporarily disappear into the inguinal canal. When the cremaster relaxes, the testis reappears only to vanish when the scrotal skin is touched again.

In comparison with a true undescended testis, the scrotum in the retractile testis is normal as opposed to underdeveloped, and the retractile testis can be gently milked from its position in the inguinal region to the bottom of the scrotum. A diagnosis of true incomplete descent should be made only if this is not possible. For retractile testes, a yearly physical examination is recommended because of the 2–50% reported risk of a retractile testis becoming an acquired undescended testis.

More than 70% of cryptorchid testes are palpable by physical examination. In the remaining 30% of cases with a non-palpable testis, the challenge is to confirm the absence or presence of the testis and to identify the location of the viable non-palpable testis. Ultrasound has a high positive predictive value for inguinal located testes, but only 45% sensitivity in

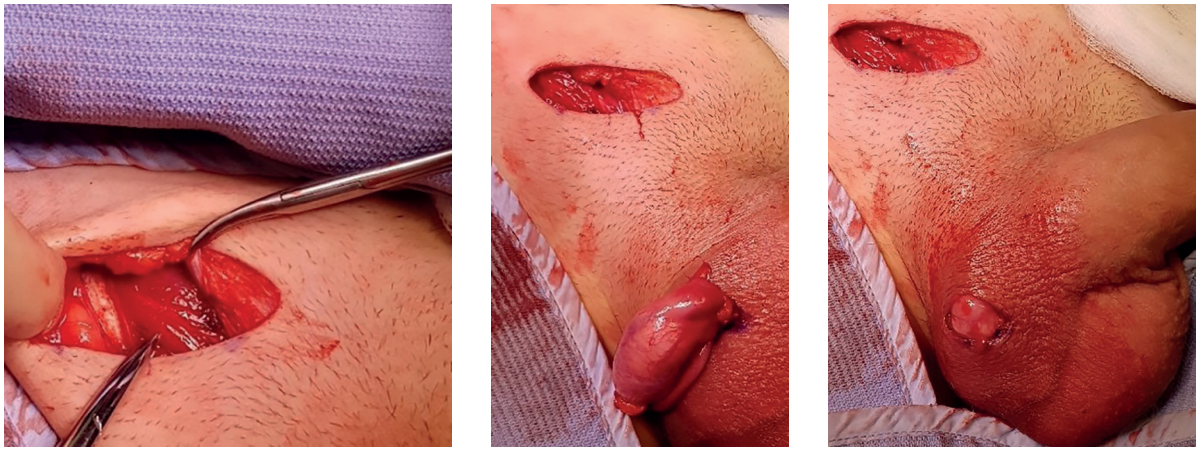

Figure 86.3 Adult undescended testis. The undescended inguinal testis is mobilised and retained in a pouch constructed between the dartos muscle and skin (courtesy of the author and Dr Mohamed Abdellatif).

localising all non-palpable testes. The cost and ionising radiation exposure associated with computed tomography (CT) scanning preclude its use. Magnetic resonance imaging (MRI) has been more widely used with greater sensitivity and specificity but has cost and availability issues, and may require anaesthesia in the paediatric population. At this time, there is no radiological test that can conclude with 100% accuracy that a testis is absent. Instead, laparoscopy has become the gold standard diagnostic method for a non-palpable testis. In addition, laparoscopy provides an option for treatment of this condition.

Summary box 86.2

Retractile testis

- Retractile testes should be differentiated from true undescended testes
- This is most easily done with the child relaxed in a warm room
- Retractile testes are more common than true undescended testes
- Retractile testes require no treatment but should be monitored

Medical treatment

There is little evidence currently for hormonal therapy to induce testicular descent, with low response rates (equivalent to placebo) and a lack of long-term efficacy.

Surgical treatment

Orchidopexy

Orchidopexy is usually performed between 6 and 18 months of age in an attempt to prevent the consequences described earlier. For premature babies, corrected age is used to determine surgery timing. The testis and spermatic cord are mobilised and the testis is repositioned in the scrotum. The operation is performed through a short incision over the deep inguinal ring. The inguinal canal is exposed by division of the external oblique aponeurosis in the direction of its fibres.

Three manoeuvres help to gain the length required to bring the testis down into the bottom of the scrotum. First, the patent processus vaginalis should be identified, separated and ligated. Second, the coverings of the spermatic cord (including the cremasteric muscle) should be divided and, third, lateral fibrous bands just inside the internal inguinal ring should be divided. Although these techniques are usually effective, the tiny vas and testicular vessels are vulnerable to injury. The empty hemiscrotum is stretched with a finger passed into it through the inguinal incision to give enough room for the testis, which is placed in a pouch constructed between the dartos muscle and the skin (***Figure 86.3***).

Orchidectomy should be considered if the incompletely descended testis is atrophic and/or there is a suspicion of malignancy, particularly in the postpubertal boy if the other testis is normal.

Impalpable testis

For non-palpable testes under anaesthesia, diagnostic laparoscopy is recommended. If a testis is found during laparoscopy, the options are:

1. Laparoscopic orchidopexy preserving the vessels: the testis is dissected off a triangular pedicle containing the testicular vessels and the vas.
2. Laparoscopic one-stage Fowler–Stephens orchidopexy: vessels are divided and the testis is dissected off a pedicle of the vas and brought down in one stage.
3. Laparoscopic two-stage Fowler–Stephens orchidopexy: vessels are divided with clips but dissection of the testis is postponed for 6 months to allow for optimal development of collaterals.

Robert Fowler Jr, b. 1928, paediatric surgeon, Royal Children's Hospital, Melbourne, Australia.
Frank Douglas Stephens, 1913–2011, paediatric surgeon, Royal Children's Hospital, Melbourne, Australia, published a landmark paper with Robert Fowler in 1959 that described the surgical management of high undescended testes by dividing the testicular vessels high from the testis to maintain a collateral blood supply.

If no testis is found during exploratory laparoscopy, one has to determine the presence of either blind-ending vessels or a testicular nubbin to completely rule out a missing testis. The vas can be dissociated from the testis and thus is not always a good guide to find the gonad.

If the internal ring is closed but vessels are going into it, a scrotal exploration usually will find a testicular nubbin. If vessels are going into an open inguinal ring, one can usually push the testis into the abdomen; if not, an inguinal or scrotal exploration would be warranted.

Absent testis

'Vanishing' testis describes a condition in which a testis develops but disappears before birth. The most likely cause for this is prenatal torsion. True agenesis of the testis is rarer. Laparoscopy is useful in distinguishing these causes of clinically absent testis from intra-abdominal maldescent.

TORSION OF THE TESTIS

Definition

Testicular torsion is the twisting of the spermatic cord and its contents such that the testicular blood supply becomes compromised. If left untreated the blood flow to the testicle ceases and the testicle dies. Testicular torsion is therefore a surgical emergency and the earlier the surgery to untwist the testis can be undertaken the better the outcome.

Incidence

Testicular torsion affects 3.8 per 100 000 males younger than 18 years annually. It accounts for 10–15% of acute scrotal disease in children.

Pathophysiology

Torsion of the testis is uncommon because the normal testis is anchored and cannot rotate. Extravaginal torsion is seen almost exclusively in neonates because of the increased mobility of the testicle before the descent into the scrotum when attached to the scrotal wall via the tunica vaginalis. Beyond this age, intravaginal torsion occurs as a result of a combination of:

- High investment of the tunica vaginalis, causing the testis to hang within the tunica like a clapper in a bell (***Figure 86.4***). This is the most common cause in adolescents and is typically a bilateral abnormality.
- Inversion of the testis: the testis is rotated so that it lies transversely or upside down.
- Separation of the epididymis from the body of the testis, permitting torsion of the testis on the pedicle that connects the testis with the epididymis (***Figure 86.4***).

Normally, when there is a contraction of the abdominal muscles, the cremaster contracts as well. In the presence of one of the abnormalities described above, the spiral attachment of the cremaster favours rotation of the testis around the vertical axis. Sudden contraction of the cremasteric muscle, which may be a response to mechanical, sexual or thermic stimulation, may cause a rotational effect on the testis as it is pulled upward. Accordingly, straining at stool, lifting of a heavy weight, sexual activity and sport can all precipitate an episode.

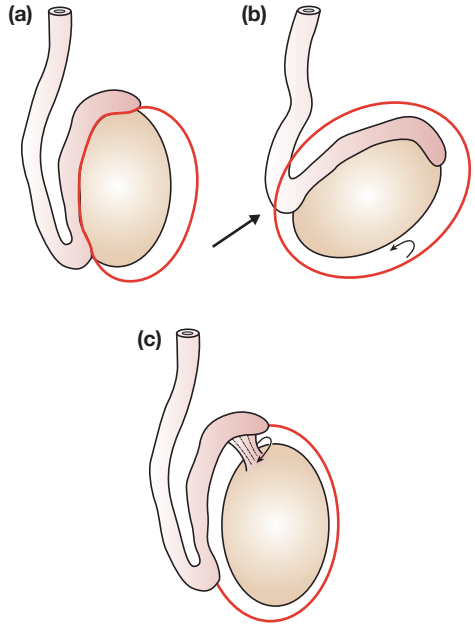

Figure 86.4 Testicular torsion. **(a)** Normal attachment. **(b)** An abnormally high attachment (arrow) of the tunica vaginalis predisposes to torsion – the 'bell-clapper'. **(c)** Separation of the testis from the epididymis – torsion about the pedicle between them.

The two main factors determining damage to the testis are the extent of the twist and the duration of the episode. Twists of 720° cause more rapid ischaemia than twists of 360° or less, and if the testis can be untwisted within 6 hours of the torsion taking place there is nearly a 100% chance of testicular salvage compared with a 20% salvage rate if the surgery is delayed for 24 hours.

Occasionally the testis untwists spontaneously without surgical treatment and 'intermittent' testicular torsion should be considered as a cause of testicular pain in adolescents.

Clinical features

Testicular torsion is most common between 10 and 25 years of age, although a few cases occur outside this age range. Typically there is sudden severe pain in the groin and the lower abdomen and the patient feels nauseated and may vomit. The scrotum is swollen and tender, while the skin is usually not erythematous initially (although it may become so with a prolonged history) and the patient is apyrexial. The testis itself is swollen and tender and seems high within the scrotum, while the tender twisted cord can often be palpated above it. The cremasteric reflex is lost.

Differential diagnosis

Skin redness and mild pyrexia may result in the condition being confused with epididymo-orchitis in the older patient; however,

Figure 86.5 Idiopathic oedema of the scrotum.

there will usually be dysuria associated with an accompanying urinary infection. Elevation of the testis reduces the pain in epididymo-orchitis but makes it worse in torsion.

Torsion of a testicular appendage cannot always be distinguished with certainty from testicular torsion. The most common structure to twist is the appendix of the testis (the hydatid of Morgagni), which is sometimes visible through the scrotal wall as a small dark spot. If the diagnosis is made clinically, conservative management is possible; if in doubt, surgical exploration should be undertaken with removal of the twisted appendage.

In mumps orchitis, the cord is not particularly thickened and the condition is often bilateral.

Idiopathic scrotal oedema is an oddity that occurs between the age of 4 and 12 years and must be differentiated from torsion. The scrotum is very swollen but there is little pain or tenderness. The swelling is usually bilateral and may extend into the perineum, groin and penis. It is thought to be an allergic phenomenon and occasionally there is eosinophilia. The swelling subsides after a day or so but may recur (***Figure 86.5***).

Very occasionally, torsion can be convincingly mimicked by a small tense strangulated inguinal hernia compressing the cord and causing compression of the pampiniform plexus.

Management

The management of the case should be determined primarily on clinical grounds. While Doppler ultrasound scanning (***Figure 86.6***) can confirm the absence of the blood supply to the affected testis, false-positive results can be seen so it is not routinely recommended. If there is any doubt as to the diagnosis, then urgent scrotal exploration is indicated. The typical window of opportunity for surgical intervention and testicular salvage is 6 hours from onset of pain. Therefore, early urological surgery consultation upon presentation may be critical even in the absence of confirmatory testing.

Exploration for torsion can be performed through a transverse or midline scrotal incision. If the testis is viable when the cord is untwisted, it should be prevented from twisting again by fixation with three non-absorbable sutures between the tunica albuginea of the testis and the scrotal raphe. The use of absorbable sutures risks the possibility of recurrent torsion at some time in the future. The other testis should also be fixed because the anatomical predisposition is likely to be bilateral. If there is clinical doubt as to testicular viability after detorsion of the testis, then it should be wrapped in a warm swab and observed over a few minutes. If a small incision in the tunica albuginea demonstrates bright red arterial bleeding then the testis may survive. An infarcted testis should be removed – the patient can be counselled later about a prosthetic replacement.

In cases where there is a history of pain for several days, the affected testis will be dead. It is not possible to recover such a testis and, although little is gained (other than pain relief) by immediate exploration, it is necessary to fix the contralateral testis.

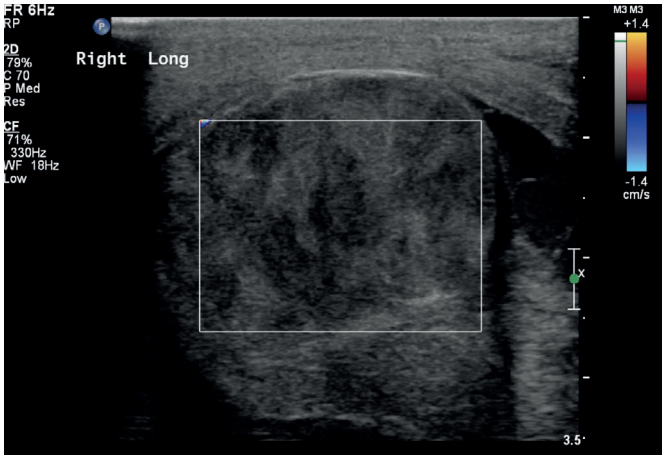

Figure 86.6 Doppler ultrasound scanning of a torted right testis showing the absence of blood flow and heterogeneous architecture indicating late necrosis (courtesy of Dr Davide Prezzi).

Summary box 86.3

Testicular torsion

- If the diagnosis of testicular torsion is possible, then surgical exploration is indicated
- Prompt exploration, untwisting and fixation is the only way to save the torted testis
- The patient should be counselled and consented for orchidectomy before exploration
- The anatomical abnormality is bilateral and the contralateral testis should also be fixed
- Non-absorbable sutures should be used for the fixation of each testis

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, University of Padua, Padua, Italy, is associated with a number of eponymous structures, including the aortic sinus, the appendix testis, the anal columns and the sternocostal triangles. He is regarded as the 'father of morbid anatomy'.
Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

VARICOCELE

Definition

A varicocele is an abnormal dilatation and enlargement of the scrotal venous plexus draining the testis.

Incidence

Varicoceles are common, affecting 10–20% of adult males. About 90% are left sided, reflecting the proximal venous anatomy – the left testicular vein empties into the relatively high-pressure left renal vein while the right empties into the low-pressure inferior vena cava below the right renal vein. If a left varicocele is identified, there is a 30–40% probability that it is a bilateral condition.

They are unusual in boys and typically develop during late childhood and adolescence. Varicoceles occur in around 15–20% of all males but are found in about 40% of infertile males.

Pathophysiology

The veins draining the testis and the epididymis form the pampiniform plexus. The veins gradually join each other as they traverse the inguinal canal and at, or near, the inguinal ring there are only one or two testicular veins, which pass upwards within the retroperitoneum. The left testicular vein empties into the left renal vein while the right empties into the inferior vena cava below the right renal vein. There is an alternative (collateral) venous return from the testes through the cremasteric veins, which drain mainly into the inferior epigastric veins.

There are three theories as to the cause of varicoceles:

1 The absence or failure of the antireflux valve usually located where the testicular vein joins the left renal vein or the inferior vena cava on the right. This causes reflux and retrograde flow in the testicular vein.
2 The 'nutcracker' effect that occurs when the left testicular vein gets trapped between the superior mesenteric artery and the aorta. This causes venous compression and testicular vein obstruction.
3 Angulation at the junction of the left testicular vein and the left renal vein.

In some cases, the dilated vessels are cremasteric veins and not part of the pampiniform plexus. While most varicoceles are idiopathic, obstruction of the testicular vein by a renal tumour or nephrectomy is a cause of varicocele in later life; characteristically, in such cases the varicocele does not decompress in the supine position. The presence of an isolated right-sided varicocele is extremely rare. Hence, imaging should be considered to exclude a retroperitoneal mass in such cases. Rarer causes include deep vein thrombosis, renal arteriovenous malformations and thrombosis of the pampiniform plexus.

Clinical features

While most varicoceles are asymptomatic, those that are symptomatic tend to present in adolescence or early adulthood, when there may be a dragging discomfort that is worse on standing at the end of the day. When examined in the erect position, the scrotum on the affected side often hangs lower than normal (***Figure 86.7a***); on palpation, with the patient standing, the varicose plexus feels like a bag of worms. There may be a cough impulse. If the patient lies down the veins empty by gravity and this provides an opportunity to ensure that the underlying testis is normal to palpation. In longstanding cases the affected testis is smaller and softer than the opposite side owing to atrophy.

Ultrasound can be helpful in the diagnosis of small varicoceles (***Figure 86.7b***), and in the less common right/bilateral varicoceles (and older men with an apparently recent onset of

varicocele), ultrasound of the kidneys is important in excluding a renal tumour.

The following classification of varicocele is useful in clinical practice:

- subclinical: not palpable or visible at rest or during a Valsalva manoeuvre, but can be shown by special tests (Doppler ultrasound studies);
- grade 1: palpable during Valsalva manoeuvre, but not otherwise;
- grade 2: palpable at rest, but not visible;
- grade 3: visible and palpable at rest.

Varicoceles and infertility

Varicoceles are present in 10–20% of adult men and in over 25% of men with abnormal semen analysis. The exact association between reduced male fertility and varicocele is unknown. The most accepted theory is that increased blood flow leads to higher intratesticular temperatures, which are the main cause of impaired sperm in varicoceles.

Large varicoceles may eventually cause testicular failure, ultimately resulting possibly in lower testosterone production, low sperm count and quality and testicular atrophy. Varicoceles can also decrease sperm nuclear DNA integrity, which has been linked to poor sperm motility, viability, counts and morphology.

A Cochrane review from 2012 concluded that there is some evidence to suggest that treatment of a varicocele in men from couples with otherwise unexplained subfertility may improve a couple's chance of spontaneous pregnancies. However, varicocele repair in men with a subclinical varicocele or normal semen parameters is considered ineffective for increasing the chances of spontaneous pregnancies. Varicocelectomy may also improve outcomes following assisted reproductive techniques in men with abnormal sperm parameters.

Treatment

Varicocele repair can be effective in men with a low sperm count, a clinical varicocele and otherwise unexplained infertility. However, treatment of varicocele in adolescents poses a risk of overtreatment: most boys with a varicocele will have no fertility problems later in life.

When the discomfort is significant, then percutaneous embolisation of the gonadal veins is the usual first-line intervention. If this is not possible, or if the varicocele recurs (as it does in around 20% after embolisation), surgical ligation of the testicular veins is the appropriate treatment, although recurrence can occur even after such surgery. Current evidence indicates that microsurgical varicocelectomy is the most effective method among the different surgical varicocelectomy techniques, with fewer complications and lower recurrence rates.

Summary box 86.4

Varicocele

- Varicocele is a common condition and 90% are left sided
- The presence of varicocele in some men is associated with progressive testicular damage from adolescence onwards and a consequent reduction in fertility
- Varicocele repair can be effective in men with a low sperm count, a clinical varicocele and otherwise unexplained infertility

HYDROCELE

Definition

A hydrocele is an abnormal collection of serous fluid in a part of the processus vaginalis, usually the tunica vaginalis around the testis and occasionally along the spermatic cord. Acquired hydroceles are primary or idiopathic, or secondary to epididymal or testicular disease.

Incidence

Hydroceles affect an estimated 1% of adult men. More than 80% of newborn boys have a patent processus vaginalis, but most close spontaneously within 18 months of age.

Pathophysiology

Embryologically, the processus vaginalis is a diverticulum of the peritoneal cavity. It descends with the testes into the scrotum via the inguinal canal around the 28th week of gestation with gradual closure through infancy and childhood.

Structurally, hydroceles are classified into three key types:

1. Communicating (congenital) hydrocele: a patent processus vaginalis permits flow of peritoneal fluid into the scrotum (tunica vaginalis); associated with indirect inguinal hernias (***Figure 86.8a***).
2. Non-communicating (vaginal) hydrocele: the processus vaginalis is closed with no communication with the peritoneal cavity. Instead, fluid accumulation can be due to excessive production and/or defective absorption by the tunica vaginalis, primarily because of disruption to the lymphatic drainage of scrotal structures (***Figure 86.8b***). If idiopathic, these are called 'primary' hydroceles.
3. The distal end of the processus vaginalis closes correctly, but the mid-portion of the processus remains patent. The proximal end may be open and communicating with the tunica vaginalis, resulting in an 'infantile' hydrocele' (***Figure 86.8c***), or closed, resulting in a hydrocele of the cord (***Figure 86.8d***).

Non-communicating primary hydroceles are the most common type of hydrocele globally. 'Secondary' hydroceles usually occur in men >40 years and may present acutely from local injury (including torsion), infection, neoplasm or radiotherapy. If a tumour is suspected, the hydrocele should not be punctured (risk of malignant needle-track implantation).

Antonio Maria Valsalva, 1666–1723, Italian physician and anatomist.

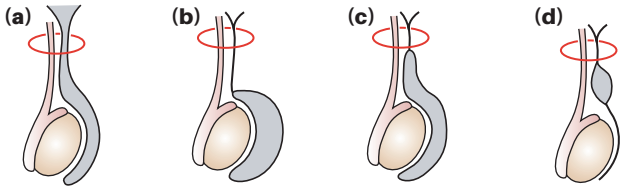

Figure 86.8 (a) Vaginal hydrocele (very common); **(b)** 'infantile' hydrocele; **(c)** congenital hydrocele; **(d)** hydrocele of the cord.

Clinical features

Examination of a scrotal swelling should be undertaken in both the upright and supine position. The examiner should ask:

1. Is it possible to get above the swelling to palpate a normal cord? If not the swelling may represent an inguinal hernia that has entered the scrotum.
2. Is the testicle or epididymis palpable or is the swelling enclosing both of those structures? A hydrocele encloses the testis and epididymis such that they may be impalpable, and it is possible to get 'above' it to palpate a normal spermatic cord.
3. Does the swelling transilluminate? Hydroceles are typically translucent.

In almost all cases of scrotal swelling an ultrasound is a useful adjunct to clarify the nature of the swelling and assess whether the testis itself is diseased.

A primary hydrocele (***Figure 86.9***) is seen most commonly in middle and later life, but can also occur in older children. Because the swelling is usually painless it may reach a significant size before the patient presents for treatment. Be wary of an acute hydrocele in a young man since there may be a testicular tumour.

In congenital hydrocele, the processus vaginalis – the communication with the peritoneal cavity – is usually too small to allow herniation of intra-abdominal contents. Pressure on the hydrocele does not always empty it but the hydrocele fluid may drain into the peritoneal cavity when the child is lying down; thus, the hydrocele may be intermittent. Ascites should be checked for if the swellings are bilateral.

A hydrocele of the cord is a smooth oval swelling that lies above the testis near the spermatic cord, which is liable to be mistaken for an inguinal hernia. The swelling moves downwards and becomes less mobile if the testis is pulled gently downwards. Hydrocele of the canal of Nuck is a similar condition in females. The cyst lies in relation to the round ligament and is always at least partially within the inguinal canal.

Treatment

Congenital hydroceles are treated by ligation of the patent processus vaginalis (herniotomy) if they do not resolve spontaneously.

Small hydroceles do not need treatment. If they are sizeable and bothersome for the patient, then surgical treatment is indicated. Established acquired hydroceles often have thick walls. There are three main surgical techniques for hydroceles:

1. **Plication**. Lord's operation is suitable when the sac is reasonably thin walled (***Figure 86.10***). There is minimal dissection and the risk of haematoma is reduced.
2. **Eversion**. The sac is opened and everted behind the testis, with placement of the testis in a pouch prepared by dissection in the fascial planes of the scrotum (Jaboulay's procedure) (***Figure 86.10***).

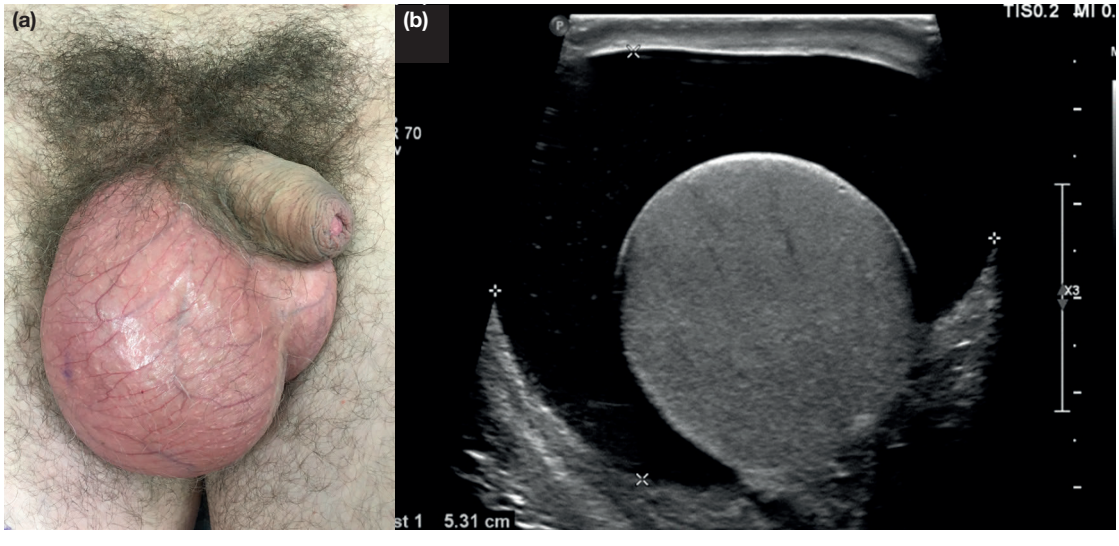

Figure 86.9 A right-sided hydrocele **(a)**. Ultrasound image **(b)** (courtesy of Dr Davide Prezzi).

Anton Nuck, 1650–1692, Professor of Anatomy and Medicine, Leiden, The Netherlands.
Peter Herent Lord, contemporary, formerly surgeon, Wycombe General Hospital, High Wycombe, UK.
Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.

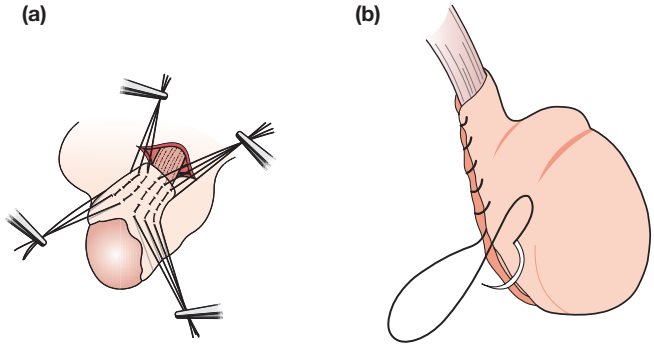

Figure 86.10 Lord's operation **(a)**. A series of interrupted absorbable sutures is used to plicate the redundant tunica vaginalis. When these are tied, the tunica bunches at its attachment to the testis. Jaboulay's procedure **(b)**. The hydrocele sac is everted and anchored with sutures. Unless great care is taken to stop bleeding after excision of the wall, haemorrhage from the cut edge is liable to cause a large scrotal haematoma. Overrunning stitches at the cut edge can be used to reduce this risk.

3 **Aspiration** of the hydrocele fluid is simple, but the fluid always reaccumulates within a week or so. It may be suitable for men who are unfit for scrotal surgery, although hydrocele surgery can be undertaken under local anaesthetic. Aspiration can result in bleeding into the hydrocele sac and haematocele formation. Injection of a sclerosant, such as tetracycline, can be effective but painful.

Summary box 86.5

Hydrocele

- A hydrocele is a collection of fluid within the tunica vaginalis
- Hydroceles surround the testis and transilluminate brightly
- Ultrasound examination is valuable, especially when the testis and epididymis are impalpable
- Hydroceles can be treated conservatively unless they are large and symptomatic
- Surgery is the mainstay of treatment
- Testicular malignancy is an uncommon cause of hydrocele that can be excluded by ultrasound examination

Filarial hydroceles and chyloceles

Filarial hydroceles and chyloceles account for up to 80% of hydroceles in tropical countries, where the parasite *Wuchereria bancrofti* is endemic. Filarial hydroceles follow repeated attacks of filarial epididymo-orchitis. Occasionally, the fluid contains liquid fat, which is rich in cholesterol. This is caused by rupture of a lymphatic varix with discharge of chyle into the hydrocele. In longstanding chyloceles, there are dense adhesions between the scrotum and its contents. Filarial elephantiasis supervenes in a small number of cases. Treatment is by rest and aspiration with chronic cases treated by excision of the sac.

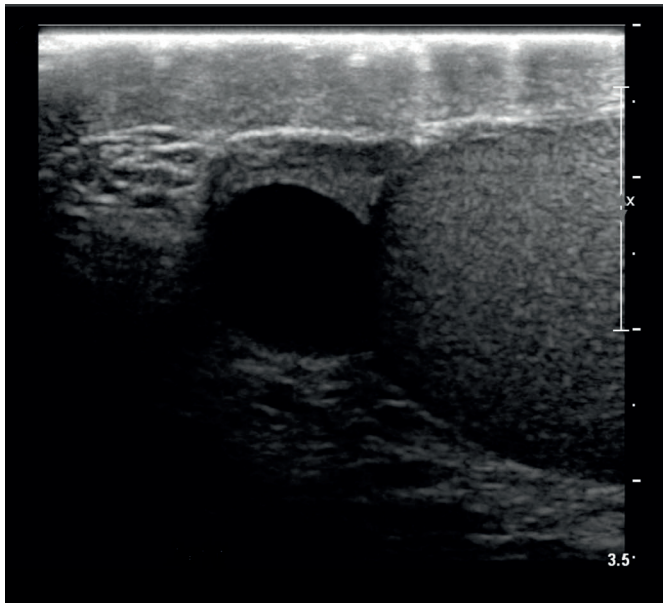

Figure 86.11 Ultrasound image of an epididymal cyst (courtesy of Dr Davide Prezzi).

CYSTS ASSOCIATED WITH THE EPIDIDYMIS

There are several types of cyst associated with the epididymis, including epididymal cysts and spermatoceles.

Epididymal cysts

These are filled with a clear fluid. They are very common, usually multiple and vary in size at presentation. They represent cystic degeneration of the epididymis. Cysts of the epididymis are usually found in middle age and are often bilateral. The clusters of tense cysts feel like tiny bunches of grapes that lie posterior to, and quite separate from, the testis. They should transilluminate. The diagnosis can by confirmed by ultrasound (***Figure 86.11***).

Aspiration is ineffective because the cysts are usually multilocular. If they are causing discomfort they should be excised. While single large cysts can be excised separately, recurrent or multilocular cysts usually require partial or total epididymectomy. Excision should be expected to interfere with the transportation of sperm from the testis on that side and young men should be counselled regarding this.

Spermatocele

This is a unilocular retention cyst derived from a portion of the sperm-conducting mechanism of the epididymis. A spermatocele typically lies in the epididymal head above and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but, like them, it transilluminates. The fluid contains spermatozoa and resembles barley water in

Otto Eduard Heinrich Wucherer, 1820–1873, German physician who practised in Brazil.
Joseph Bancroft, 1836–1894, English physician working in Australia.

appearance. Spermatoceles are usually small. Small spermatoceles can be ignored. Larger ones can be excised.

Summary box 86.6

Cysts associated with the epididymis

- Lie posterior to and separate from the testis and they transilluminate
- Diagnosis can be confirmed by ultrasound examination
- Can be treated conservatively unless they are large or uncomfortable

INFECTIONS OF THE TESTIS AND EPIDIDYMIS

Epididymo-orchitis

Definition

Inflammation confined to the epididymis is epididymitis; if this inflammation, usually due to infection, involves the testis it is called epididymo-orchitis.

Incidence

Epididymitis, commonly preceding epididymo-orchitis, occurs in about 1 in 1000 men annually. Acute epididymitis most commonly occurs in men aged 20–59 years (43% in men aged 20–39 years and 29% in men aged 40–59 years). Childhood (prepubertal) epididymitis is rare; torsion is more common in this age group. Forty-seven per cent of prepubertal boys with epididymitis have associated urogenital abnormalities, including ectopic vas deferens or ureters, and urethral abnormalities.

Pathophysiology

Infection reaches the epididymis via the vas from a primary infection of the urethra, prostate or seminal vesicles. A general rule is that epididymitis arises in sexually active young men from a sexually transmitted genital infection, while in older men it more usually arises from a urinary infection or may be secondary to an indwelling urethral catheter.

In young sexually active men, the most common cause of epididymitis is now *Chlamydia trachomatis*, but gonococcal epididymitis is still occasionally seen. In older men with bladder outflow obstruction, epididymitis may result from a urinary infection – it is proposed that a high pressure in the prostatic urethra might cause reflux of infected urine up the vasa. Blood-borne infections of the epididymis are less common but may be suspected when there is epididymal infection without evidence of urinary infection; it is presumably the only possible mechanism in men who have previously undergone a vasectomy. Acute epididymo-orchitis can follow any form of urethral instrumentation and it is particularly common when an indwelling catheter is associated with infection of the prostate.

Infection usually starts in the tail of the epididymis and spreads to the rest of the epididymis and occasionally to the testis. Complications include abscess formation, testicular infarction, testicular atrophy, chronic induration and inflammation and infertility.

Clinical features

While there may be initial symptoms of a urinary or a genital infection, such symptoms are not always seen. The development of an ache in the groin and a fever can herald the onset of epididymitis. The epididymis and testis swell and become painful. The scrotal wall, at first red, oedematous and shiny, may become adherent to the epididymis.

Investigation should include a urethral swab, a urine specimen for culture, nucleic acid amplification testing (NAAT) of either a urine specimen or a urethral swab and scrotal ultrasound. Urinalysis will usually show leukocytes and may show a formal urinary tract infection. NAAT is a sensitive way of identifying both gonococcal and chlamydial urethritis. Ultrasound is useful in the initial assessment of epididymitis (***Figure 86.12***) and will identify abscess formation.

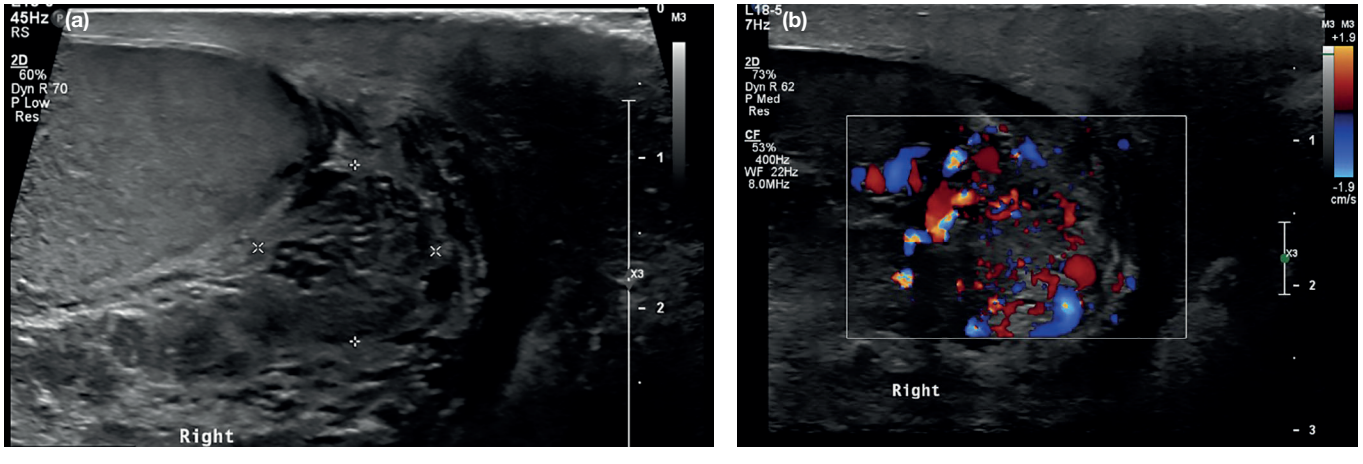

Figure 86.12 Ultrasound findings in epididymitis. Enlarged epididymis with a heterogeneous echotexture (grey-scale ultrasonography) **(a)** and increased blood flow (Doppler ultrasonography) **(b)** (courtesy of Dr Davide Prezzi).

In adolescents, the differential diagnosis is testicular torsion; if there is any clinical doubt as to the diagnosis then testicular exploration should always be performed.

Treatment

To prevent complications and transmission of sexually transmitted infections, presumptive therapy is indicated at the time of the visit before all laboratory test results are available.

Presumptive therapy is based on risk for chlamydia and gonorrhoea (usually younger men) and/or gut organisms (usually older men). The aims of treatment of acute epididymitis are (i) cure of infection, (ii) improvement of signs and symptoms, (iii) prevention of transmission of chlamydia and gonorrhoea to others, and (iv) a decrease in potential epididymitis complications (e.g. infertility and chronic pain). Local sensitivities do change with increasing antibiotic resistance. Examples of regimens are shown below from the 2021 Sexually Transmitted Infections Treatment Guidelines from the US Centers for Disease Control and Prevention (https://www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf).

- For acute epididymitis most likely caused by sexually transmitted chlamydia and gonorrhoea:
  - Ceftriaxone intramuscularly (IM) single dose and oral doxycycline for 10 days.
- For acute epididymitis most likely caused by sexually transmitted and enteric organisms (men who practise insertive anal sex):
  - Ceftriaxone IM single dose and levofloxacin for 10 days.
- For acute epididymitis most likely caused by enteric organisms:
  - Levofloxacin for 10 days.
- There should be contact tracing of the partner and treatment if necessary.

In older men, quinolones are the usual initial treatment; however, if there is evidence of systemic sepsis, intravenous antibiotics may be valuable. If an organism is isolated from the urine, this simplifies the choice of antibiotic.

Local measures including scrotal support and analgesia are helpful. Oral antibiotic treatment should continue for at least 10 days or until the inflammation has subsided. If abscess formation occurs, drainage is necessary.

Chronic disease

Chronic non-tuberculous epididymitis usually follows the failure of resolution of an acute episode of epididymitis. Patients typically complain of intermittent episodes of discomfort and the epididymis feels thickened and tender. Treatment involves use of antibiotics (usually quinolones or doxycycline) and anti-inflammatory agents for 4–6 weeks. Epididymectomy or orchidectomy can be considered if there is no resolution, although up to 50% of patients continue to have pain despite such surgery.

Summary box 86.7

Acute epididymo-orchitis

- In young men usually arises secondary to a sexually transmitted genital infection
- In older men usually arises secondary to urinary infection
- May be a complication of catheterisation or instrumentation of the urinary tract
- May need aggressive treatment with parenteral antibiotics

Tuberculous epididymo-orchitis

Chronic tuberculous epididymo-orchitis usually begins insidiously. The frequency with which the lower pole of the epididymis is involved first indicates that the infection is usually retrograde from a tuberculous focus in the seminal vesicles.

Clinical features

Typically, there is a firm, uncomfortable discrete swelling of the lower pole of the epididymis. The disease progresses until the whole epididymis is firm and craggy behind a normal-feeling testis. There is a lax secondary hydrocele in 30% of cases, and a characteristic beading of the vas may be apparent as a result of subepithelial tubercles. The seminal vesicles feel indurated and swollen. In neglected cases, a tuberculous 'cold' abscess forms, which may discharge. The body of the testis may be uninvolved for years but the contralateral epididymis often becomes diseased. In two-thirds of cases there is evidence of renal tuberculosis or previous disease. Otherwise, patients typically appear healthy.

The urine and semen should be examined repeatedly for tubercle bacilli in all patients with chronic epididymo-orchitis. Imaging of the chest and upper urinary tract should be performed. Ultrasound will demonstrate a thickened epididymis.

Treatment

Secondary tuberculous epididymitis may resolve when the primary focus is treated. Treatment with antituberculous drugs is less effective in genital tuberculosis than in urinary tuberculosis. If resolution does not occur within 2 months, epididymectomy or orchidectomy is advisable. A course of antituberculous chemotherapy should be completed even if there is no evidence of disease elsewhere.

Other common forms of orchitis

Mumps orchitis, which is the most common form of orchitis, develops in 20–30% of postpubertal patients with a mumps virus infection and it usually develops as the parotid swelling is waning. Evidence of immunoglobulin M antibodies in the serum supports the diagnosis. The main complication is testicular atrophy, which may cause infertility if the condition is bilateral. Partial testicular atrophy is associated with persistent testicular pain.

Syphilitic orchitis is now uncommon. It can cause bilateral orchitis (which is a feature of congenital syphilis), interstitial fibrosis (which causes painless destruction of the testis) or, rarely, a gumma of the testis (which presents as a unilateral slowly growing painless swelling). The last presentation may be difficult to distinguish from a neoplasm without surgical exploration. Diagnosis is confirmed by serology.

TUMOURS OF THE TESTES

Incidence

Testicular cancer represents around 1–1.5% of male neoplasms and there is clear evidence of an increased incidence of these tumours in the past 30 years with 3–10 new cases per 100 000 males/per year in western societies. The predominant histology is germ cell tumours (GCTs) (90–95% of cases). The peak incidence of seminomas is in the fourth decade of life, with the non-seminomatous germ cell tumours (NSGCT) being more common in the third decade of life. They are the commonest form of tumour in young men. A specific genetic marker – an isochromosome of the short arm of chromosome 12 (i12p) – is pathognomonic of all types of adult GCTs as well as germ cell neoplasia *in situ* (GCNIS). Epidemiological risk factors include cryptorchidism, male factor infertility (including Klinefelter syndrome), familial history of testicular tumours among first-grade relatives and the presence of a contralateral tumour or GCNIS.

Classification and pathology

Tumours of the testis are classified according to their predominant cellular type:

- **GCTs** (90–95%): these include seminoma, embryonal cell carcinoma, yolk sac tumour, teratoma and choriocarcinoma;
- **sex cord–stromal tumours** (1–2%): these include Leydig cell tumours;
- **lymphoma** (3–7%);
- **other tumours** (1–2%).

Seminoma

A seminoma typically has a cut surface that is homogeneous and pinkish cream in colour. It appears to compress neighbouring testicular tissue (***Figure 86.13***). It consists of oval cells with clear cytoplasm and large, rounded nuclei with prominent acidophilic nucleoli. Sheets of cells resembling spermatocytes are separated by a fine fibrous stroma. Active lymphocytic infiltration of the tumour suggests a good host response and a better prognosis. Seminoma accounts for 50% of all testicular germinal cell tumours. They seldom occur in childhood, in young adults or in patients over 70 years of age.

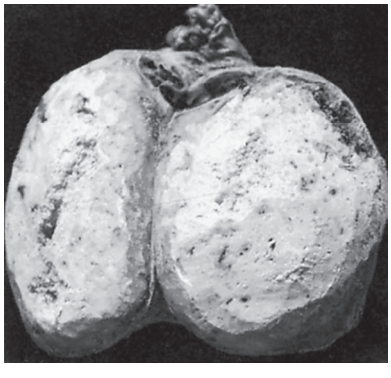

Figure 86.13 Seminoma of the testis.

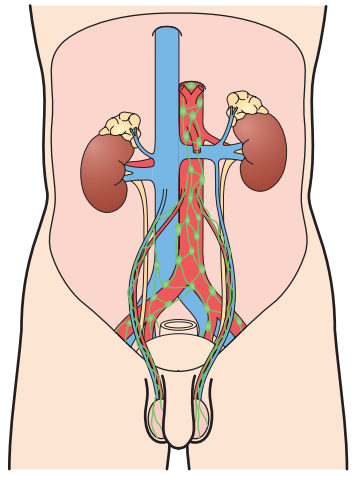

Figure 86.14 Lymphatic drainage of the testes to para-aortic lymph nodes.

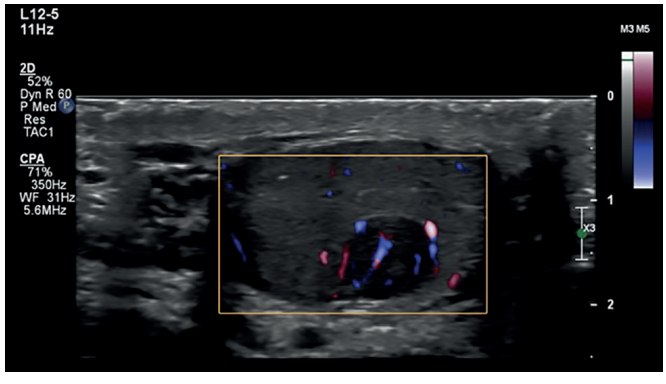

Figure 86.15 Ultrasound of a small seminoma with minimal distortion of the tunica albuginea (courtesy of Dr Davide Prezzi).

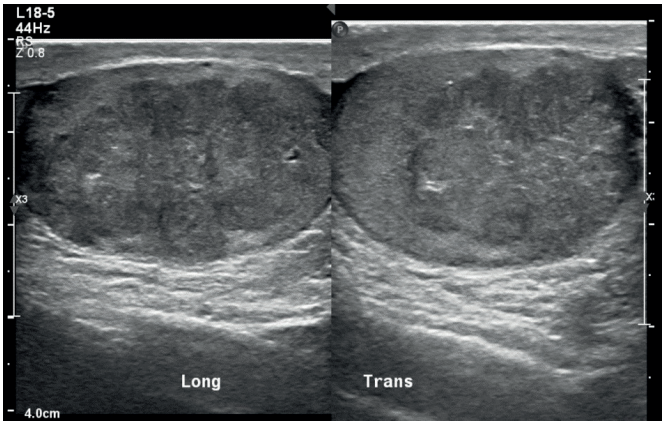
Seminomas metastasise mainly via the lymphatics (***Figure 86.14***) and haematogenous spread is uncommon. The lymphatic drainage of the testes is to the para-aortic lymph nodes near the origin of the gonadal vessels. The contralateral para-aortic lymph nodes are sometimes involved by tumour spread, but the inguinal lymph nodes are affected only if the scrotal skin is involved. Ultrasound is the first-line investigation (***Figure 86.15***).

Non-seminomatous germ cell tumours

There are a number of histological types of NSGCT, which may coexist within a single tumour:

- **Embryonal carcinoma** (***Figure 86.16***). Highly malignant tumours that occasionally invade cord structures.
- **Yolk sac tumour**. Usually present with a loose stroma and a component similar to embryonal carcinoma, sometimes with liver and intestinal tissue differentiation. It appears as a single tumour type in children and part of a

Harry Fitch Klinefelter Jr, 1912–1990, physician of Baltimore, MD, USA, described this syndrome in 1942.



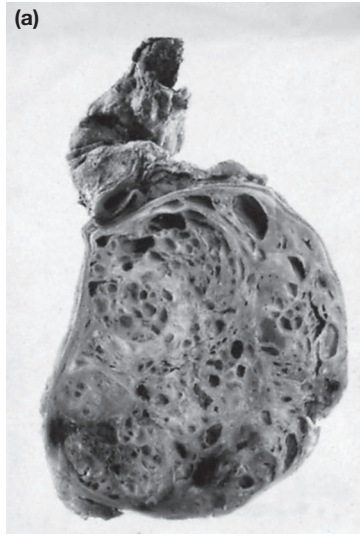


Figure 86.16 Ultrasound of a large embryonal carcinoma occupying nearly the whole testis; long, longitudinal view; trans, transverse view (courtesy of Dr Davide Prezzi).

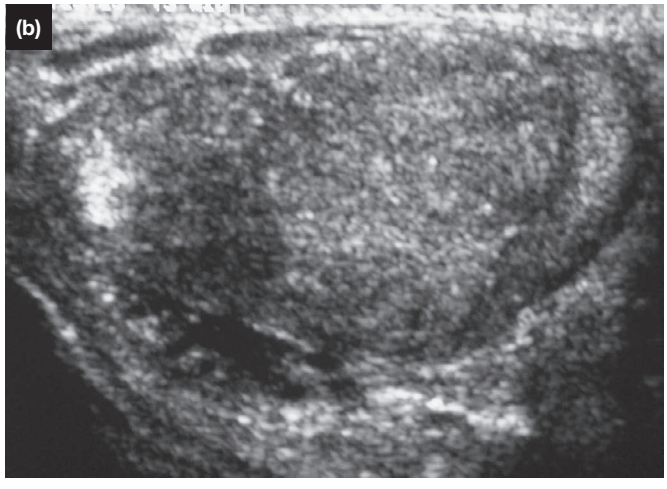

Figure 86.17 Teratoma of the testis specimen (a). Note the solid and cystic areas (courtesy of Dr Keith Simpson, London, UK). Testicular ultrasound (b). The homogeneous tissue of the testicular teratoma on the left of the image produces multiple ultrasound reflections.

mixed tumour in adults. They produce alpha-fetoprotein (AFP), which can be measured in serum.

- **Teratoma** (*Figure 86.17*). Teratomas consist of different tissues derived from ectoderm, endoderm and mesoderm. Immature components are often neuroectodermal or mesenchymal tissue, while more mature tissue is often cystic with epithelial differentiation or consists of smooth muscle, connective tissue or cartilage. Since most teratomas consist of a mixture of tissues, the old separation into mature and immature types has been abandoned. All can metastasise.
- **Choriocarcinoma**. This is part of a testicular GCT in 25% of tumours in adults. It very seldom appears as the single tumour component. Choriocarcinoma is almost never seen in childhood. This tumour produces human chorionic gonadotropin (HCG), which can be detected in blood. This is a highly malignant tumour that metastasises early via both the lymphatics and the bloodstream.

Spermatocytic seminoma

This tumour was earlier believed to be a variant of seminoma, but is now considered to be a separate tumour type, accounting for 1–2% of all GCTs of the testis. Only seen in adult men usually >50 years old, they rarely metastasise; therefore, an orchidectomy is the only necessary treatment, even in large tumours. Development of sarcomas has been reported when left untreated for long time.

Sex cord–stromal tumours

Sex cord–stromal tumours are rare and constitute less than 5% of testicular neoplasms.

Leydig cell tumour

Leydig cell tumours are the most common type of sex cord–stromal tumours, constituting 1–3% of adult testicular tumours and 3% of testicular tumours in infants and children. These tumours occur in about 8% of patients with Klinefelter's syndrome. They are well delineated on histology and usually up to 5 cm in diameter. They are solid, yellow to tan in colour with haemorrhage and/or necrosis in 30% of cases. Most of these tumours are benign. Malignant transformation occurs in 10% and is related to increased size (>5 cm), increased cellular atypia, increased cell proliferation, necrosis, vessel invasion and DNA aneuploidy.

Sertoli cell tumour

Sertoli cell tumours account for less than 1% of testicular tumours, and the mean age at diagnosis is around 45 years, with sporadic cases under 20 years of age. Rarely, these occur in patients with androgen insensitivity syndrome and Peutz–Jeghers syndrome. The rate of malignancy ranges between 10% and 22%.

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John's Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

Granulosa cell tumour

Granulosa cell tumours of the testis are extremely rare in adult men, but a juvenile type accounts for 6% of testis tumours in childhood.

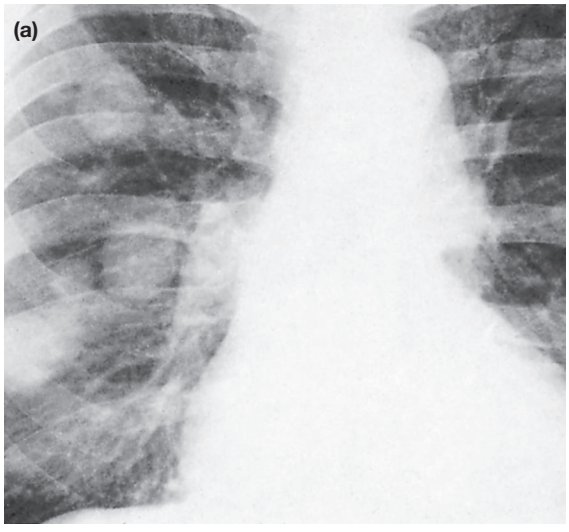
Mixed germ cell/sex cord tumour: gonadoblastoma

This tumour consists of two cell types: large germinal cell-like seminoma cells and small granulosa-like or Sertoli cells or rarely Leydig/luteinised cells. Gonadoblastoma is seen in individuals with mixed gonadal dysgenesis (risk 15–25%), which is associated with cryptorchidism, hypospadias, gynaecomastia or female internal genitalia. It seldom occurs in phenotypical and genotypical males.

Clinical features

Usually the patient presents with a painless testicular lump. A sensation of heaviness can occur if large, but few patients experience pain. Occasionally, an episode of trauma calls attention to the swelling. Some cases may simulate epididymo-orchitis and, rarely, acute painful enlargement of the testis occurs because of haemorrhage into the tumour, which can mimic testicular torsion.

Rarely, the predominant symptoms are those of metastatic disease. Intra-abdominal disease may cause abdominal or lumbar pain. Lung metastases are usually silent, but they can cause chest pain, dyspnoea and haemoptysis in the later stages of the disease. The primary tumour may not have been noticed by the patient, and indeed may be detected only by ultrasound (***Figure 86.15***).



On examination there is an intratesticular solid mass. A secondary hydrocele may be present. The epididymis can become more difficult to feel. Around 5% of cases have gynaecomastia (mainly NSGCT). Metastatic disease is rarely apparent clinically and is more usually identified by formal staging investigations. In 1–2% of cases the tumour is bilateral at diagnosis.

Investigation and staging

The diagnosis is confirmed by ultrasound scanning of the testis (***Figure 86.16***), which is also able to assess the contralateral testis. It is a mandatory test in all suspected cases of testicular tumour.

In confirmed cases, staging is an essential step in planning treatment. Blood is taken prior to orchidectomy to measure the levels of tumour markers, which are raised in around 50% of cases. A rise in AFP is seen in around 50–70% of NSGCTs and a rise in HCG is seen in 40–60% of NSGCTs and around 30% of seminomas. Lactate dehydrogenase (LDH) is expressed on chromosome 12p, which is often amplified in testis cancer cells. LDH is less specific for testis cancer than HCG or AFP. However, elevated LDH levels are associated with high tumour burden in seminoma and recurrence in NSGCT.

When raised, these markers are used to monitor the response to treatment. The mean serum half-lives of AFP and HCG are 5–7 days and 2–3 days, respectively, and reassessment of the markers following orchidectomy can indicate whether all the tumour tissue has been removed.

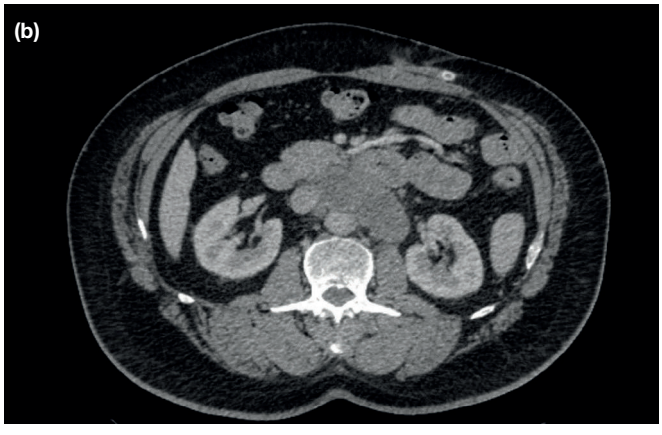


Figure 86.18 (a) Chest radiograph showing cannonball metastases from carcinoma of the testis and **(b)** computed tomography showing large para-aortic lymph node metastasis from carcinoma of the testis resulting in retroperitoneal mass (courtesy of Dr Davide Prezzi).

While a chest radiograph can show the 'classical' cannonball metastases (***Figure 86.18a***) CT scanning of the chest, abdomen and pelvis has taken over as the most useful means of detecting metastases and monitoring the response to therapy (***Figure 86.18b***).

Summary box 86.8

Testicular tumours

- A solid testicular lump that cannot be felt separately from the testis may be a malignant tumour
- Lymphatic spread is to the para-aortic lymph nodes
- Ultrasound is a mandatory investigation in all cases of suspected testicular tumour
- Tumour markers (AFP, HCG and LDH) should be measured prior to orchidectomy

Treatment

Men should be offered semen analysis and sperm banking prior to interventions such as surgery and chemotherapy that may render them infertile.

Surgery: radical orchidectomy

The orchidectomy is undertaken via an inguinal incision. The spermatic cord is displayed by dividing the external oblique aponeurosis and a soft clamp is placed across the cord to stop dissemination of malignant cells as the testis is mobilised into the wound. If there is a tumour the cord should be double transfixed and divided at the level of the internal inguinal ring and the testis removed.

Management by staging and histological diagnosis (after orchidectomy)

The treatment of patients with GCTs of the testis is usually successful, even in advanced cases. This largely reflects the excellent response of these tumours to chemotherapy and (for seminomatous tumours) to radiotherapy. Prognostic groups can be defined according to non-metastatic (stage I) and metastatic disease (lymph node metastasis – stage II; distant metastasis or nodal metastasis with elevated tumour markers – stage III). (The exact classification details can be found in the *TNM Classification of Malignant Tumours*, 8th edn; see ***Further reading***.) Between 75% and 80% of patients with seminoma and about 55–64% of patients with NSGCT have stage I disease at diagnosis.

The management strategies below are adapted from the European Association of Urology's current guidelines.

Non-metastatic disease (stage I)

Seminoma. About 15% of patients with clinical stage I (CSI) seminoma have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchidectomy alone.

Surveillance. Recurrence rates of 6% have been described in patients with low-risk features, including tumours size <4 cm and no stromal rete testis invasion with cancer-specific survival rate reported with surveillance at >95%. The main limitation of surveillance is the need for intensive follow-up.

Adjuvant chemotherapy. One course of adjuvant carboplatin therapy compared with radiotherapy shows no significant difference in recurrence rate, time to recurrence and survival after a median follow-up of 4 years.

Adjuvant radiotherapy. Seminomas are radiosensitive. Radiotherapy to a para-aortic field or to para-aortic and ipsilateral iliac nodes reduces the relapse rate to 1–3%. The rate of severe radiation toxicity is <2%. The main concern is the long-term risk of secondary malignancies.

NSGCT. Up to 50% of patients with NSGCT with CSI disease have subclinical metastases and will relapse during surveillance.

- *Surveillance.* 14–48% of CSI-NSGCT patients undergoing surveillance have recurrence within 2 years of orchidectomy. Careful surveillance can be an option for compliant, risk-stratified (based on the presence of lymphovascular invasion) patients who are well informed about the expected recurrence rate as well as the salvage treatment.
- *Adjuvant chemotherapy.* One cycle of bleomycin–etoposide–cisplatin (BEP) is now the recommended strategy with recurrence rates of around 3%. The very long-term side effects, particularly cardiovascular, remain to be ascertained.
- *Retroperitoneal lymph node dissection (RPLND).* The role of this surgery has now decreased with 2-year recurrence-free survival with adjuvant BEP × 1 versus RPLND favouring chemotherapy with recurrence-free survival of 99.5% versus 91%.

Metastatic disease (stages II and III)

Treatment for metastatic testicular cancer is chemotherapy. Previously, radiotherapy was often used for early stage II seminoma but the cardiovascular and second malignancy risks have led to chemotherapy (three cycles of BEP or four cycles of etoposide and cisplatin [EP]) being the preferred alternative. Both are similarly effective, with a trend towards greater efficacy for chemotherapy in stage IIB seminoma. The initial treatment is chemotherapy (BEP) in all advanced cases of NSGCT except postpubertal teratoma without elevated tumour markers, which can be managed by RPLND surgery.

Sex cord–stromal tumours

Most of these tumours are benign (around 80%), so conservative treatment of small lesions with organ-sparing surgery is feasible, if the diagnosis is considered. For larger tumours, orchidectomy is necessary with multimodality treatment for those with the rare malignant forms of these tumours.

Summary box 86.9

Testis tumour staging and treatment

- Tumour markers (AFP, HCG and LDH) help to make the diagnosis and to follow the response to treatment
- CT scanning of chest, abdomen and pelvis is central to the staging of testicular tumours
- Testicular tumours are extremely sensitive to platinum-based chemotherapy
- Prognosis is excellent when the patient is treated with combination chemotherapy in a cancer centre

Testicular tumours in children

Paediatric testicular tumours are distinct from adult testicular tumours. GCTs in adults represent about 95% of all testicular tumours but only 60–75% in children. The most common malignant tumour in children is the yolk sac tumour, which is very rare in its pure form in adults. Surgical treatment usually begins with radical orchidectomy, which is often recommended whenever the AFP level is elevated (suggesting the presence of a yolk sac tumour at age >1 year). A normal AFP level in children suggests a strong likelihood of a benign tumour. For such tumours, as in cases of epidermoid cysts, testis-sparing surgery of the mass rather than radical orchidectomy can be considered.

TUMOURS OF THE EPIDIDYMIS

Paratesticular tumours are rare and account for about 5% of all intrascrotal tumours. Between 70% and 80% of all these tumours are benign and 30% of these occur in the epididymis. Epididymis tumours are commonly soft tissue or mesothelial neoplasm in origin. Benign cystadenomas, papillary tumours and adenomatoid tumours are the most common, although malignant sarcoma or secondary metastasis from a carcinoma may also occur. They are extremely rare.

THE SCROTUM

Fournier's gangrene

Fournier's gangrene is an uncommon and nasty condition (***Figure 86.19***) characterised by a polymicrobial infection of the soft tissues of the perineum, external genitalia and perianal region. It is a form of necrotising fasciitis. There is rapid onset of gangrene leading to exposure of the scrotal contents. Although it can occur in conjunction with sepsis of the testis, epididymis or perianal region, an obvious cause is absent in over half the cases. It can arise following minor injuries or procedures in the perineal area, such as a bruise, scratch, urethral dilatation, injection of haemorrhoids or opening of a periurethral abscess. Many patients have concurrent illnesses that diminish their defences, most notably diabetes mellitus and alcoholism.

There is a mixed infection of aerobic and anaerobic bacteria in a fulminating inflammation of the subcutaneous tissues, which results in an obliterative arteritis of the arterioles to the scrotal skin that in turn results in gangrene. The condition can spread rapidly to involve the fascia and skin of the penis, perineum and abdominal wall.

Figure 86.19 Fournier's gangrene with an area of necrotic skin overlying an area of scrotal inflammation.

Clinical features

The hallmark of Fournier's gangrene is intense pain and tenderness in the genitalia. The clinical course usually progresses through the following phases:

1. prodromal symptoms of fever and lethargy for 2–7 days;
2. intense genital pain usually associated with oedema of the overlying skin; pruritus may be present;
3. increasing genital pain with progressive erythema of the overlying skin;
4. dusky appearance of the overlying skin; subcutaneous crepitation;
5. obvious gangrene of part of the genitalia; purulent discharge from wounds.

Early on, pain may be out of proportion to the physical findings. As gangrene develops, pain may subside as nerve tissue becomes necrotic. Systemic effects of this process vary from local tenderness to massive septic shock, with the greater the necrosis the more severe the systemic effects.

Treatment

Treatment of a case of Fournier's gangrene is a surgical emergency. Initial management involves intravenous fluid resuscitation and broad-spectrum intravenous antibiotics. Urgent wide surgical excision of the dead and infected tissue is essential and the extent of the internal necrosis is typically much greater than the external appearances suggest, with extensive debridement often necessary. Urinary and faecal diversion may be necessary. Supportive care is essential because patients often become severely septic.

Early review of the wounds is helpful to confirm that all dead tissue has been removed; when the infection has been controlled, vacuum-assisted dressing is helpful, if it is available. If the patient survives the acute episode, skin grafting is often necessary. Despite best therapy, mortality rates as high as 50% are often reported.

Summary box 86.10

Fournier's gangrene

- Fournier's gangrene requires early and aggressive treatment if the patient is to survive
- Treatment involves urgent surgical debridement of necrotic tissue in combination with early use of intravenous broad-spectrum antibiotics

Jean Alfred Fournier, 1832–1915, syphilologist, founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

Figure 86.20 Scrotal cancer.

Carcinoma of the scrotum

'Chimney sweep's cancer' was the first reported occupational cancer (described by Percival Pott in 1775). It is a rare cancer that has also been seen in other workers who come into contact with oil and coal products. Animal studies suggest that aromatic cyclic hydrocarbons are the aetiological factor. Nowadays, this tumour is rarely associated with any obvious aetiological factor.

The growth starts as a wart or ulcer (***Figure 86.20***); as it grows it may involve the testis. The tumour should be excised with a margin of healthy skin. The management of the inguinal nodes parallels the management of penile cancer, and nodal assessment, either with sentinel node biopsies or bilateral groin dissections, is indicated.

TRAUMA TO THE TESTIS

The testis can be damaged either by blunt or by penetrating trauma. Injuries can range from simple bruising, through significant intratesticular haematomas to rupture of the tunica albuginea, with very significant collections of blood within the tunica vaginalis (haematocele) (***Figure 86.21***). If the tunica ruptures, the blood can track into the groin and perineum.

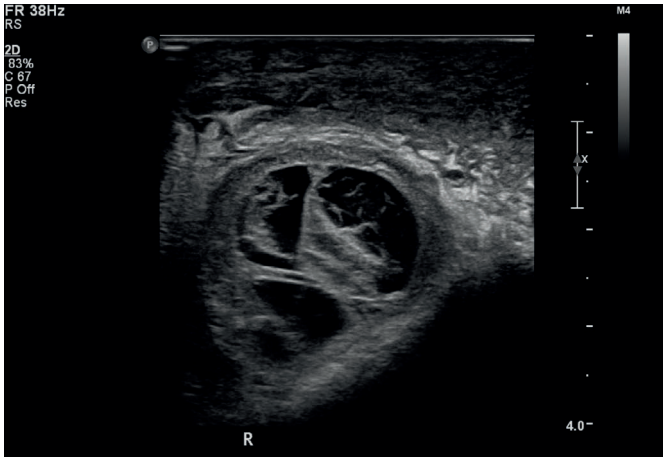

Figure 86.21 Ultrasound of a ruptured testicle with a haematocele (courtesy of Dr Davide Prezzi).

Careful clinical assessment, together with the use of ultrasound examination, is central to the management of men with a scrotal injury. Ultrasound has excellent sensitivity and specificity in the diagnosis of testicular rupture. If there is testicular rupture, there is good evidence that early surgical exploration, with debridement and repair of the tunica albuginea, is more likely to preserve useful testicular function. Also, early intervention results in orchidectomy in less than 10% compared with the 50% rate in delayed surgery.

Summary box 86.11

Scrotal trauma

- In cases of scrotal trauma, surgical exploration is indicated when there is testicular rupture or when there is a rapidly expanding scrotal haematoma
- Ultrasound is important in the assessment of the injury

PART 12 | Genitourinary

CHAPTER

87 Gynaecology

Learning objectives

To understand:

- Pelvic anatomy
- Early pregnancy complications (ectopic pregnancy)
- Common causes of an acute abdomen and chronic abdominal pain
- Causes of abnormal uterine bleeding in the non-pregnant state
- Surgical management of endometriosis, adenomyosis, uterine fibroids, uterovaginal prolapse and ovarian tumours

ANATOMY

The reproductive structures of the dividing embryo differentiate after the seventh week of development. The gonads and internal and external genitalia constitute the sex organs. In the female, the Müllerian ducts develop into the uterus, fallopian tubes, cervix and upper third of the vagina. The urogenital sinus in turn forms the lower two-thirds of the vagina.

The female external genitalia are described as the vulva, which is bordered by the mons pubis anteriorly and the labiocrural folds posterolaterally. The opposing skin that covers the introitus is known as the labia majora. The labia minora are folds of skin that fuse anteriorly around the clitoris, which contains erectile tissue similar to the penis in the male. The posterior part of the introitus is referred to as the fourchette and this stretches considerably during childbirth to allow delivery of the baby.

The vagina is an elastic, distensible tube, approximately 6–7 cm long, passing upwards and backwards from the introitus. The cervix protrudes into the vault of the vagina, dividing it into the anterior, posterior and lateral fornices. Pelvic structures can be felt in the posterior and lateral fornices on bimanual examination, as the vaginal vault sits just below the pouch of Douglas (the area at the bottom of the pelvic cavity bordered by the uterus anteriorly and rectum posteriorly). The urethra and bladder neck sit above the anterior wall of the vagina; the perineal body and rectum behind the posterior wall (***Figure 87.1***).

The uterus consists of a body and a cervix (neck of the uterus) and is an upside-down pear-shaped structure that is flattened anteroposteriorly, giving its cavity a flat, triangular shape. The uterus is supported partly by ligaments attached to the cervix (transverse cervical, pubocervical and uterosacral) that consist of condensed connective tissue. The cervix is a canal, approximately 2–3 cm long in the non-pregnant woman, connecting the external os, which can be seen on speculum examination, to the internal os, where the cervix enters the uterine cavity. The uterine cavity to cervical length ratio varies through hormonal influences and developmental phases, with the uterine body increasing in size as puberty progresses.

The cervical canal is located within the centre of the bony cavity of the pelvis, with the uterus pivoted around this point. It is more commonly angled forwards (anteverted) relative to the vagina. It is usually freely mobile, with filling of the bladder

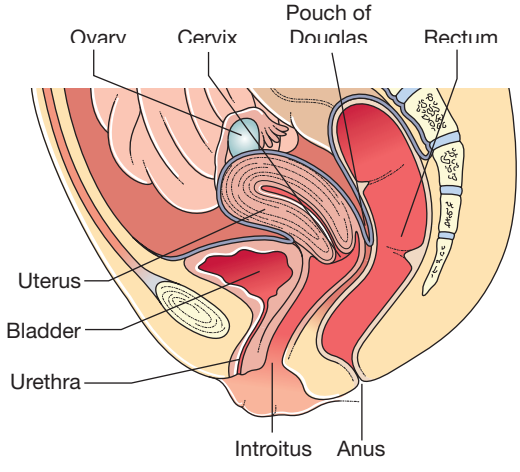

Figure 87.1 Female anatomy.

Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany, described the paramesonephric duct in 1825.
James Douglas, 1675–1742, anatomist, midwife and physician to Queen Caroline, London, UK, helped expose the fraudulent claims of Mary Toft, who, in 1726, famously tricked a number of doctors into believing that she had given birth to rabbits.
Gabriele Falloppio (Fallopius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy. He carried out what may have been the first clinical trial in over 1000 men of the use of condoms to prevent transmission of syphilis.

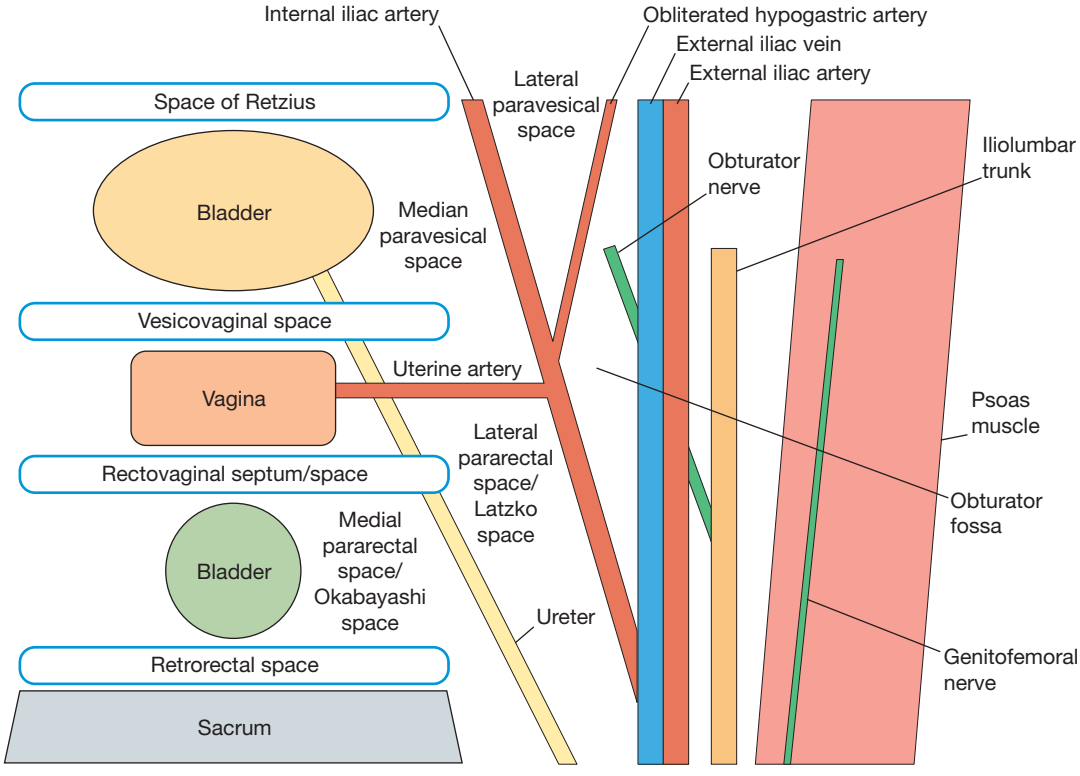

Figure 87.2 Surgical anatomy of the pelvis, including the key surgical spaces, vessels and nerves in relation to the pelvic organs (illustrative representation of anatomical spaces by PR Supramaniam).

or changes in position rotating it backwards. In others, it can be retroverted, a variation of normal, or secondary to weak ligaments or because it becomes adherent as the result of a disease process such as endometriosis. The uterus may also be angled forwards (anteflexed) relative to the cervix or backwards (retroflexed), which can be determined through bimanual examination.

The uterine walls are 1–2 cm thick and composed of smooth muscular tissue (myometrium). The uterine cavity is lined with endometrium, a tissue that undergoes cyclical changes in response to ovarian hormones. The endometrium has both a basal and functional layer. The basal layer lies adjacent to the myometrium and from it develops the functional layer. The basal layer is not shed during menstruation, unlike the functional layer. The functional layer is influenced by oestrogen and progesterone, which thicken it, preparing the lining for implantation. This layer is completely shed during menstruation should conception not occur.

In the lean patient, the uterine size can be estimated on palpation. This is usually a subjective assessment outside of imaging modalities. The most common cause of an enlarged uterus, apart from pregnancy, is fibroids (benign tumours of the myometrium) growing inside or outside of the uterus. In the presence of fibroids or other conditions causing enlargement of the uterus, the uterine size is often described in terms of the number of weeks' gestation it approximates to, were the woman pregnant.

At the uterine fundus, on either side, are the cornua, which connect the uterus to the fallopian tubes. These are thin, muscular tubes, approximately 10 cm long. They are divided into four parts: intramural, isthmus, ampulla and the fimbriated opening, which picks up the oocyte following its release at the time of ovulation. The tubes are very narrow in the isthmic and intramural parts but widen at the ampullary region. Each tube is contained within the upper part of the broad ligament, a fold of peritoneum on either side of the uterus, which also contains blood vessels as well as the round and ovarian ligaments. The fimbriated opening and part of the ampulla, however, are free and closely associated with the ovary on either side. The ovaries are flattened, ovoid structures, approximately 3–4 cm in dimension, suspended from the back of the broad ligament on either side of the pelvic side wall by the ovarian ligament, which originates from the uterine body. The ovarian blood vessels are contained within the infundibulopelvic ligaments, which are continuations of the broad ligament to the pelvic brim on either side.

A sound understanding of pelvic anatomy is key to surgical excellence and safety (***Figure 87.2***).

The sacral promontory is considered a crucial landmark and the summit of the pelvis. While pelvic pathology may reach into the abdominal cavity, the origin is always below the sacral promontory. The sacrum is a bony prominence that is used as a point of reference in surgery and in surgical anatomy. The sacral promontory is the level at which the common iliac vessels bifurcate into the external and internal iliac vessels, and the level at which the ureter transverses from the lateral to medial side. Another key structure at this level is the superior hypogastric nerve plexus (autonomic nerve plexus), which is

formed from the convergence of the right and left hypogastric nerves.

The aorta bifurcates at the level of the L4 vertebral body, where it forms the right and left common iliac vessels. The common iliac vessel then further bifurcates as described above at the level of the sacral promontory. The external iliac artery mainly supplies the lower limbs and has one anterior branch known as the inferior epigastric artery. Note should be made of the position of this artery when determining placement of lateral ports during laparoscopy, to avoid vascular injury. The internal iliac artery divides further into the anterior and posterior divisions. The anterior division is the main blood supply to the vital organs of the pelvis. The posterior division mainly supplies the gluteal region. The anterior division travels parallel to the ureter and gives off its first branch, the uterine artery, followed by the superior vesical artery, and continues as the obliterated umbilical artery. There is often a 5- to 6-cm distance from the origin of the anterior division prior to the first branch. This is often the level at which surgeons perform internal iliac artery ligation to manage cases of massive haemorrhage during obstetric surgery and prophylactically in pelvic exenteration surgery.

The pelvic structures are supplied by the autonomic nervous system. The inferior hypogastric nerve (T10–L2) provides sympathetic fibres and the pelvic splanchnic nerve provides parasympathetic fibres. These fibres merge to supply both the ureter and urinary bladder and can often be injured in complex pelvic surgery, leading to complications of residual bladder dysfunction and sexual dysfunction.

Pelvic spaces have recently featured in surgical anatomy as a key learning point to aid surgeons in performing safe surgery. The retroperitoneal spaces are divided into those that are present bilaterally (pararectal and paravesical spaces) and those that are present in the midline (space of Retzius, rectovaginal space and the retrorectal space). The pararectal space is bound medially by the rectum and laterally by the internal iliac artery. The posterior leaf of the broad ligament forms the roof and the levator ani muscle forms the floor. Cranially, the space is bordered by the uterine artery. The pararectal space is further divided into medial and lateral spaces by the ureter, with the medial pararectal space also known as the Okabayashi space and the lateral pararectal space called the Latzko space.

The paravesical space is a retroperitoneal space that is lateral to the urinary bladder. Medially it is bound by the urinary bladder, laterally by the pelvic walls and inferiorly by the uterine artery. The paravesical space is further divided into medial and lateral spaces by the obliterated hypogastric artery. The floor of the medial paravesical space is formed by the levator ani muscle. The obturator and pelvic lymph nodes are contained in the lateral paravesical space, important during a radical hysterectomy, and the limit of dissection is bounded by the posterior limit of the obturator nerve.

The space of Retzius is the midline retroperitoneal space between the bladder and the anterior abdominal wall. It is connected to the paravesical space and is enclosed laterally by the obliterated hypogastric artery. This space is often used in urogynaecological procedures as the bladder neck is exposed, aiding surgery performed for incontinence. It is also used in deep endometriosis surgery during management of bladder nodules to aid in tension-free closure of the cystotomy.

The rectovaginal space refers to the posterior retroperitoneal space that is formed by the uterus anteriorly and the rectum posteriorly. The lateral borders of this space are provided by the uterosacral ligament. This space is often explored to aid in radical hysterectomy and deep endometriosis surgery.

The retrorectal space is a retroperitoneal space that is bound by the rectum anteriorly. It is often explored in complex pelvic surgery and deep endometriosis surgery associated with excision of the rectum. The presacral vein that lies posterior to Waldeyer's fascia is often an area of concern because, if not carefully dissected, it can lead to severe uncontrollable haemorrhage.

EARLY PREGNANCY COMPLICATIONS

Ectopic pregnancy

An ectopic pregnancy refers to a pregnancy that grows outside of the uterine cavity, most commonly within the fallopian tube. To facilitate management of an ectopic pregnancy it is important to be able to describe the location of the pregnancy as accurately as possible. The newly agreed terminology broadly divides ectopic pregnancies into uterine (defined by evidence of trophoblast invasion beyond the endometrial–myometrial junction, but not outside the uterine visceral/broad ligament peritoneum) and extrauterine ectopic pregnancies (***Table 87.1***). They are further described as being complete (solely confined to the myometrium) or partial (involving both the myometrium and the uterine cavity).

Additional variations include rudimentary horn pregnancies. These are rare, with a reported incidence of 1 in 75 000–150 000 pregnancies. They are able to develop into the second trimester if not diagnosed early through the identification of a single interstitial portion of the fallopian tube attached to the main unicornuate uterine body, with products of conception completely surrounded by myometrium, presenting with severe pain and uterine rupture.

A residual ectopic pregnancy refers to an ectopic pregnancy that remains visible on ultrasound scan 3 months after a negative urinary pregnancy test and serum beta-human chorionic gonadotropin (βHCG) level of <20 IU/L.

As the ectopic pregnancy grows, the placental tissue can infiltrate the blood vessels surrounding the fallopian tube, leading to bleeding within the tube and into the peritoneal cavity. Further growth of the ectopic pregnancy can rupture the fallopian tube, causing significant intraperitoneal blood

Anders Retzius, 1796–1860, Swedish anatomist.
Hidekazu Okabayashi, 1884–1953, Japanese gynaecologist, demonstrated the first nerve-sparing radical hysterectomy in Kyoto Imperial University Hospital, Kyoto, Japan, 1921.
Wilhelm Latzko, 1863–1945, Austrian gynaecologist, described a technique for vaginal closure of vesicovaginal fistula following a hysterectomy, 1914.
Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921, Professor of Pathological Anatomy, Berlin, Germany.

TABLE 87.1 Examples of uterine and extrauterine ectopic pregnancies.

Uterine ectopic pregnancies	Extrauterine ectopic pregnancies
• Cervical (the gestational sac is present below the level of the internal os with absence of the 'sliding sign' and evidence of blood flow around the gestational sac using colour Doppler) • Caesarean scar (the gestational sac is located low in the uterus, close to the internal os with trophoblast invading into the anterior myometrium) (*Figure 87.3*) • Intramural (located above the level of the internal os)	• Tubal (*Figure 87.4*) (further divided into interstitial [*Figure 87.5*], isthmic and ampullary) • Ovarian (colour Doppler can help identify an area of increased vascularity within the ovary that is representative of peritrophoblastic blood flow separate from that of the corpus luteum) (*Figure 87.6*) • Abdominal (commonly the broad ligament, pouch of Douglas, uterovesical pouch and surfaces of the tubes and uterus)

loss. This constitutes a gynaecological emergency. An ectopic pregnancy occurs in 11 per 1000 pregnancies, and there is a maternal mortality rate of 0.2 per 1000 estimated ectopic pregnancies. The major risk factors for an ectopic pregnancy are shown in ***Summary box 87.1***.

Summary box 87.1

Risk factors for an ectopic pregnancy

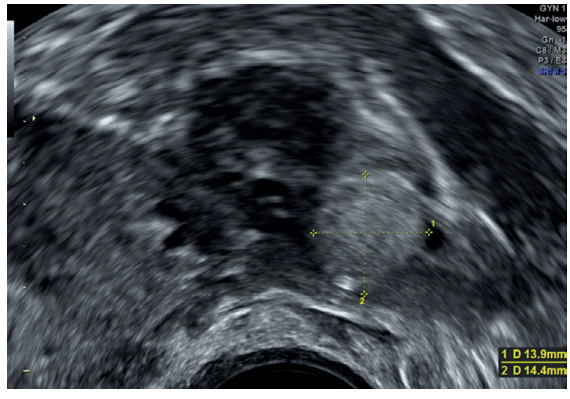
- Previous pelvic inflammatory disease (PID)
- Smoking
- History of infertility
- Use of an intrauterine contraceptive device (IUCD)
- Previous ectopic pregnancy
- Previous abdominal/pelvic surgery, e.g. myomectomy, hysteroscopic resection
- Previous tubal surgery, e.g. sterilisation, salpingostomy, tuboplasty
- Endometriosis

An ectopic pregnancy may be suspected on clinical grounds, but making the diagnosis can be difficult (***Table 87.2***).

TABLE 87.2 Symptoms and signs of an ectopic pregnancy.

Symptoms	Signs
• Abdominal or pelvic pain • Amenorrhoea or missed period • Vaginal bleeding • Breast tenderness • Gastrointestinal symptoms • Dizziness, fainting, syncope • Shoulder tip pain • Rectal pressure or pain on defecation • Asymptomatic	• Pelvic, abdominal and/or adnexal tenderness or fullness • Signs of peritonism • Pallor • Abdominal distension • Cervical motion tenderness (pain on moving the cervix) • Enlarged uterus • Tachycardia, hypotension • Shock, collapse • Orthostatic hypotension

Figure 87.3 Ultrasound image of a caesarean scar ectopic pregnancy.



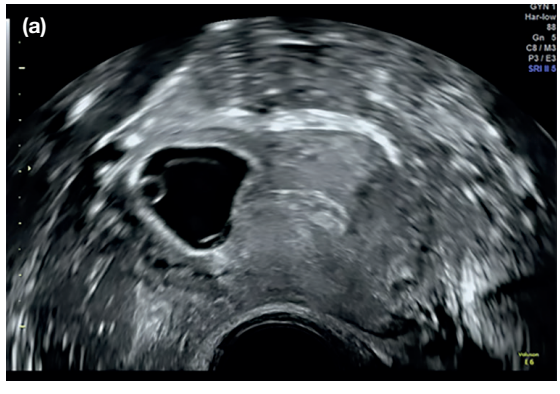


Figure 87.4 Ultrasound image of a tubal ectopic pregnancy.

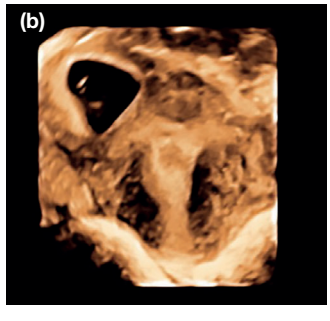

Figure 87.5 (a, b) Ultrasound images of an interstitial ectopic pregnancy.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

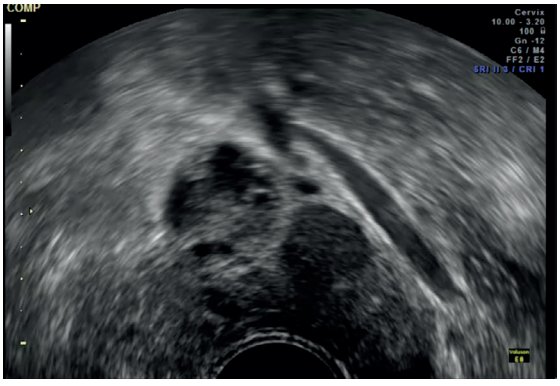

Figure 87.6 Ultrasound image of an ovarian ectopic pregnancy.

The presentation of an ectopic pregnancy is variable and the differential diagnoses include:

- miscarriage;
- urinary tract infection;
- ovarian cyst accident;
- appendicitis.

A transvaginal ultrasound scan should be performed if the diagnosis is suspected (see ***Table 87.1*** for the defining ultrasound characteristics of uterine and extrauterine ectopic pregnancies). The complete absence of an intrauterine gestational sac with a positive pregnancy test increases the probability of an ectopic pregnancy unless the pregnancy is not sufficiently advanced for the sac to be seen on ultrasound scan. An ectopic pregnancy is more likely if free fluid is seen in the pouch of Douglas or an adnexal mass is identified on ultrasound scan.

In equivocal cases, serial measurements of serum βHCG levels, 48 hours apart, can help to establish the diagnosis. A rise in the βHCG level by at least 63% is more indicative of a viable intrauterine pregnancy and an ultrasound scan should be offered between 7 and 14 days. Levels that halve when taken 48 hours apart are more suggestive of a failing pregnancy and a urinary pregnancy test should be repeated after 14 days. Levels that remain static or show a suboptimal increase or decrease over a 48-hour period are more likely to be representative of an ectopic pregnancy. Furthermore, a single level above approximately 1500 IU/L, in association with an empty uterus on ultrasound scan, in the absence of a heavy bleed, is suggestive of an ectopic pregnancy. Laparoscopy can also be used as a diagnostic tool (***Figure 87.7***); occasionally, however, a false-negative diagnosis is obtained when the pregnancy is not sufficiently advanced and is, therefore, too small to be seen within the fallopian tube.

Management of an ectopic pregnancy can be divided into expectant, medical (methotrexate) or surgical treatment. The choice of treatment is dependent on: the haemodynamic stability of the patient; ultrasound features of the ectopic pregnancy (presence of free fluid, presence or absence of fetal cardiac activity); serum βHCG level; and the patient's understanding of the diagnosis, commitment to follow-up and choice.

Expectant management and medical management in the form of methotrexate can be offered to women who are clinically stable and pain free, who have a serum βHCG level

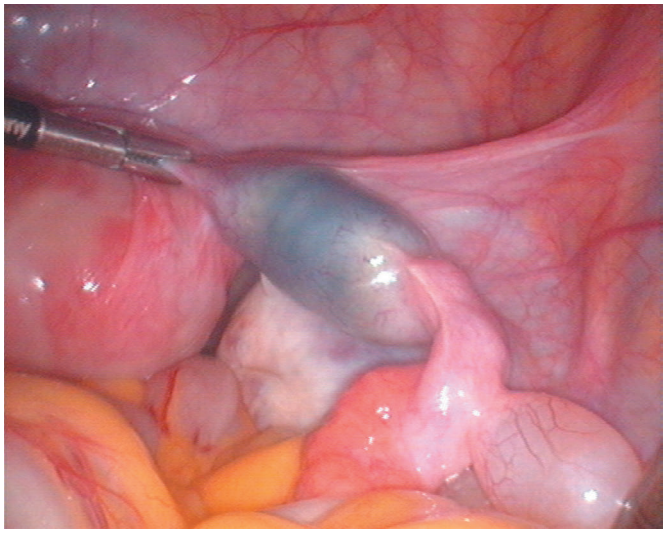

Figure 87.7 Laparoscopic image of a tubal ectopic pregnancy.

<1500 IU/L for expectant management and between 1500 and <5000 IU/L for medical management, who are committed to the follow-up protocol and where the ectopic pregnancy is not alive and measures <35 mm. In these circumstances, repeat serum βHCG levels are recommended on days 4 and 7. A fall of ≥15% is considered reassuring and should be repeated weekly thereafter until <20 IU/L. If the levels deviate from this, then the patient should be reviewed further to plan ongoing management. Women should be advised of the risk of rupture and the need for additional/alternative treatment if the situation should change.

Methotrexate is a folic acid antagonist that interferes with DNA synthesis. Significant side effects include hepatotoxicity. Further pregnancies should be avoided for a minimum of 3 months following treatment with methotrexate. Careful patient selection is vital. Furthermore, some patients fail to respond to this medication and will require surgical management.

Surgical management should be offered to women who prefer to have surgery or those who are unable to commit to follow-up as well as those with significant pain, those who have a rising serum βHCG level of ≥5000 IU/L and/or those in whom the ectopic pregnancy is considered to be live and measures ≥35 mm.

Surgical options include a salpingectomy (removal of the fallopian tube) or salpingostomy (opening of the fallopian tube and extraction of the pregnancy tissue) (***Figure 87.8***). This is ideally performed laparoscopically in a stable patient as it

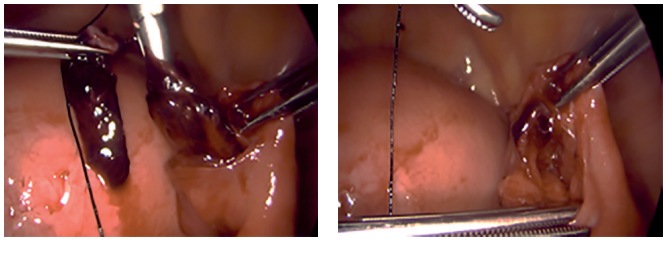

Figure 87.8 Laparoscopic salpingostomy.

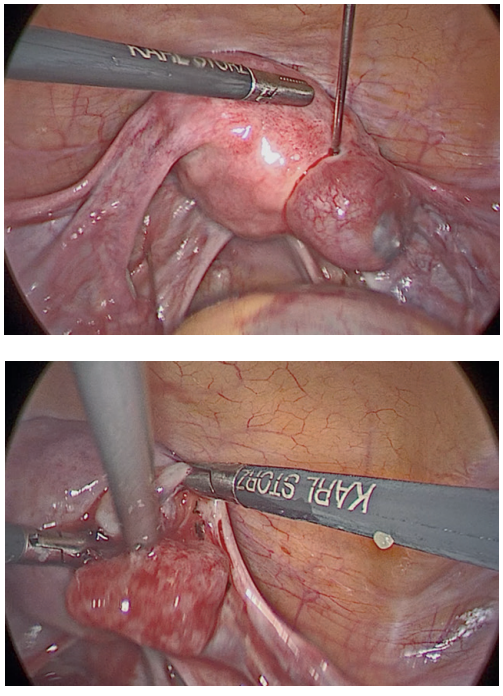

Figure 87.9 Laparoscopy of an interstitial ectopic pregnancy.

is associated with shorter operative times, less intraoperative blood loss, shorter hospital stays and similar subsequent intrauterine pregnancy rates. A laparotomy may be required if the woman is haemodynamically unstable. A salpingectomy is the preferred technique in the presence of a contralateral healthy fallopian tube. A salpingostomy is associated with an 8% risk of persistent trophoblastic tissue, intra-abdominal bleeding and an increased risk of a repeat ectopic pregnancy. These patients are subsequently followed up with serial serum βHCG levels until a negative result is obtained to exclude the presence of residual trophoblastic tissue. If a further ectopic pregnancy occurs within the same fallopian tube, then a salpingectomy is recommended regardless of the condition of the contralateral fallopian tube.

The management of non-tubal ectopic pregnancies (e.g. interstitial ectopic pregnancies [*Figure 87.9*], caesarean section scar ectopic pregnancies) can be complex and associated with more significant complications, such as bleeding, leading to an increased risk of a hysterectomy. These cases are best managed in tertiary centres. The management plan will be guided by the haemodynamic stability of the patient and the location of the ectopic pregnancy, including the expertise of the clinician managing the case.

These patients should be counselled regarding their increased risk of further ectopic pregnancies in subsequent conceptions. In view of this, they are encouraged to present as early as possible in any subsequent pregnancy to establish its location. Anti-D immunoglobin should be administered to non-sensitised rhesus (Rh)-negative women.

ACUTE ABDOMEN

Abdominal pain is one of the most challenging presenting complaints in the emergency department. Common causes of acute lower abdominal pain in the non-pregnant woman include:

- adnexal torsion;
- ovarian cyst accident, e.g. rupture;
- PID;
- endometriosis;
- appendicitis;
- bowel obstruction.

Adnexal torsion

An adnexal torsion is commonly the result of an ovary, and occasionally a fallopian tube, twisting along its pedicle and interrupting its arterial supply, leading to ischaemia. Rapid identification and intervention are necessary to preserve ovarian function. *Table 87.3* lists the presenting characteristics, recommended investigations and management options of an ovarian torsion.

TABLE 87.3 Presenting characteristics, recommended investigations and management options of an ovarian torsion.

Characteristics	
Symptoms and signs	• Abdominal pain (sudden onset) • Nausea/vomiting • Diarrhoea • Abdominal/pelvic tenderness • Palpable adnexal mass • Signs of peritonism • Non-specific and, therefore, a high clinical suspicion is necessary
Risk factors	• Enlarged ovary, e.g. cyst • Para-ovarian cyst • Hydrosalpinx • Previous torsion
Investigations	
Ultrasound	• Unilateral ovarian enlargement and ovarian tissue oedema, with less defined borders. Comparison with the contralateral ovary will show a distinct difference • Peripheral displacement of follicles; follicular ring sign • Central placement of the ovarian/adnexal mass in the suprapubic region • The affected ovary may appear as a solid mass with hypo- and hyperechoic areas, in keeping with haemorrhage and necrosis • The pedicle that is twisted may be seen as a 'whirlpool' that is visible both in grey-scale and on colour Doppler • Abnormal Doppler signals, e.g. coiling of the ovarian vessels (early/subacute), complete absence of perfusion (late) • Free fluid in the pelvis
Bloods	• Raised inflammatory markers (can also be normal)
Management	
Laparoscopy (*Figure 87.10*)	• Detorsion • Ovarian cystectomy to be performed at the same time or at a later date once the ovary is reperfused and the degree of oedema has diminished to reduce the likelihood of an oophorectomy

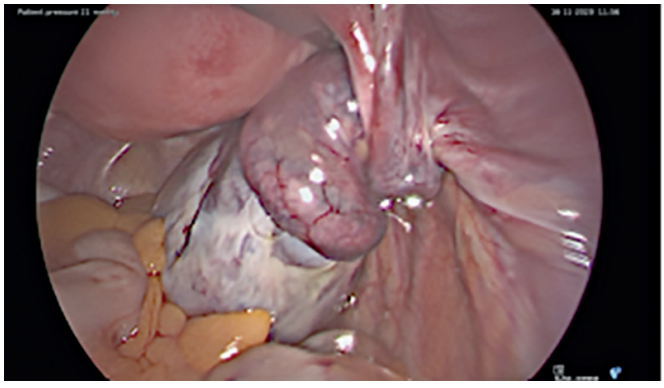

Figure 87.10 Laparoscopic image of ovarian torsion.

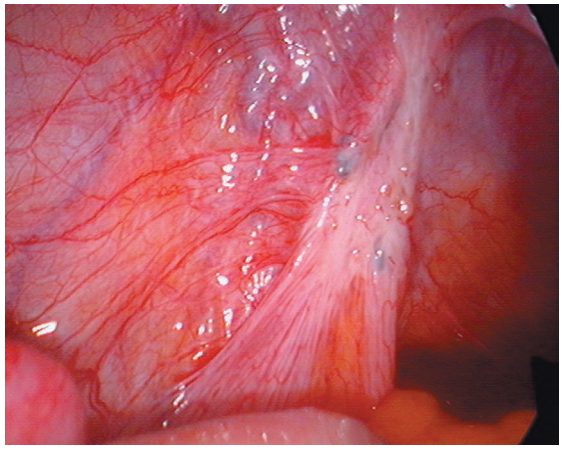

Figure 87.12 Endometriosis seen on the uterosacral ligament.

CHRONIC ABDOMINAL PAIN

Endometriosis

Endometriosis is a common inflammatory condition and is diagnosed by the presence of endometrium-like tissue in extrauterine sites. The most commonly affected sites are the pelvic organs and peritoneum, although distant sites such as the lungs are occasionally affected (resulting in symptoms such as recurrent haemoptysis at the time of menstruation or recurrent pneumothoraces) (***Figure 87.11***). The exact pathognomonic mechanism remains elusive, but it is widely believed that most endometriotic lesions develop from retrograde menstruation. It is estimated to affect 5–10% of women, mainly of reproductive age, with the incidence reported to be higher in certain subgroups, e.g. women with a history of infertility. Endometriosis may be associated with a number of symptoms, but the predictive value of any one symptom or set of symptoms remains uncertain as each can have other causes (e.g. irritable bowel syndrome or interstitial cystitis), with a significant proportion of affected women remaining asymptomatic. The most common symptom is pain. Other symptoms include: cyclical and non-cyclical pain; dysmenorrhoea (pain related to menstruation); deep dyspareunia (pain during intercourse); dyschezia (pain on opening the bowels); and dysuria. Many women also suffer from fatigue, haematuria, chronic pelvic pain, infertility and rectal bleeding (haematochezia).

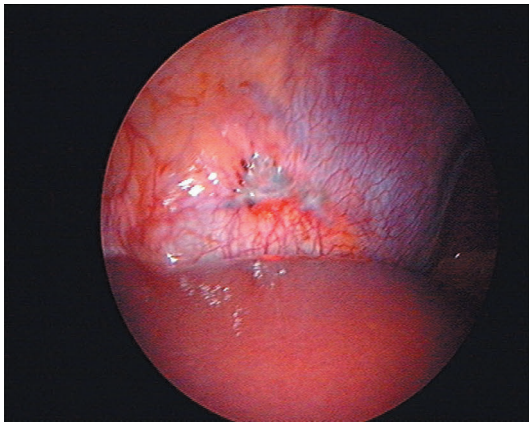

Figure 87.11 Endometriosis seen on the peritoneal surface of the diaphragm.

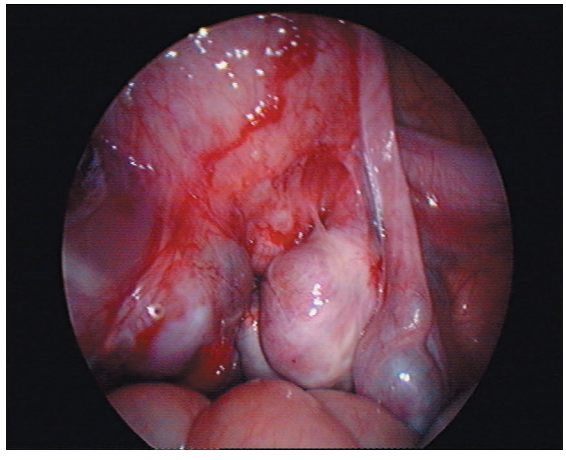

Figure 87.13 Bilateral ovarian endometriosis with pelvic adhesions.

The extent of the disease varies from a few small peritoneal lesions on otherwise normal pelvic organs to deep endometriosis and large ovarian endometriotic cysts (endometriomas). The identification of endometriomas has been synonymous with deep disease. There can be extensive fibrosis in structures such as the uterosacral ligaments (***Figure 87.12***), and adhesion formation causing marked distortion of the pelvic anatomy (***Figure 87.13***). Disease severity can be assessed by describing the operative findings, or quantitatively using various classification systems, but there is little correlation between such systems and the type or severity of symptoms experienced.

Endometriosis typically appears as superficial 'powder burn' or 'gunshot' lesions on the ovaries, serosal surfaces and peritoneum – black, dark brown or bluish puckered lesions, nodules or small cysts containing old haemorrhage surrounded by a variable extent of fibrosis. Atypical or 'subtle' lesions are also common, including red implants (petechial, vesicular, polypoid, haemorrhagic, red flame-like) and serous or clear vesicles. Other appearances include white plaques or scarring and yellow-brown discoloration of the peritoneum. Ovarian

endometriomas usually contain thick fluid-like tar and have been reported in 17–44% of women with endometriosis. They are distinguishable from simple haemorrhagic ovarian cysts because typically they are densely adherent to the peritoneum of the ovarian fossa, fallopian tube and posterolateral aspect of the uterus. The surrounding fibrosis may also involve the bowel. Deep endometriosis represents another disease type. This is defined by the presence of endometrium-like tissue 5 mm beneath the peritoneum, with growth seen in the uterosacral ligaments, vagina, bowel, bladder or ureters; when such lesions grow into the vagina they may be visible on speculum examination as 'blue-domed' cystic lesions in the posterior fornix. Lesions infiltrating the bowel may mimic cancer in their presentation.

The gold standard for making a diagnosis of endometriosis is through laparoscopy with histological confirmation; non-invasive diagnostic tools, such as ultrasound scanning (transvaginal and transrectal), can reliably detect only severe forms of the disease, i.e. endometriomas or deep endometriosis of the pelvis. MRI can detect haemosiderin deposits in abdominal organs to suggest deep endometriosis. A sigmoidoscopy may also provide additional information on the level of disease involvement in cases of deep endometriosis involving the bowel. The distance between the inferior border of a bowel lesion and anal verge can impact on the proposed surgical intervention and degree of associated risks. Excision of low rectal lesions (5–8 cm from the anal verge) has been associated with a higher risk of anastomotic leaks and transient neurogenic bladder dysfunction.

Finding pelvic tenderness, a fixed retroverted uterus, tender uterosacral ligaments or enlarged ovaries on examination is suggestive of endometriosis. The diagnosis is more certain if deeply infiltrating nodules are found on the uterosacral ligaments or in the pouch of Douglas and/or visible lesions are seen in the vagina or on the cervix. A digital rectal examination should also be conducted to assess for disease involving the rectosigmoid area, as well as lateral and dorsal extension of the disease suggesting involvement of the hypogastric vessels and/or nerves. The findings may, however, be normal.

The treatment options are limited because the cause is uncertain. These include: conservative management; medical management (simple analgesia or hormonal drugs to suppress ovarian function [progestogens, the levonorgestrel intrauterine system, gonadotropin-releasing hormone agonists in conjunction with add-back hormone replacement therapy]); and surgical management (ablation or excision of endometriotic lesions). Women may require multiple admissions for surgery and/or prolonged treatment with costly drugs that can have problematic side effects. Surgical planning needs to be aware of the proximity of the disease to the ureter and the risk of ureteric stricture leading to hydronephrosis and renal dysfunction. The surgical risks include those for any laparoscopic procedure, including damage to the bowel, bladder and ureters (2 in 1000 women); the risks are increased if deep endometriosis is present secondary to anatomical displacement of structures such as the ureter, as well as in repeat surgical cases where repeated ureterolysis can increase the risk of ureteral ischaemia and repeated bowel shavings can reduce the integrity of the bowel wall increasing the risk of fistula formation. Bowel resection or injury increases the risk of faecal peritonitis. Bowel integrity can be assessed by stretching the bowel over a rectal manipulator to identify thinned areas, filling the pelvis with fluid and then pushing air into the rectal lumen whilst looking for bubbles or injecting methylene blue in the rectum and looking for leaks. Consideration should be given to ureteral stent insertion in cases of bladder endometriosis close to the trigonum which can usually be removed after approximately 6 weeks. A catheter will be needed for 8–10 days postoperatively, followed by a cystogram checking for suture integrity prior to removal. Rarely, infection in an endometrioma will result in the formation of a tubo-ovarian abscess.

For a woman who has completed her family, hysterectomy plus bilateral salpingo-oophorectomy with total excision of endometriotic disease offers a good chance of cure. Surgical treatment, however, in a woman who wishes to retain her fertility needs to be as conservative as possible, ensuring that ovarian function is preserved. The aim is to remove the endometriotic tissue while restoring the pelvic anatomy. The preferential method to retain ovarian function is ovarian drainage with directed spot ablation (electrocoagulation, thermal coagulation, laser or plasma energy) over cystectomy. Counselling needs to include the increased risk of recurrence with cyst drainage versus a cystectomy, as well as consideration for preoperative oocyte cryopreservation, especially in the presence of bilateral ovarian disease. Furthermore, bowel shaving versus bowel resection is associated with the risk of incomplete disease resection.

Several classification and staging systems have been proposed for the diagnosis, management and prognosis of endometriosis. Currently, there is a need for an internationally accepted system. The endometriosis fertility index has demonstrated good predictive value in the determination of fecundity after endometriosis surgery. Endometriosis is also associated with an increased risk of ovarian cancer (endometrioid and clear-cell types) and non-Hodgkin's lymphoma, adding to the burden of the disease.

Adenomyosis

Adenomyosis is a benign uterine disorder characterised by the presence of ectopic endometrium or endometrium-like structures within the myometrium accompanied by smooth muscle hypertrophy or hyperplasia. The ectopic endometrium can be present either diffusely or focally within the myometrium. The complexity of the condition is contributed to by its variable presentation and difficulty in making an accurate diagnosis, and, subsequently, its management. The true prevalence of the condition is unknown because of variable diagnostic criteria, and ranges from 1% to 70%. ***Table 87.4*** outlines the presenting characteristics, recommended investigations and management options.

Thomas Hodgkin, 1798–1866, curator of the museum and demonstrator of morbid anatomy, Guy's Hospital, London, UK.

TABLE 87.4 Presenting characteristics, recommended investigations and management options for adenomyosis.

Presenting characteristics	
Symptoms	• Non-specific • Dysmenorrhoea • Abnormal uterine bleeding • Chronic pelvic pain • Subfertility • Presentation in the fourth and fifth decades of life • Asymptomatic • Dyspareunia
Signs	• Uterine enlargement • Uterine tenderness • Abnormalities identified at hysteroscopy (irregular endometrium with endometrial defects, cystic haemorrhagic lesions, altered vascularisation)
Risk factors	• Increased/longer oestrogen exposure (early menarche [≤10 years of age], short menstrual cycles [≤24 days in length], elevated body mass index, oral contraceptive use, increasing age, tamoxifen use) • Spontaneous miscarriage and multiple pregnancies • Increasing parity • Uterine instrumentation/incision (caesarean sections, surgical termination of pregnancy, SMM, endometrial curettage) • Endometrial hyperplasia • Leiomyomas that breach the endometrial–myometrial interface • Endometriosis • Smoking
Diagnosis	
Ultrasound	• The Morphological Uterus Sonographic Assessment (MUSA) group recommends commenting on eight morphological features in its classification of adenomyosis (presence, location, differentiation, cystic or non-cystic, myometrial layer, the extent of disease, size of the lesion and vascularity). Typical features include an enlarged globular uterus with asymmetrical thickening of the myometrium, myometrial cysts, echogenic subendometrial lesions, hyperechogenic islands, fan-shaped shadowing, an irregular junctional zone and vascularity on colour Doppler (*Figures 87.14–87.17*) • Three or more sonographic criteria are usually required to make a diagnosis of adenomyosis
Magnetic resonance imaging	• Can help differentiate an adenomyoma from fibroids
Histology	• Historically obtained at the time of hysterectomy; considered the gold standard • Limited in those wishing to preserve their fertility
Management	
Medical management	• Analgesia (i.e. NSAIDs) • Hormonal preparations (i.e. levonorgestrel IUS [off-label use]; combined oral contraceptive pill; progestogens, i.e. dienogest; GnRH agonists and antagonists; danazol; aromatase inhibitors, i.e. letrozole; selective progesterone receptor modulators)
Radiological interventions/ minimally invasive treatment options	• HIFU or MRgFUS: adverse effects include abdominal pain, skin burns and leg pain secondary to thermal injury of the sciatic nerve, intestinal perforation and temporary acute renal failure • UAE: postembolisation syndrome is reported, which consists of pelvic pain, nausea, fever secondary to necrosis and haematoma formation at the femoral artery puncture site. In addition, complications such as those associated with radiation exposure, haemorrhage, unplanned surgery, infections and an age-related impairment of ovarian reserve have also been reported
Surgical management (uterus preserving) (adenomyomectomy)	Different techniques: • Non-excisional surgical techniques (thermal coagulation of diseased myometrium) • Partial reduction surgeries (i.e. for diffuse adenomyosis including wedge resections, wedge-shaped uterine wall removal, modified reductive surgery and transverse H incisions) • Complete adenomyotic excision (i.e. for focal adenomyosis including the double- or triple-flap method and asymmetric dissection method)
Surgical management (non-uterine preserving)	• Hysterectomy: a total hysterectomy is preferred over a subtotal procedure as recurrence of the disease has been reported within the cervical stump and rectovaginal septum • Endometrial ablation/resection
Postoperative complications	• Uterine rupture (6% [>1% following an adenomyomectomy versus 0.26% following a myomectomy]), silent uterine rupture • Higher incidence of placenta accreta, increta and percreta compared with caesarean sections and myomectomies • Asherman's syndrome • Disease recurrence

GnRH, gonadotropin-releasing hormone; HIFU, high-intensity focused ultrasound; IUS, intrauterine system; MRgFUS, magnetic resonance-guided focused ultrasound; NSAID, non-steroidal anti-inflammatory drug; SMM, surgical management of miscarriage; UAE, uterine artery embolisation.

Joseph (Gustav) Asherman, 1889–1968, Czech–Israeli gynaecologist. This syndrome was first described by Heinrich Fritsch in 1894, Asherman further characterised it in 1948.

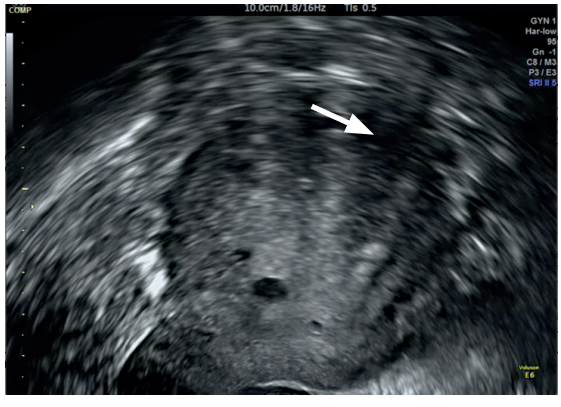

Figure 87.17 Ultrasound features of adenomyosis. Fan-shaped shadowing (arrow).

ABNORMAL UTERINE BLEEDING IN THE NON-PREGNANT STATE

Bleeding in the non-pregnant state may occur at the time of an expected menstrual period, between periods (intermenstrual bleeding; IMB), after intercourse (postcoital bleeding; PCB) or following the menopause (postmenopausal bleeding; PMB). Menopause is diagnosed in women who have not had a menstrual period after 12 months without the use of hormonal contraception. Vaginal bleeding may also occur after surgical instrumentation of the uterus and/or cervix, including insertion of an IUCD. The principal causes of uterine and vaginal bleeding in the non-pregnant state can be divided into structural and non-structural causes (***Table 87.5***) and their relationship to menses or coitus (***Table 87.6***).

The mainstay of management is to identify and treat the associated pathology. Investigations include a pregnancy test and ultrasound assessment of the pelvic anatomy (two-dimensional/three-dimensional ultrasound scan or saline sonogram) as well as an endometrial biopsy of the uterine cavity, performed either under direct vision at hysteroscopy or blindly with a Pipelle® biopsy. Hysteroscopy combined with endometrial biopsy improves the sensitivity and specificity for detection of endometrial pathology compared with either performed alone (***Figure 87.18***). The indications for undertaking an endometrial biopsy are shown in ***Summary box 87.2***. A colonoscopy may also be indicated to exclude colorectal pathology as a potential cause for the bleeding.

Women taking tamoxifen, a selective oestrogen receptor modulator used in the treatment of breast cancer, represent a special group as the drug can induce uterine abnormalities in 10–40% of women, such as the development of endometrial polyps, hyperplasia, cancer and, rarely, uterine sarcomas, which are much more aggressive. Tamoxifen treatment results in a doubling of the risk of endometrial cancer after 1–2 years and has a quadrupling effect after 5 years. The relationship is time dependent but dose independent. The risk does not decrease on cessation of treatment. There is no consensus regarding the need for screening and which method to use; the alternative, more common approach is to investigate only those women who develop abnormal uterine bleeding with tamoxifen use. Aromatase inhibitors such as anastrozole, letrozole and exemestane are also used in the treatment of breast cancer, but their effects are not mediated via the oestrogen receptor so they have been associated with less endometrial pathology than tamoxifen. They may also reverse abnormalities induced by tamoxifen use.

TABLE 87.5 Structural and non-structural causes of uterine and vaginal bleeding.

Structural	• Endometrial or endocervical polyp • Fibroids (leiomyoma) • Endometrial hyperplasia • Malignancy of the genital tract
	• Endometriosis • Adenomyosis • Coagulopathy, e.g. thrombocytopenia, von Willebrand's disease • Ovulatory dysfunction, e.g. polycystic ovary syndrome • Endometrial, e.g. endometritis • Iatrogenic, e.g. exogenous sex steroid administration, IUCD, hormonal contraceptive use • Other, e.g. arteriovenous malformations, chronic renal/hepatic disease

IUCD, intrauterine contraceptive device.

TABLE 87.6 Uterine and vaginal bleeding in the non-pregnant state in relation to menstrual bleeding.

Menstrual	• Endometrial polyp/malignancy[a] • Fibroids
Intermenstrual	• Vaginal trauma/malignancy[a] • Cervical polyp/malignancy • Endometrial polyp/malignancy[a]
Postcoital	• Vaginal malignancy[a] • Cervical ectropion/polyp/malignancy

[a]These cancers occur principally in postmenopausal women.

Summary box 87.2

Indications for an endometrial biopsy

Endometrial biopsy should be considered in the following cases:

- Women with suspected endometrial pathology
- All women >45 years old in whom medical treatment has been unsuccessful
- Women with persistent intermenstrual bleeding
- Endometrial thickness >4 mm in postmenopausal women or persistently thickened or abnormal appearance of the endometrium in premenopausal women and endometrial thickness >7 mm in women with known polycystic ovarian syndrome
- Irregular or unscheduled bleeding while on hormone replacement therapy after the initial 3 months
- Younger women with major risk factors for endometrial hyperplasia/cancer:
  - Polycystic ovarian syndrome
  - Obesity
  - Treatment with tamoxifen
- Irregular bleeding while on unopposed oestrogen
- Irregular bleeding in high-risk populations, such as family history of endometrial/colon cancer, especially hereditary non-polyposis colorectal cancer

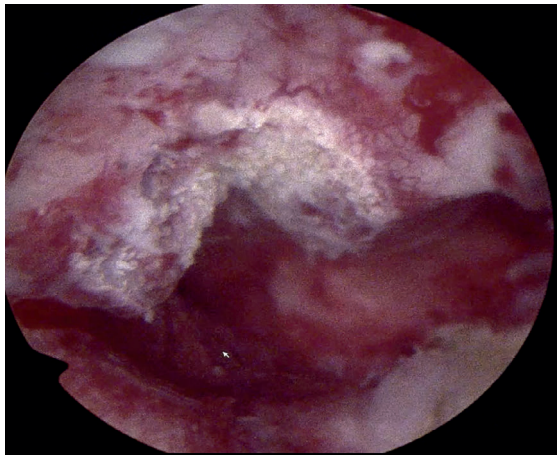

Figure 87.18 Hysteroscopic biopsy of endometrial cancer (cystic endometrium is visible at hysteroscopy).

Women known to have Lynch syndrome (hereditary non-polyposis colorectal cancer) and those considered at risk of inheriting a mismatch repair gene abnormality are another special group, as their lifetime risk of developing endometrial cancer is as high as 60%. Unlike sporadic cases of endometrial cancer, which are usually diagnosed during the sixth and seventh decades, the mean age at diagnosis in Lynch syndrome is the fifth decade. However, it appears that the 5-year survival rate in patients with Lynch syndrome-associated endometrial cancer is similar to that in women with sporadic disease. International guidelines suggest that these women should be screened annually from the age of 35 years with transvaginal ultrasound to measure the endometrial thickness and an endometrial biopsy.

Abnormal bleeding can also be caused by invasive carcinoma of the cervix, the incidence of which has been reduced by screening programmes that aim to detect the precancerous state, cervical intraepithelial neoplasia (CIN), using cervical cytology. The sample is checked for high-risk serotypes of human papillomavirus (HPV) (16, 18, 31 and 33) that can cause changes to the cervical cells. If these types of HPV are not identified on the sample, then no further action is required. If, however, these high-risk HPV serotypes are identified, the sample is checked for cervical cell changes, with the aim of treating these before they get a chance to turn into cervical cancer. In the UK, this is carried out every 3 years in women aged 25–49 years, and every 5 years in women aged 50–64 years. In women aged 65 years or older, a cervical screen will be conducted if one of the last three tests was abnormal or no test had been performed since the age of 50 years. Abnormalities in cervical cytology are followed up by microscopic examination of the cervix (colposcopy). CIN may be treated with local ablation (cryocautery, cold coagulation, electrocoagulation or laser) or excision (large loop excision of the transformation zone [LLETZ]).

Erik Adolf von Willebrand, 1870–1949, physician, Helsinki, Finland.
Henry T Lynch, 1928–2019, Professor of Preventative Medicine, Creighton University, Omaha, NE, USA, discovered familial susceptibility to certain kinds of cancer.

TABLE 87.7 Investigation and management of heavy menstrual bleeding.

Investigations	
Radiological imaging	TVUS has high sensitivity and specificity; MRI may be indicated if the women declines a TVUS or the findings are unclear. Identification of potential pathology such as polyps, fibroids
Hysteroscopy and histology	Direct visualisation of pathology with guided samples taken for histopathology
Management	
Medical management	• Tranexamic acid, NSAIDs (off-label use) • Oestrogen suppression with hormonal treatments (i.e. levonorgestrel IUS [after 1 year of use, there is a 71–95% reduction in menstrual blood loss with approximately 50% of women becoming amenorrhoeic], combined oral contraceptive pill [off-label use], progestogens, i.e. desogestrel [off-label use], GnRH agonists with or without add-back hormone replacement therapy) • GnRH agonists aim to shrink fibroids by inducing a hypo-oestrogenic state. This class of drug, however, is limited by its association with a loss in bone mineral density; in addition, fibroids tend to regrow to their original size when treatment is discontinued • Ulipristal acetate (Esmya®), an SPRM, is only licensed for use in premenopausal women in whom surgical procedures (including uterine fibroid embolisation) are not appropriate or have not worked. This drug should be used with caution as it has been associated with severe liver injury and liver function should be monitored during its use
Radiological interventions/minimally invasive treatment options	• HIFU or MRgFUS: adverse effects include abdominal pain, skin burns and leg pain secondary to thermal injury of the sciatic nerve, intestinal perforation and temporary acute renal failure • UAE involves blocking the blood supply to the fibroids using a technique in which particles are embolised into each uterine artery via an angiographic catheter (*Figure 87.19*). This technique has shown more value in the presence of a single large fibroid than in a multifibroid uterus. Postembolisation syndrome is reported, which consists of pelvic pain as a result of uterine ischaemia, nausea, fever secondary to necrosis and haematoma formation at the femoral artery puncture site. In addition, complications such as those associated with radiation exposure, haemorrhage, unplanned surgery, infection, thrombosis and an age-related impairment of ovarian reserve have also been reported
Surgical management (uterus preserving)	• Hysteroscopic polypectomy (risks include uterine perforation; damage to surrounding organs) • Transcervical resection of fibroids (complications include hyponatraemic fluid overload and thermal injury to surrounding structures) • Myomectomy (open or laparoscopic [*Figure 87.20*]). Surgical complications include bleeding and damage to surrounding structures, with the risk of conversion to a hysterectomy <1% secondary to excessive bleeding. Morcellation is described in further detail in *Uterine fibroids (leiomyoma)*
Surgical management (non-uterine preserving)	• Endometrial ablation/resection (risks include thermal injury to surrounding organs and fluid overload; not recommended in women wishing to retain their fertility). The aim of ablative methods is to reduce the menstrual bleeding by ablating the endometrium down to the basalis layer using electrical, thermal or laser energy. More than 90% of women report a reduction in menstrual blood loss without the need for further treatment at 2 years of follow-up, with 25–35% experiencing amenorrhoea. The criteria for endometrial ablation are described in *Table 87.8* • Hysterectomy: a total hysterectomy is preferred over a subtotal procedure as persistence of symptoms is reported within the cervical stump (risks include damage to surrounding organs and fistula formation)

GnRH, gonadotropin-releasing hormone; HIFU, high-intensity focused ultrasound; IUS, intrauterine system; MRgFUS, magnetic resonance-guided focused ultrasound; MRI, magnetic resonance imaging; NSAID, non-steroidal anti-inflammatory drug; SPRM, selective progesterone receptor modulator; TVUS, transvaginal ultrasound scan; UAE, uterine artery embolisation.

Cervical cancer is one of the leading causes of mortality in the world. To improve the uptake of the cervical screening programme, testing for HPV in the comfort of a woman's own home is being investigated.

Current vaccination programmes against HPV serotypes are aimed at reducing the incidence of cervical carcinoma. In the UK, the vaccination is currently offered to girls and boys aged 12–13 years with a repeat dose offered 6–24 months later, prior to becoming sexually active. The vaccine helps protect against mouth, throat, anal and genital cancers as well cervical cancer.

Menstrual bleeding may be excessively heavy, irregular or frequent in the absence of pathology; this is known as dysfunctional uterine bleeding. NICE guidance in the UK has suggested a three-step hierarchal treatment approach to the management of heavy menstrual bleeding (*Table 87.7*).

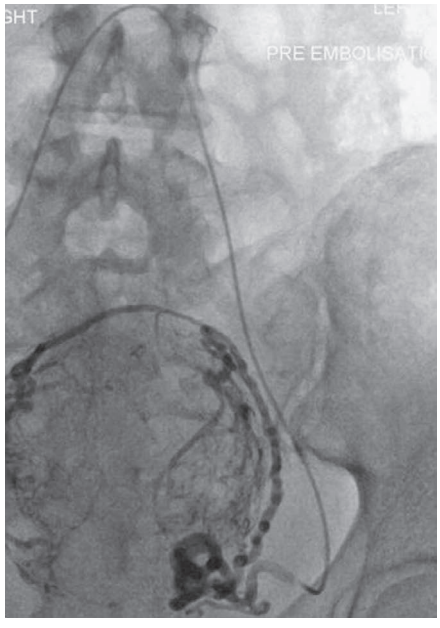

Figure 87.19 Pre-embolisation angiogram showing catheterisation of the left uterine artery and blood supply to a large fundal fibroid (courtesy of Dr Mark Bratby, Consultant Vascular and Interventional Radiologist, John Radcliffe Hospital, Oxford, UK).

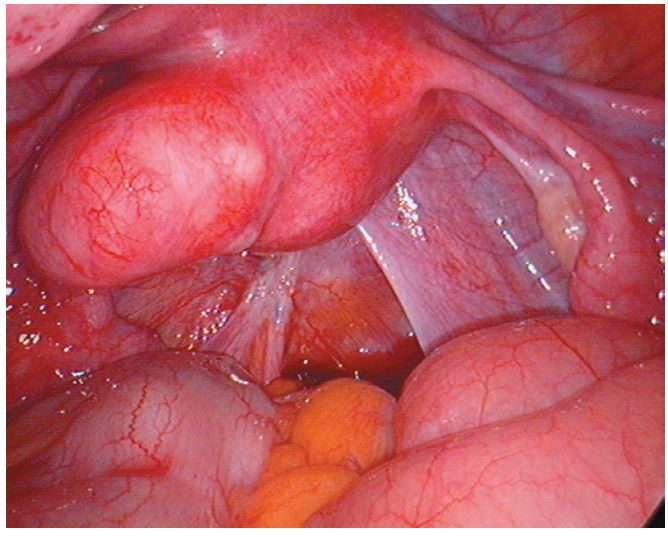

Figure 87.20 Laparoscopic view of a uterine fundal fibroid.

TABLE 87.8 Criteria for endometrial ablation.

- Uterus <10 cm in length
- Absence of major intrauterine pathology that would distort the uterine cavity
- No history of previous endometrial ablation procedures
- No evidence of endometritis
- Family is complete

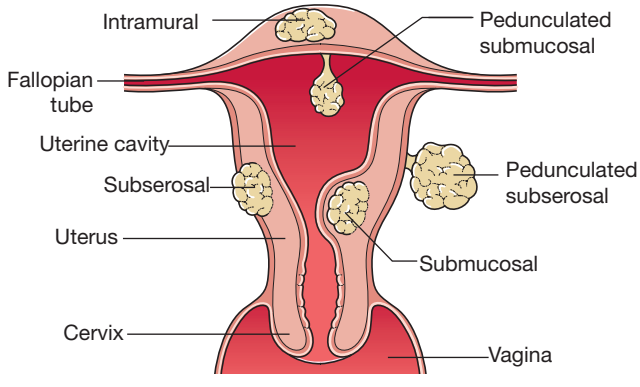

Figure 87.21 Uterine fibroids.

The management plans are individualised for the patient, taking into account concomitant symptoms and fertility requirements.

A hysterectomy can be carried out by three different routes: vaginally, abdominally or laparoscopically. The route of entry is dependent on a number of factors, including: uterine size; presence of other pathology; mobility and descent of the uterus; history of previous surgery; and skill of the operating surgeon. No difference in prolapse symptoms, sexual satisfaction or pelvic pain has been reported between a total or subtotal (conservation of the cervix) hysterectomy. Furthermore, it is now recommended that the fallopian tubes are removed in conjunction with the uterine body, whether the ovaries are conserved or not. The fallopian tubes have no continued functionality following a hysterectomy but can be a potential source of malignancy if retained. Conservation or removal of the ovaries is dependent on the woman's age, presence of coexisting pathology and/or risk factors for malignancy.

Uterine fibroids (leiomyoma)

Fibroids are usually benign, well-circumscribed, smooth muscle tumours of the uterus. Less than 1% of fibroids undergo malignant transformation (leiomyosarcoma). They are more common in certain populations (African–Caribbean women) and vary in size and number. They are typically found in the following locations (***Figure 87.21***):

- Subserosal: may cause pressure-type symptoms; if pedunculated, they can be difficult to distinguish from an ovarian tumour.
- Intramural: may similarly cause pressure-type symptoms; can be associated with infertility and heavy periods if they lead to endometrial distortion.
- Submucosal: associated with infertility, recurrent pregnancy loss and heavy periods; if pedunculated, they may occasionally extrude through the cervical os.
- Rare: sites include the broad ligament and cervix.

Women with uterine fibroids may present with heavy and/or irregular menstrual bleeding, anaemia, pressure-type symptoms or infertility, especially if the fibroid is distorting the uterine cavity. The pressure-type symptoms can include pelvic discomfort, urinary incontinence, frequency and retention, constipation and backache. When large fibroids are present, back pressure may cause or exacerbate varicosities. Although these symptoms are common, it is important to note that some women with fibroids are asymptomatic. Rarely, women may present acutely with pain arising from torsion of a pedunculated fibroid or red degeneration, especially in pregnancy.

A diagnosis can usually be made on bimanual and/or abdominal examination, in the presence of an enlarged uterus with attached swellings. The principal differential diagnosis is an ovarian tumour; in general, if an ovarian tumour is present, the uterus is felt separately on vaginal examination, although not if the structures are adherent to each other. A pelvic ultrasound scan is the first-line investigation with high sensitivity and specificity. An MRI can be performed if an ultrasound is declined by the patient or is inconclusive (***Figure 87.22***).

Treatment can be divided into: conservative if the woman is asymptomatic; medical to reduce the quantity of menstrual bleeding; hormonal manipulation to control menstrual bleeding or to shrink the fibroids; or surgical (uterus-preserving or non-uterus-preserving methodologies) (***Table 87.7***). The choice of treatment depends upon the woman's age and fertility intentions, the size and number of fibroids as well as their location. Emergency surgical treatment is only required if there is substantial menstrual bleeding or uncontrollable pain; these are rare events.

Morcellation

This is the process whereby larger tissue is broken down into smaller pieces, facilitating their removal through smaller incisions in the abdomen. In gynaecology, this is usually offered in the context of a laparoscopic myomectomy to remove fibroids or a laparoscopic subtotal hysterectomy to remove the body of the uterus. This procedure is undertaken with an instrument called a morcellator. The risks associated with morcellation include parasitic spread of tissue where the cut tissue deposits itself elsewhere and grows (1:120 to 1:1200) and the upstaging of previously undiagnosed malignancies (noting that this is also considered a risk during an open myomectomy if the fibroid capsule is breached), as well as missed malignancies owing to lost anatomy. Retrieval bags have been proposed to prevent dissemination of the tissue but the evidence regarding their use is currently awaited. In view of this, careful case selection is important. The risk of an uterine sarcoma increases as age increases, in the perimenopausal and postmenopausal stages of life, in the presence of *BRCA* mutations and Lynch syndrome, and in the context of rapidly growing fibroids non-responsive to oestrogen deprivation.

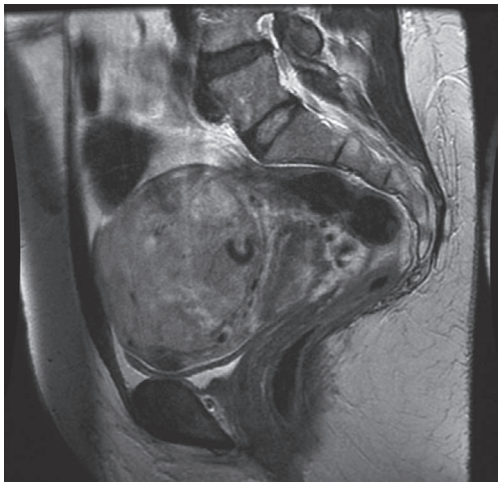

Figure 87.22 Magnetic resonance imaging of uterine fibroids.

UROGYNAECOLOGY

Urinary incontinence

Urinary incontinence is defined as the involuntary leakage of urine. It is said to affect approximately 30% of women, with a higher prevalence seen in older age groups. It can have a significant impact on quality of life.

Incontinence can be classified into:

- stress urinary incontinence (SUI) (involuntary leakage of urine secondary to increased intra-abdominal pressure, e.g. coughing, sneezing);
- overactive bladder (OAB); urinary urgency, usually with urinary frequency and nocturia, with or without urinary incontinence;
- mixed urinary incontinence (combination of both OAB and SUI).

It can result from both functional and anatomical causes, including:

- multiparity;
- childbirth complications and vaginal delivery;
- risng female age - menopause;
- fistulae;
- urethral diverticulum/congenital anomalies, e.g. ectopic ureters;
- immobility, constipation or urinary tract infection;
- chronic medical conditions, e.g. congestive heart failure, diabetes mellitus, multiple sclerosis;
- medications, e.g. loop diuretics;
- secondary to pelvic masses;
- obesity and weight gain.

Common symptoms and complaints include:

- storage symptoms:
  - frequency (increased frequency of more than eight times during the day)
  - urgency
  - nocturia (increased frequency of voiding more than once a night)
- emptying symptoms:
  - hesitancy
  - slow stream
  - incomplete emptying
  - straining to urinate
- urinary leakage with exertion/coughing

- haematuria (in women >40 years of age, additional investigations should be performed to rule out malignancy).

Investigations include:

- urinary incontinence-specific symptom and quality of life questionnaire, including a bladder diary;
- digital examination;
- urine analysis and a midstream urine sample for microscopy, culture and sensitivity;
- urodynamics, including an assessment of postvoid residual volumes – if conservative measures have failed, the type of incontinence is unclear or there is a recurrence of symptoms following surgical intervention;
- ultrasound of the kidneys, ureters and bladder in patients with recurrent urinary tract infections/haematuria;
- cystoscopy if pathology is suspected.

Management can be divided into conservative methods, medical therapy or surgical intervention (***Tables 87.9–87.11***). The treatment of choice is dependent on the underlying cause.

Treatments can be combined and are individualised for the patient. Should initial therapy be unsuccessful or repeat procedures be required, then the patients should be discussed within a multidisciplinary team (MDT) setting.

TABLE 87.9 Management options for overactive bladder (OAB).

Conservative	• Lifestyle changes (i.e. limit fluid intake, avoid diuretics such as tea/coffee, weight loss) • Behavioural modification (e.g. bladder drills) for a minimum of 6 weeks • Review of coexistent medications (e.g. diuretics) • Pelvic floor training (physiotherapy) for at least 3 months, comprising at least eight contractions three times per day • Bladder catheterisation-intermittent self catheterisation if increased post void residuals
Medical therapy	• Anticholinergics (e.g. oxybutynin [avoid in elderly frail women at risk of cognitive impairment], tolterodine); side effects include a dry mouth and constipation • Selective β_3-adrenoreceptor agonist (e.g. mirabegron) for the management of urge incontinence • Desmopressin specifically used to treat symptoms of nocturia
Surgical	• Intravesical botulinum toxin A • Neuromodulation (tibial nerve stimulation or sacral neuromodulation) • Bladder reconstruction (augmentation cystoplasty – risks include bowel disturbance, metabolic acidosis, mucus production and/or retention in the bladder, urinary tract infection, urinary retention and malignancy) • Urinary diversion only when non-surgical management has failed and if botulinum toxin type A, percutaneous sacral nerve stimulation and augmentation cystoplasty are not appropriate or are unacceptable

TABLE 87.10 Management options for stress urinary incontinence (SUI).

Conservative	• Pelvic floor training (physiotherapy) for at least 3 months, comprising at least eight contractions three times per day • Management of a persistent cough • Bladder catheterisation-intermittent self catheterisation if increased post void residuals
Medical therapy	• Serotonin and noradrenaline (norepinephrine) reuptake inhibitors (e.g. duloxetine) (can be used when conservative measures have failed and surgical treatment is contraindicated or declined)
Surgical	• Colposuspension (bladder neck suspension) • Autologous rectus fascial sling procedures and retropubic midurethral mesh slings • Periurethral bulking agents • Artificial urinary sphincter • Do not offer: anterior colporrhaphy; needle suspension; paravaginal defect repair; porcine dermis sling; the Marshall–Marchetti–Krantz procedure

TABLE 87.11 Management options for specific conditions causing urinary incontinence.

Pelvic masses	• Surgical approach, e.g. myomectomy or hysterectomy
Recurrent urinary tract infections	• Antibiotics – treatment, low dose prophylaxis, rescue course • 3 month course of vaginal oestrogen in post menopausal women
Fistulae or ectopic ureters	• Surgical correction

Uterovaginal prolapse

Pelvic organ prolapse refers to the protrusion or displacement of the pelvic organs from their normal anatomical position into or through the vagina to varying degrees (***Figure 87.23***). It is said to affect up to 40% of women at some point in their lifetime. A prolapse can have a detrimental impact on normal organ performance, including anorectal, urinary and sexual function.

A prolapse is more common in certain groups, including:

- older women;
- parous women, increased parity, prolonged labours, vaginal deliveries;
- obese women;
- women who have chronic constipation;
- women with occupations that involve heavy lifting;
- women with oestrogen deficiency;
- women with a family history or genetic risk;
- women with connective tissue disorders, e.g. Ehlers–Danlos syndrome, Marfan syndrome.

Edvard Laurits Ehlers, 1863–1937, dermatologist, Copenhagen, Denmark.
Henri-Alexandre Danlos, 1844–1912, dermatologist, Paris, France.
Antoine Bernard-Jean Marfan, 1858–1942, paediatrician, Paris, France.

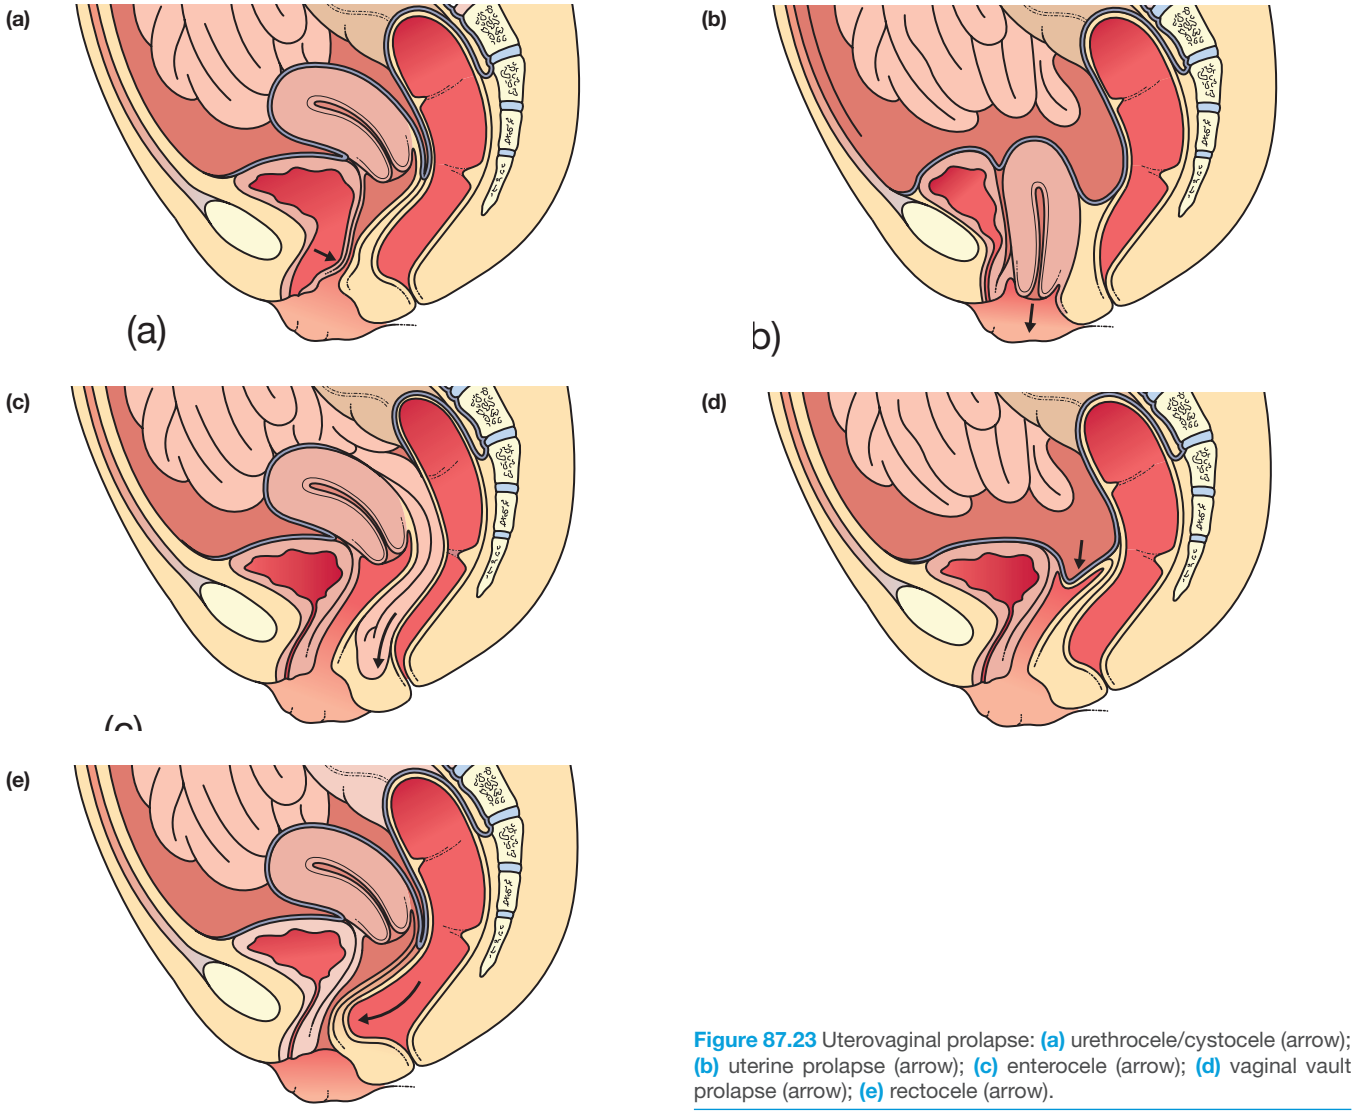

Figure 87.23 Uterovaginal prolapse: **(a)** urethrocele/cystocele (arrow); **(b)** uterine prolapse (arrow); **(c)** enterocele (arrow); **(d)** vaginal vault prolapse (arrow); **(e)** rectocele (arrow).

Women with minor prolapses may be asymptomatic, but those with more significant degrees may present with a sensation of 'something coming down'. A cystocele (bladder prolapse) and a cystourethrocele (prolapse of the bladder and urethra) can lead to the sensation of a lump in the vagina and may be associated with urinary urgency (OAB symptoms) and recurrent urinary tract infections. Uterine descent can lead to a lump in the vagina or a dragging sensation; with complete prolapse of the uterus (procidentia) there may be associated vaginal discharge, ulceration of the vaginal mucosa and bleeding. A rectocele (prolapse of the rectum into the vagina) may cause difficulties with defecation or a sensation of incomplete emptying, which can be relieved by digital reduction of the prolapse.

The degree of prolapse is graded in terms of descent. Currently, the commonly used grading system is the Pelvic Organ Prolapse Quantification System (POP-Q):

- grade 0: no prolapse is demonstrated;
- grade 1: the most distal portion of the prolapse is >1 cm above the level of the hymen;
- grade 2: the most distal portion of the prolapse is ≤1 cm above or below the level of the hymen;
- grade 3: the most distal portion of the prolapse is >1 cm below the level of the hymen but 2 cm less than the total vaginal length;
- grade 4: maximal descent.

Non-surgical management of a uterovaginal prolapse includes: lifestyle changes (avoidance of constipation); physiotherapy to help strengthen the pelvic floor muscles for at least 16 weeks for those with grade 1 or 2 organ prolapse; topical oestrogen replacement for oestrogen deficiency to help increase tissue strength and elasticity; and vaginal pessaries. There are a number of different pessaries available and they are replaced every 3–6 months, with the ring pessary being the most frequently used. It is inserted between the posterior fornix and the pubic bone. The main complications are of vaginal ulceration and infection leading to discharge and bleeding; it is advisable, therefore, to replace the ring frequently.

Surgical management aims to correct the prolapse. The surgical procedures are intended to restore the uterovaginal anatomy and position. They may be carried out using a vaginal or abdominal (open or laparoscopic) approach (***Table 87.12***).

TABLE 87.12 Surgical treatments for uterovaginal prolapse.

Condition	Treatment	Complications
Urethrocele/cystocele (*Figure 87.23a*)	• An anterior vaginal wall repair (anterior colporrhaphy) without the use of mesh	• Bleeding • Infection • Fistula formation • Voiding dysfunction • Unmasking of occult SUI • Failure • Recurrence
Uterine prolapse (*Figure 87.23b*)	• If the patient's family is complete, a vaginal hysterectomy with or without vaginal sacrospinous fixation can be performed • Uterus-preserving surgery includes: amputation of the cervix with suturing of the transverse cervical ligaments vaginally (Manchester repair); laparoscopic plication of the uterosacral ligaments (McCall suture); or hysteropexy, which may be vaginal (attaching the cervix to the sacrospinous ligaments using non-absorbable sutures) or laparoscopic/abdominal (sacrohysteropexy using a polypropylene mesh to suspend the uterus to the sacral promontory) • A colpocleisis can be considered in women who no longer wish to have penetrative intercourse	• Bleeding • Infection • Injury to the bladder, bowel or ureters • Voiding dysfunction • Dyspareunia • Failure • Recurrence • Conversion to a laparotomy • A Manchester repair can specifically be associated with infertility, miscarriage and dystocia
Enterocele (*Figure 87.23c*)	• A similar technique to repair of a hernia is used. The vaginal mucosa is opened and the hernial sac repaired	• Bleeding • Infection • Rectal or small bowel injury (fistula formation) • Dyspareunia • Failure • Recurrence
Vaginal vault prolapse (*Figure 87.23d*)	• Sacrospinous fixation performed vaginally: the vault is attached to the right sacrospinous ligament using a non-absorbable suture/mesh, avoiding the rectosigmoid colon on the left • Sacrocolpopexy performed abdominally or laparoscopically: the vaginal vault is attached to the sacral promontory using a mesh • A colpocleisis can be considered in women who no longer wish to have penetrative intercourse	• Bleeding • Infection • Injury to the bowel or ureter • Unmasking of occult SUI • Right buttock pain • Sexual dysfunction
Rectocele (*Figure 87.23e*)	• Posterior colpoperineorrhaphy without mesh: the posterior vaginal wall is opened, the rectum returned to its normal position and redundant vaginal mucosa excised	• Bleeding • Infection • Rectal or small bowel injury (fistula formation) • Dyspareunia • Failure • Recurrence

SUI, stress urinary incontinence.

Approximately 30% of women in their lifetime report a recurrence of their symptoms following surgical treatment. This figure increases with subsequent procedures.

Mesh

In the UK, mesh-related surgery is considered to be a high-vigilance operation, whereby use of synthetic mesh to treat SUI or urogynaecological prolapse has been restricted nationally secondary to a number of safety concerns that have been raised:

- pain or sensory change in the back, abdomen, vagina, pelvis, leg, groin and/or perineum;
- vaginal problems, including discharge, bleeding, dyspareunia, penile trauma or pain in sexual partners;
- urinary problems, including recurrent infections, incontinence, retention, difficulty or pain during voiding;
- bowel problems, including difficulty or pain on defecation, faecal incontinence, rectal bleeding or passage of mucus.

In view of this, an MDT approach is recommended to manage complex pelvic floor dysfunction and mesh-related problems. For women with a confirmed mesh-related complication or unexplained symptoms after a mesh procedure, referral should be made to regional centres specialising in the diagnosis and management of mesh-related complications. Continence surgery requiring mesh usage such as transvaginal tapes and

The **Manchester repair** was introduced at St Mary's Hospital for Women and Children, Manchester, UK.
Milton Lawrence McCall, 1911–1963, obstetrician, Magee-Women's Hospital, Pittsburgh, PA, USA.

transobturator tapes has been replaced by open/laparoscopic continence surgery in the form of colposuspension or insertion of an autologous fascial sling. Uterine prolapse and vaginal vault prolapse surgery requiring the use of mesh during hysteropexy and sacrocolpopexy procedures can be undertaken following detailed counselling and MDT agreement.

TUMOURS

Benign ovarian tumours and cysts

Overall, 90% of ovarian tumours are benign, with an increased risk of malignancy in older women: the malignant potential of an ovarian cyst in a premenopausal woman is 1:1000, increasing to 3:1000 at the age of 50 years. Ovarian tumours are subdivided into five main categories according to the World Health Organization's classification system (***Table 87.13***).

TABLE 87.13 Classification of ovarian tumours.

Surface epithelial tumours	• Represent approximately 65% of all ovarian tumours and 90% of ovarian malignancies • Further classified by cell type (serous, mucinous, endometrioid, clear cell, transitional cell, epithelial–stromal [undifferentiated]) and atypia (benign, borderline or malignant)
Germ cell tumours	• Represent approximately 15% of all ovarian neoplasms • Mature teratomas are the most common type of ovarian germ cell tumour (benign), often called a dermoid cyst. They most commonly occur in women of reproductive age and contain a variety of tissues, including skin, hair follicles, sweat glands, bone and teeth • Malignant germ cell tumours include immature teratomas, dysgerminomas, yolk sac tumours, choriocarcinomas and embryonal carcinomas
Sex cord–stromal tumours	• Represent approximately 10% of all ovarian neoplasms
Metastatic tumours	• Represent approximately 5% of ovarian malignancies; usually arise from breast, colon, endometrium, stomach and cervical cancers
Other/miscellaneous	• A small number of other types of neoplasms, which develop from ovarian soft tissue or non-neoplastic processes

Benign ovarian tumours are often asymptomatic and may present incidentally, for example when an abdominal radiograph reveals the appearance of a tooth in the abdomen or pelvis. Conversely, they may present with pain, abdominal swelling, pressure-type symptoms, nausea or vomiting. Sudden-onset pain with vomiting and raised inflammatory markers can be more diagnostic of ovarian torsion (see ***Adnexal torsion***).

Management will depend on the age of the woman and the characteristics of the cyst (***Summary box 87.3***). In older women, a conservative approach is only reasonable if the risk of malignancy is low (see ***Ovarian cancer***). In perimenopausal women, the cyst can be followed by serial ultrasound scanning as many will regress. If there is uncontrollable pain, haemodynamic compromise, suspicion of torsion or the cyst does not regress, then surgical management is advised. In most cases this would involve a laparoscopic ovarian cystectomy with conservation of ovarian tissue as the treatment of choice. As the vast majority of oocytes lie within 5 mm of the surface of the ovary, a carefully carried out cystectomy can leave a normally functioning ovary (***Figure 87.24***).

Summary box 87.3

Management of benign ovarian cysts

- Commonly, an incidental finding, but may be suggested by symptoms and signs
- A pregnancy test should be performed to exclude an ectopic pregnancy (however, it is important to note that HCG can also be positive in dysgerminomas and choriocarcinomas)
- TVUS is the mainstay diagnostic tool with high sensitivity and specificity in being able to differentiate a benign mass from a malignant one (*Table 87.14*). If the results are indeterminate, an MRI or CT scan may help; an MRI is more useful than a CT scan for the assessment of complex cysts/endometriosis. Masses with radiographic characteristics of cancer (e.g. cystic and solid components, surface excrescences, multilocular appearance, irregular shape) require removal
- Tumour markers may help in the diagnosis of specific masses (see *Ovarian cancer*)
- In women of reproductive age, simple, thin-walled cystic adnexal masses of a maximum diameter of 50 mm without characteristics of cancer do not require further investigation unless they persist for >3 months. A follow-up scan can be arranged after 4 months to check for resolution. In postmenopausal women, this is conducted every 4 months in conjunction with a serum blood test for the cancer antigen 125 (CA-125) for a duration of 1 year; if no change is detected, the women can be discharged
- Perimenopausal women with simple cysts measuring 50–70 mm in diameter should undergo annual ultrasound follow-up
- Women with larger cysts (>70 mm) or persistent cysts may benefit from an MRI scan or surgical intervention
- Cyst removal (ovarian cystectomy) is preferably performed laparoscopically. Cyst aspiration is associated with a high risk of recurrence but can be considered after detailed counselling if the woman wishes to retain her fertility. Bilateral salpingo-oophorectomy is preferable for postmenopausal women if surgery is indicated
- An oophorectomy may become necessary if the cyst cannot be surgically removed from the ovary

TABLE 87.14 International Ovarian Tumor Analysis (IOTA) group classification for the ultrasound assessment of ovarian cysts.

Benign features (B-rules)	Malignant features (M-rules)
• Unilocular cysts • Solid components, the largest of which is <7 mm • Acoustic shadowing • Smooth multilocular tumour <100 mm • No blood flow	• Irregular solid tumour • Ascites • Minimum of four papillary structures • Irregular multilocular tumour ≥100 mm • Blood flow

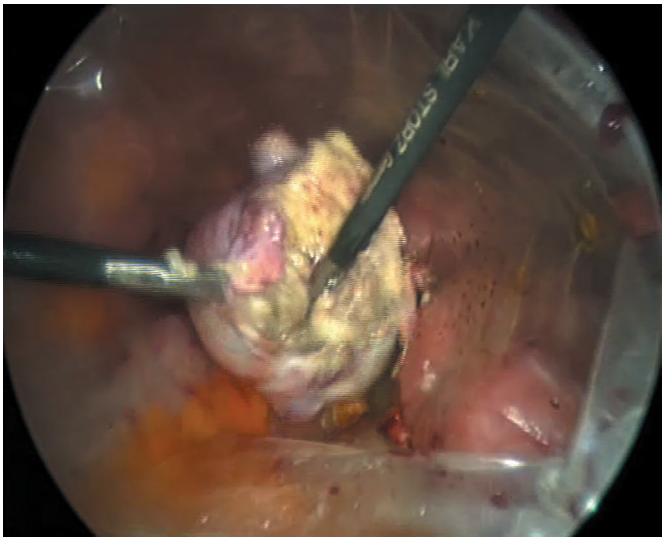

Figure 87.24 Ovarian cystectomy.

Ovarian cancer

Ovarian cancer is the sixth most common malignancy in women, behind breast, lung, bowel, uterine cancer and malignant melanoma. In the UK, over 7000 women are diagnosed with ovarian cancer each year. Over 90% of cancers arise from the surface epithelium of the ovary (which has the same embryological origins as the peritoneum); the majority arise sporadically rather than secondary to inheritance. The peak incidence is in the age range 65–69 years. The overall 5-year survival rate is <50% because approximately two-thirds of women present with advanced disease.

The common presenting symptoms are:

- abdominal distension and/or pain;
- change in appetite;
- weight gain and increased girth (ascites);
- urinary obstruction.

Over half of all women, however, present initially to a speciality other than gynaecology, with often vague symptoms caused by metastatic disease, e.g. shortness of breath, gastrointestinal disturbance or a change in bowel habit. Consequently, it is important to include ovarian cancer in the differential diagnosis of any woman presenting with a recent onset of persistent, non-specific, abdominal symptoms (including those whose abdomen and pelvis appear normal on clinical examination). A pelvic mass in conjunction with ascites usually indicates ovarian cancer but may also be indicative of Meigs' syndrome (a benign fibroma with ascites and the presence of a pleural effusion). ***Summary box 87.4*** addresses the basic tests that can be conducted to diagnose ovarian malignancy.

CA-125 is a glycoprotein expressed on tissue derived from coelomic and Müllerian epithelia; the normal cut-off value is 35 U/mL. Elevated levels are found in 50% of patients with stage I disease and >90% of those with advanced disease. It primarily detects epithelial ovarian cancers. However, CA-125 is a non-specific marker with raised levels also seen in other cancers, e.g. pancreatic, breast, lung and colon. Levels may also be increased during menstruation; in benign conditions such as endometriosis, PID and liver disease; if ascites or other effusions are present; and after a recent laparotomy. Combining menopausal status, ultrasound features and CA-125 measurements using the risk of malignancy index (RMI) algorithm (***Summary box 87.5***) can help guide management and identify those who require an onward referral to a gynaecological oncologist in a cancer centre.

Summary box 87.4

Basic tests on suspicion of ovarian malignancy

- Ultrasound scan is considered the first-line investigation (***Table 87.12***)
- A staging CT or MRI is carried out prior to surgery to determine the extent of disease
- Tumour markers, including βHCG, lactate dehydrogenase, alpha-fetoprotein (αFP), CA-125, CA-19-9 and carcinoembryonic antigen (CEA), should be measured. Lactate dehydrogenase, αFP, inhibin and βHCG are particularly recommended in women <40 years old with a suspected complex ovarian mass, to exclude germ cell tumours

Summary box 87.5

Risk of malignancy index (RMI)

- RMI = U × M × CA-125

  U, ultrasound features scoring 1 for each malignant feature (multilocular, solid components, metastases, ascites, bilateral lesions); M, menopausal status with 1 for premenopausal and 3 for postmenopausal; CA-125, CA-125 level in U/mL

There is currently no national screening programme for ovarian cancer in the UK (including for women at high risk of the disease) because no test has been identified to reliably pick up ovarian cancer at an early stage. The UK Collaborative Trial of Ovarian Cancer Screening aimed to establish the effect of early detection of the disease by screening on ovarian cancer mortality. The preliminary study recruited over 200 000 women aged between 50 and 74 years and randomised them to either a control arm or one of two screening strategies: primary screening using measurement of serum CA-125 levels followed by TVUS as a second-line test; or TVUS alone. The two screening procedures were found to be similar in terms of sensitivity for all primary ovarian and fallopian tube cancers, but specificity was higher with combined screening.

Some genetic mutations are known to predispose women to ovarian cancer, e.g. *BRCA1* and *BRCA2* and the mismatch repair genes associated with Lynch syndrome families. *BRCA1* mutations confer a 39% lifetime risk of ovarian cancer up to the age of 70 years; this is 11–17% for *BRCA2* mutations up to the age of 70 years. The mismatch repair genes confer an increased lifetime risk of ovarian cancer of 9–12% in addition to the increased risk of endometrial cancer. Referral to a specialist cancer genetics service is advisable. Women at high risk of ovarian cancer may be offered risk-reducing surgery in the form of prophylactic bilateral salpingo-oophorectomy,

Joe Vincent Meigs, 1892–1964, gynaecological surgeon, Massachusetts General Hospital, Boston, MA, USA.

especially as they may also be at increased risk of breast cancer with some evidence suggesting that an oophorectomy can reduce the risk of breast cancer in these women.

Surgical staging of ovarian cancer (*Table 87.15*) is performed at laparotomy via a midline incision if disease is suspected preoperatively by:

- careful evaluation of all peritoneal surfaces;
- four washings of the peritoneal cavity: diaphragm, right and left abdomen, pelvis;
- infracolic omentectomy;
- selected lymphadenectomy of the pelvic and para-aortic lymph nodes;
- biopsy and/or resection of suspicious lesions, masses and adhesions;
- random blind biopsies of normal peritoneal surfaces, including that from the undersurface of the right hemidiaphragm, bladder reflection, cul-de-sac, right and left paracolic recesses and both pelvic side walls;
- total abdominal hysterectomy and bilateral salpingo-oophorectomy;
- appendicectomy for mucinous tumours; if a routine appendicectomy results in an intraoperative suspicion of a mucinous tumour, the surgeon should take washings and a biopsy from suspicious area(s).

TABLE 87.15 Condensed staging of ovarian cancer.

Stage I	Growth limited to the ovaries
Stage II	Growth involving one or both ovaries with pelvic extension (uterus, bladder, sigmoid colon, rectum) or primary peritoneal cancer but not including the lymph nodes
Stage III	Tumour involving one or both ovaries with histologically confirmed peritoneal implants outside of the pelvis including spread to retroperitoneal lymph nodes (pelvic and/or para-aortic) only
Stage IV	Growth involving one or both ovaries with distant metastases

The general principle is cytoreductive surgery followed by combination chemotherapy; only a minority of patients with ovarian cancer require a bowel resection during the primary procedure or surgery for recurrent disease. The only exception to this rule is a young woman with stage I disease or a borderline tumour who requests a unilateral oophorectomy to conserve her fertility.

Fertility preservation in the form of controlled ovarian stimulation with oocyte or embryo cryopreservation has been undertaken in patients with low-grade tumours (grade IA/B) who wish to preserve their fertility; however, the effect of this on the underlying disease process is not known, with the additional risk of seeding the cancer during oocyte retrieval. This must, therefore, be carried out with caution and under the guidance of oncological specialists. Ovarian tissue cryopreservation at the time of cytoreductive surgery has also been undertaken, holding the promise for *in vitro* maturation of oocytes in the future. Autologous transplantation would be contraindicated as it has the risk of cancer recurrence.

PART 13 | Transplantation

CHAPTER 88

Kidney transplantation and the principles of transplantation

Learning objectives

To recognise and understand:

- The immunological basis of allograft rejection
- The principles of immunosuppressive therapy
- The side effects of immunosuppressive therapy
- The major issues concerning organ donation
- The main indications for organ transplantation
- The surgical principles of organ transplantation
- The expected outcomes after transplantation
- The potential future developments in transplantation

INTRODUCTION

Successful solid organ transplantation represents one of the great medical advances of the twentieth century. The field continues to be an exciting and fast-moving one. Unfortunately, there continues to be a shortage of suitable donor organs for transplantation. In the UK there are approximately 4000 patients waiting for a kidney but only 3750 transplants are performed annually. This has led to a median waiting time for transplantation of around 3 years. Similar shortages exist for heart, lung, liver and pancreas transplantation across the world. Most transplant organs are from deceased donors, of which there are two types: donation after brainstem death (DBD) and donation after circulatory death (DCD). Living donation is limited to kidney, liver and lung transplantation.

ORGAN DONATION

Donation after brainstem death

Brainstem death occurs after severe brain injury as a result of either trauma or a cerebrovascular accident. Potential DBD donors are in an apnoeic coma that requires mechanical ventilation on the intensive care unit (ICU). There must be a known cause of irreversible brain damage demonstrated by a computerised tomography (CT) scan. Brainstem death is defined as the permanent loss of the capacity for consciousness and spontaneous breathing. These two essential functions are controlled by the brainstem. The reticular activating formation controls consciousness and is diffuse throughout the brainstem; the respiratory centre is in the medulla oblongata.

In this situation the circulation can be maintained for a period of time after death and DBD donors were formerly called heart-beating donors. In most countries it is accepted that brainstem death equates in medical, legal and religious terms to the death of the patient.

Before brainstem death testing can be considered, all reversible causes of coma must be excluded. These include: hypothermia, muscle relaxants, drugs with central nervous system depressive effects, alcohol intoxication, hypothyroidism, uraemic encephalopathy, hepatic encephalopathy, hypoglycaemia and hyponatraemia. When these preconditions are met then formal brainstem death testing can be undertaken (*Table 88.1*).

The UK guidelines state that the tests should be performed twice by two clinicians who are independent of the transplant team. One of them should be a consultant and the other must have been registered with the General Medical Council for at least 5 years.

TABLE 88.1 Clinical testing for brainstem death.

Cranial nerve reflexes	**1.** Pupillary reflex (cranial nerves II and III) **2.** Corneal reflex (cranial nerves V_1 and VII) **3.** Oculocephalic (doll's eyes movements – cranial nerves III, IV and VI) **4.** Vestibulo-ocular (cranial nerves VIII, III and VI) **5.** Cough/gag reflex (cranial nerves IX and X) **6.** It is not possible to test cranial nerves I and XII in unconscious individuals
Motor response	Absence of cranial nerve motor response to supraorbital pressure (cranial nerves V and VII) and absence of motor response in the cranial nerve distribution to adequate stimulation of any somatic area (commonly nail-bed pressure)
Apnoea test	After preoxygenation with 100% oxygen the patient is disconnected from the ventilator for >5 minutes in order to achieve a $PaCO_2$ ≥6.0 kPa (and pH<7.4). If there are no respiratory movements in response to the progressive hypercarbia then the test confirms that the brainstem respiratory centre has been destroyed. To prevent hypoxia during the apnoeic period, O_2 (6 L/min) is delivered via an endotracheal catheter

$PaCO_2$, partial pressure of carbon dioxide.

In DBD donors the organs continue to be perfused with oxygenated blood during the procurement surgery. The thoracic and abdominal organs are accessed through a median sternotomy and a midline laparotomy incision and their inflow vessels are cannulated. The organs to be recovered are usually dissected and mobilised with the heart beating. Ice-cold cardioplegia solution is then perfused into the coronary arteries via a cannula in the ascending aorta to stop the heart. At the same time the abdominal organs are perfused with ice-cold preservation solution via cannulae in the abdominal aorta and the portal vein. Each organ is removed and stored in fresh preservation solution and then packed in crushed ice for transport.

Donation after circulatory death

Donation after circulatory death describes the recovery of organs for transplantation after death confirmed by circulatory criteria. These donors were formerly called asystolic or non-heart-beating donors. There have been very significant increases in DCD programmes in many countries over the last decade. The modified Maastricht classification is widely used to categorise DCD (***Table 88.2***). Organ donation after unexpected and irreversible cardiac arrest is referred to as uncontrolled DCD. Donation after death resulting from the planned withdrawal of life-sustaining cardiorespiratory support is called controlled DCD.

In DCD donors cardiorespiratory arrest occurs prior to starting organ retrieval. The organs are therefore warm but not being perfused with oxygenated blood for a period of time before they are flushed with cold preservation solution. This warm ischaemia period should be limited as much as possible.

Controlled DCD donors are ICU-based and have suffered massive and irreversible cerebral damage but have an intact brainstem so that they are self-ventilating. In a situation where further attempts at treatment would be futile, the withdrawal of supportive treatment inevitably leads to cardiorespiratory arrest, and this usually occurs within a short time. In the UK, after cardiac arrest there is a mandatory 'no-touch' period of 5 minutes. This is deemed to be the time beyond which there is irreversible loss of cardiac and cerebral function. The donor is transferred from ICU to the operating department and a rapid median sternotomy and midline laparotomy are performed. The ascending aorta and abdominal aorta are cannulated and the organs are perfused with ice-cold preservation fluid *in situ* without any initial dissection. The warm ischaemic period is usually less than 10 minutes. Organ procurement is then carried out in standard fashion.

Uncontrolled DCD donors have usually suffered an unexpected and irrecoverable cardiac event either outside or inside hospital. After a period of attempted, but failed, cardiopulmonary resuscitation (CPR) and observation of the 5-minute rule, CPR with administration of high-concentration oxygen is recommenced, often using a mechanical resuscitation device. *In situ* renal cooling is performed by placing a double-balloon, triple-lumen perfusion catheter into the aorta via a femoral artery cut-down (***Figure 88.1***). The donor can then be transferred to the operating theatre and the kidneys are removed using standard techniques. Uncontrolled DCD donation is usually reserved for the kidneys only as they are able to recover from warm ischaemic periods of up to 45 minutes.

TABLE 88.2 Modified Maastricht classification of donation after circulatory death (DCD).

Category	Description	Type of DCD	Location
I	Dead on arrival at hospital	Uncontrolled	ED
II	Unsuccessful resuscitation after cardiac arrest	Uncontrolled	ED
III	Anticipated cardiac arrest after withdrawal of support	Controlled	ICU
IV	Cardiac arrest in brain-dead donor	Controlled	ICU
V	Unexpected cardiac arrest in ICU	Uncontrolled	ICU

ED, emergency department; ICU, intensive care unit.

Evaluation of the deceased donor

The absolute contraindications to organ donation include active systemic sepsis and transmissible infection. Malignancy within the last 5 years is also an absolute contraindication with the exception of tumours that do not metastasise (primary brain tumours, non-melanotic skin cancer and *in situ* carcinoma of the cervix). However, there is now evidence that organs from high-risk donors can be transplanted safely and

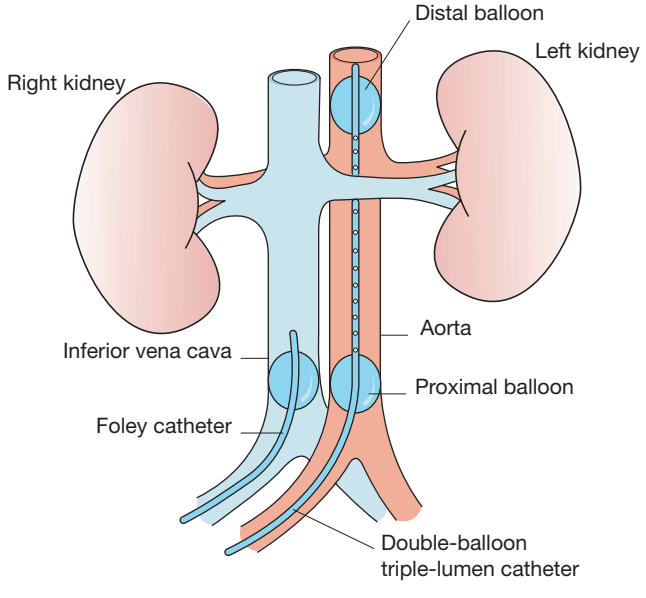

Figure 88.1 *In situ* perfusion of kidneys in a non-heart-beating donor (donation after circulatory death [DCD]). A double-balloon aortic catheter is introduced through a groin incision and 10–15 litres of chilled preservation solution is administered. The perfusate is vented through a Foley catheter introduced into the femoral vein.

Frederic Eugene Basil Foley, 1891–1966, urologist, Ancker Hospital, St Paul, MN, USA.

yield transplant outcomes that are equivalent to those from conventional donors. Thus, as a further response to the organ donor shortage, organs are now being transplanted from donors with meningitis/encephalitis, human immunodeficiency virus (HIV), hepatitis B and C and high-risk behaviour with the potential for blood-borne infection.

Living donation

Living kidney donation is possible because most individuals have two healthy kidneys and it is possible to live a normal life with a single kidney. Parts of non-paired organs can also be removed from live donors; these include liver and lung lobes, the tail of the pancreas and segments of small intestine.

The majority of liver transplants performed in India are from live donors and the number of programmes has expanded rapidly in recent years. The liver has the capacity to regenerate following resection of a segment or lobe. The growth of new liver tissue happens quickly and the liver returns to its pre-resectional mass. Liver resection is difficult because of the complex segmental anatomy (***Figure 88.2***). In children, the left lateral segment (segments II and III) of an adult provides enough liver function and this is a relatively straightforward procedure. In adult-to-adult live donor liver transplantation the whole right lobe of the liver is removed from the donor (segments V–VIII). This is a more complex operation and the risk of donor mortality is 0.5–1%.

Transplants from live donors have a number of advantages over deceased donor organs. Live donor organs are from healthy individuals without the comorbidities commonly seen in deceased donors. In the agonal period before death deceased donors exhibit marked changes in physiology related to a catecholamine storm and this can cause organ dysfunction. Clearly, live donor organs are not subjected to this insult. Potential live donors undergo a rigorous assessment process that includes imaging of the relevant vasculature by CT or magnetic resonance angiography (MRA) and tests of organ functional capacity. The operations are planned elective procedures undertaken in daylight hours and often adjacent theatres so that the cold ischaemia time is very short. It is usual for live donor organs to function immediately after transplantation and this is essential for liver and lung transplants. As a result of these advantages the long-term outcomes of live donor transplantation are superior to deceased donor outcomes.

Set against these advantages for the recipient is the fact that the live donor is subjected to a major operation that they do not need. All live donor operations have uncommon but potentially life-threatening morbidity rates and there is a small risk of death. The ethical issues raised by live donation are understandably complex.

ORGAN PRESERVATION

Transplant organs need to be stored and preserved in the period between procurement from the donor and transplantation into the recipient. Static cold storage is the traditional method of organ preservation, but more recently there have been developments in preservation by machine perfusion.

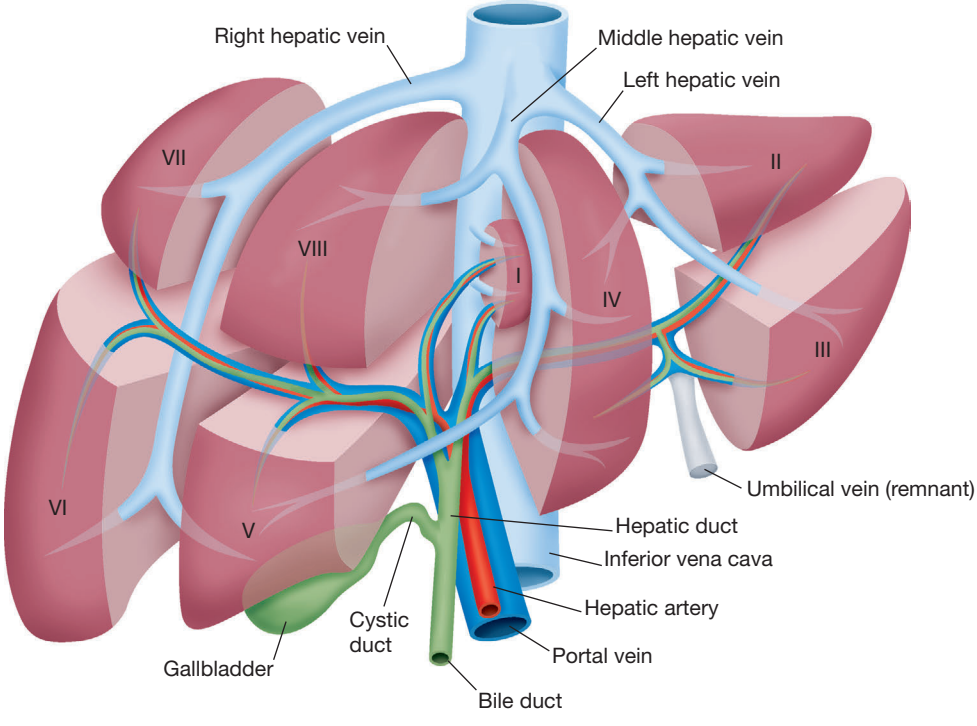

Figure 88.2 Segmental anatomy of the liver (Couinaud segments).

Claude Couinaud, 1922–2008, French surgeon and anatomist, described the segmental anatomy of the liver in his seminal book *Le Foie: Études anatomiques et chirurgicales*.

Pathophysiology of ischaemia

In the absence of oxygen, organs switch from aerobic to anaerobic metabolism. The mitochondrial electron transport chain cannot function without oxygen as the final electron acceptor. Oxidative phosphorylation ceases and, in consequence, so does the tricarboxylic acid (Krebs) cycle and the link reaction (conversion of pyruvate to acetyl coenzyme A). This leaves glycolysis as the only source of adenosine triphosphate (ATP). Anaerobic metabolism of one glucose molecule produces only two ATP molecules compared with the 36 ATP molecules that are produced during aerobic metabolism. Consumption of ATP rapidly exceeds production, leading to depletion of cellular ATP. Na^+/K^+ ATPase pumps are disabled and this leads to an influx of Na^+ ions into the cell down their concentration gradient. Na^+ ions are followed by H_2O by osmosis and this causes swelling and disruption of membrane-bound intracellular organelles and lysis of the cell membrane. Anaerobic glycolysis generates lactate and promotes intracellular acidosis. At low pH phospholipase and protease enzymes are activated and cause lysosomal damage and eventually cell death. ATP-dependent active transport of calcium out of cells is impeded, leading to the intracellular accumulation of Ca^{2+} ions and activation of the calcium-dependent processes. This leads to breakdown of the cytoskeleton and loss of cell structure.

Static cold storage

Hypothermia suppresses metabolism to maintain organ viability. The first requirement is to flush the donor organs with an appropriate preservation solution at a temperature of approximately 4°C (***Figure 88.3***). This is normally done *in situ* via cannulae placed in the donor aorta and portal vein. This process has three effects: (i) it flushes blood out of the microcirculation to prevent thrombosis; (ii) it cools the organs to a temperature of <5°C and so reduces tissue oxygen requirements; (iii) it replaces the normal extracellular fluid with the preservation fluid.

Figure 88.3 After removal from the donor, the kidney is flushed with chilled organ preservation solution and, if necessary, stored briefly on ice until transplanted into the recipient.

Preservation solutions have three main components: electrolytes, an impermeant and a buffer. In general, the electrolyte composition mimics the high K^+ ion concentration and low Na^+ ion concentration of intracellular fluid. This eliminates ionic fluxes, and therefore the movement of H_2O across cell membranes. Impermeants such as mannitol, lactobionate and raffinose are large osmotically active molecules. They cannot pass through the cell membrane and remain in the extracellular space. Here, they prevent cellular swelling by counteracting the osmotic force from intracellular proteins. The buffer component of preservation fluids is based on either HCO_3^- or PO_4^{3-} and acts to maintain a stable physiological pH in the extracellular space. A number of different preservation solutions are available, but the University of Wisconsin (UW) solution is widely regarded as the current gold standard.

Hypothermic machine perfusion

The transplant organ is placed in a sterile chamber and cold preservation fluid is continually recirculated through the vasculature at low temperature and pressure (30 mmHg) (***Figure 88.4***). The perfusion fluid is based on UW solution and some systems include oxygenation. This technique flushes the microcirculation more effectively. There are trial and meta-analysis data showing that hypothermic machine perfusion reduces the rate of delayed graft function (DGF) in renal transplantation, but the effect size is small.

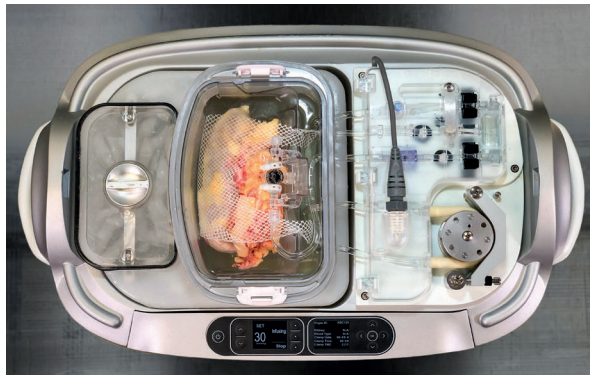

Figure 88.4 The LifePort® hypothermic perfusion machine (LifePort® Kidney Transporter courtesy of Organ Recovery Systems).

Normothermic machine perfusion

Normothermic machine perfusion (NMP) utilises the principles of cardiopulmonary bypass technology and has been used for heart, lung, liver and kidney preservation. Warmed and oxygenated red blood cell-based perfusate is circulated through the donor organ (***Figure 88.5***). This provides a more physiological environment that restores graft function *ex vivo* and replenishes depleted ATP levels. NMP restores organ function *ex vivo* and this allows for assessment of allograft quality and viability. This has led to increased utility of marginal organs that would previously have been discarded on the basis of adverse clinical parameters. NMP may also improve early

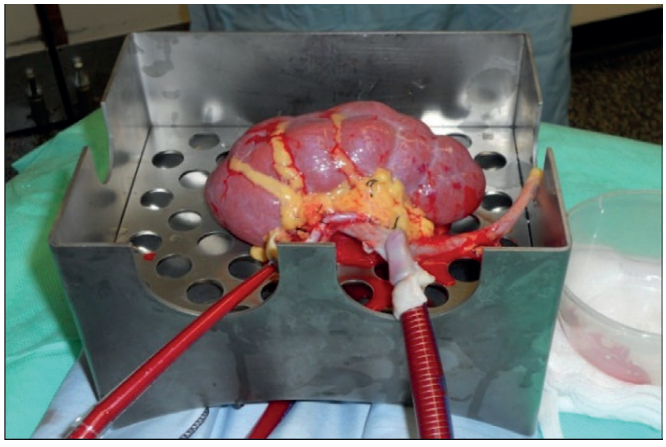

Figure 88.5 Donor kidney undergoing normothermic machine perfusion.

allograft function and is being developed as a platform for the delivery of pretransplant therapies.

Normothermic regional perfusion

This technique has been developed for donation after circulatory arrest. A cardiopulmonary bypass system is used to recirculate the donor's own blood through the thoracic and abdominal organs for 2 hours. The underlying principle is to avoid early cold ischaemia injury. The early experience of normothermic regional perfusion in DCD liver preservation and transplantation shows reduced rates of early allograft dysfunction.

IMMUNOLOGY OF TRANSPLANT REJECTION

ABO blood groups

ABO blood group antigens are glycoproteins with different carbohydrate components. ABO antigens are expressed not only on the surface of red blood cells but also on endothelial cells. In all organ transplants there must therefore be ABO blood group compatibility between the recipient and the donor organ, using the same rules for blood transfusion (*Table 88.3*).

TABLE 88.3 Blood group compatibility.

Donor blood group	Permissible recipients
O (universal donor)	O, A, B and AB
A	A and AB
B	B and AB
AB (universal recipient)	AB

HLA matching

Allograft rejection is directed against human leukocyte antigens (HLAs). These are a group of cell surface glycoprotein molecules. HLA molecules are divided into class I (A, B and C) and class II (DR, DP and DQ). Class I molecules are expressed on the surface of all nucleated cells, but class II are only expressed by antigen-presenting cells (APCs) such as dendritic cells and B lymphocytes. HLA molecules are encoded for in the major histocompatibility complex (MHC) on chromosome 6. They are highly polymorphic, i.e. their amino acid sequences differ widely between individuals. To give an example, there are >1000 variants of the HLA-B gene. This genetic variability means that most transplant donors and recipients have different HLA profiles. Donors and transplant recipients are HLA-typed using DNA sequencing. The antigens at HLA-A, -B and -DR are together described as the tissue type.

The level of mismatch between the HLA molecules determines the strength of the immune response. Every individual has two copies of each HLA gene and so for each locus (A, B or DR) it is possible to have 0, 1 or 2 mismatched genes. As the number of mismatches increases so does the chance of immune recognition and rejection. The best matched grafts are described as having a mismatch of 0–0–0, i.e. no mismatches at A, B or DR, respectively. A completely mismatched graft would be annotated as a 2–2–2 mismatch. The effects of the different HLA antigens are not uniform. DR mismatches have a more powerful effect than B mismatches, and A mismatches are the least important. The tissue types of potential renal transplant recipients are held by national organisations, such as NHS Blood and Transplant in the UK, and used to allocate donor organs to patients with the lowest level of HLA mismatch.

The immune response to a transplanted organ

The main immune cells involved in transplant immunology are APCs and T and B lymphocytes. These cell types interact by a series of specific surface molecules that are designated by CD (cluster of differentiation) numbers. Cell surface receptors can only interact if they have the correct complementary three-dimensional structures.

The immune response to an allograft is orchestrated by T lymphocytes. When T cells encounter foreign transplant HLA antigens they become activated and then proliferate into clones of cells that attack the allograft. Full T-cell activation requires a number of signals (*Figure 88.6*). Transplant antigen

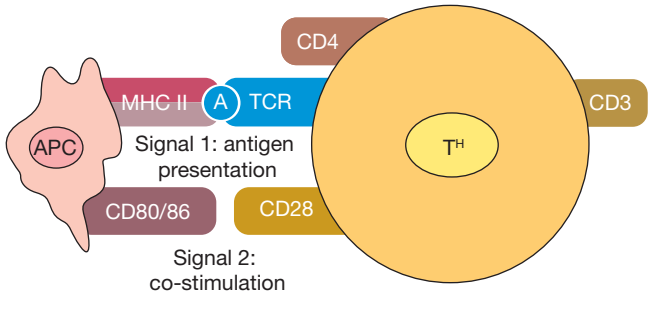

Figure 88.6 Interaction between an antigen-presenting cell and a CD4+ T-helper cell. A, antigen; APC, antigen-presenting cell; CD, cluster of differentiation; MHC II, major histocompatibility complex class II; TCR, T-cell receptor; T^H, T-helper cell. (Adapted with permission from Clatworthy M, Watson C, Allison M, Dark J. *Transplantation at a glance*. John Wiley and Sons Ltd, 2012.)

is presented to T-helper cells (CD4+) on self-MHC class II molecules by specialised APCs. The class II/peptide antigen complex is recognised by the T-cell receptor (signal 1). CD4+ T-helper cell activation also requires a co-stimulatory signal involving the interaction of pairs of molecules, one on the surface of the T cell and the other on the surface of the APC (signal 2). An example of signal 2 is the interaction of T-cell CD28 with CD80 on the APC. When both signal 1 and signal 2 are received the CD4+ T-helper cell will upregulate expression of the interleukin-2 (IL-2) receptor (CD25) on its cell surface. Binding of IL-2 to its receptor causes further activation of the T cell (signal 3). The T cell will then proliferate and release more IL-2, which, in turn, leads to activation and clonal proliferation of T-killer cells (CD8+). These cytotoxic killer cells infiltrate the allograft and cause cell death by the release of molecules called perforin and granzyme. Perforin punches holes in the target cell membrane and this allows passive diffusion of granzyme into the cell, where it activates caspase enzymes and causes cell death by apoptosis.

Antigen presentation in transplantation

There are two main types of antigen presentation to T lymphocytes (***Figure 88.7***). Direct antigen presentation involves donor APCs showing intact and unprocessed donor HLA (class I or class II) molecules on their cell surface to recipient T cells. In contrast, indirect presentation is performed by recipient APCs. These internalise foreign donor HLA molecules from the graft, process them into short peptide fragments and then load them into the peptide groove of recipient (self) HLA class II molecules. The donor peptide–recipient HLA class II complex is then expressed on the cell surface and presented to recipient T cells. Direct antigen presentation only occurs for the first 6–12 weeks after transplantation because this is the lifespan of the donor passenger APCs that are present in the allograft. As indirect presentation involves recipient APCs it is a long-lived response.

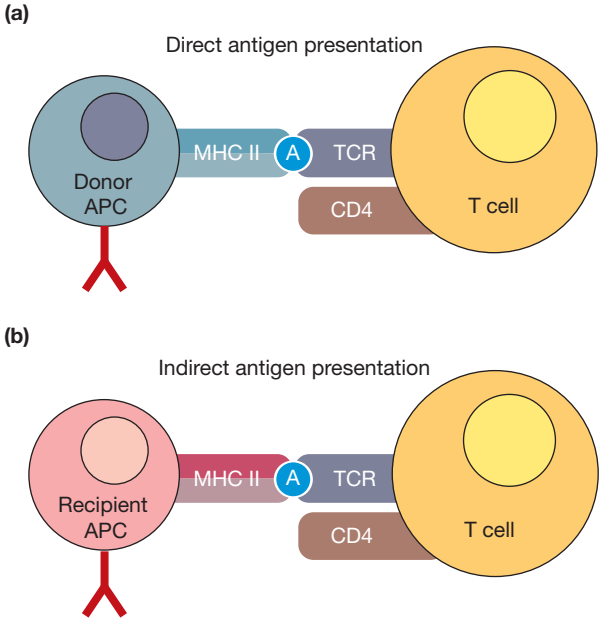

Figure 88.7 Direct **(a)** and indirect **(b)** antigen presentation. A, antigen; APC, antigen-presenting cell; CD, cluster of differentiation; MHC II, major histocompatibility complex class II; TCR, T-cell receptor. (Adapted with permission from Clatworthy M, Watson C, Allison M, Dark J. *Transplantation at a glance*. John Wiley and Sons Ltd, 2012.)

TRANSPLANT REJECTION

Allograft rejection can be divided into distinct types.

Hyperacute rejection

Hyperacute rejection is extremely rare. It can result from an inadvertent ABO blood group-incompatible transplantation after a clerical error in recording blood groups. It may also occur when there are preformed circulating donor-specific HLA antibodies (DSA) or ABO antibodies. In either case, immediately after revascularisation of the transplant antibodies will bind to ABO or HLA antigens on the surface of the graft vascular endothelial cells. The antibodies are complement fixing and this leads to activation of the complement cascade and phagocytes. This leads to endothelial damage with release of tissue factor and activation of the clotting cascade. Widespread intravascular thrombosis causes infarction of the allograft within minutes or hours. This is untreatable and inevitably results in graft loss.

Acute cell-mediated rejection

In the era of modern immunosuppressive drugs, the incidence of acute cell-mediated rejection (CMR) is only 10–20%. Acute CMR is largely mediated by direct antigen presentation. As donor APCs in the allograft have a lifespan of only a few weeks, the peak incidence of acute CMR is in the first 3 months post transplantation. The characteristic biopsy finding of acute CMR is a marked interstitial lymphocytic infiltrate (***Figure 88.8***). In the kidney, the presence of lymphocytes inside the basement membrane of the renal tubular epithelium is referred to as tubulitis and is diagnostic of acute CMR. Initial treatment is by high-dose pulsed intravenous steroids (methylprednisolone 0.5 g intravenously for 3 days), which is

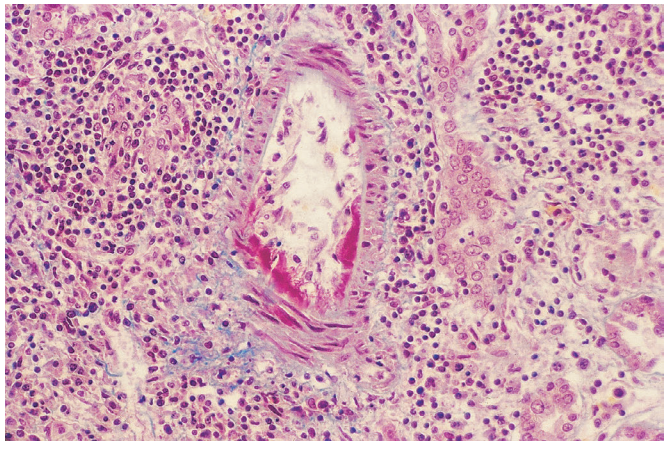

Figure 88.8 Severe acute renal allograft rejection with a heavy mononuclear cell infiltrate and intimal arteritis.

successful in up to 90% of cases. Severe or steroid-resistant rejection is treated with lymphocyte-depleting intravenous antithymocyte globulin (ATG).

Acute antibody-mediated rejection

Acute antibody-mediated rejection (AMR) occurs in <5% of renal transplants but is more serious and more difficult to treat than cell-mediated rejection. It is caused by HLA DSA, which are produced by a sensitising episode from a previous transplant, a blood transfusion or pregnancy. Binding of DSA to mismatched HLA antigens on the surface of allograft endothelial cells leads to activation of the complement system and tissue injury. In the kidney, transplant biopsy will show inflammation of the vessels (vasculitis) and deposition of the complement component C4d in the peritubular capillaries (***Figure 88.9***). Treatment is by plasma exchange to remove circulating antibodies. Rituximab, an anti-CD20 monoclonal antibody, can also be used to destroy B cells and prevent further production of DSA.

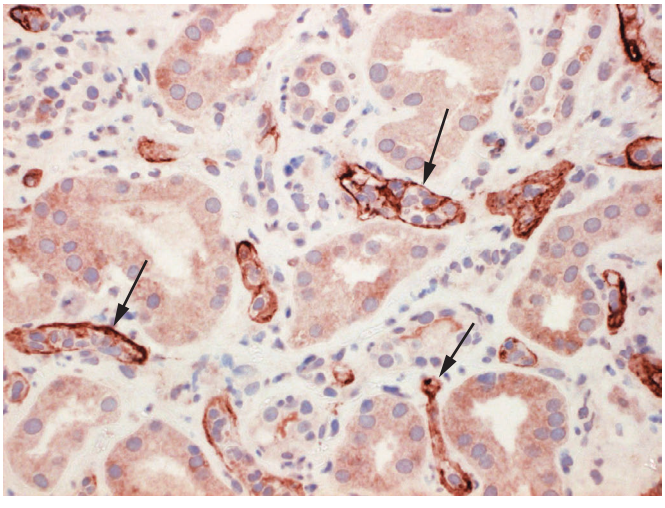

Figure 88.9 Acute antibody-mediated renal allograft rejection. There is widespread staining for the complement component C4d within the peritubular capillaries (arrows), which indicates alloantibody binding to the graft vasculature.

Chronic antibody-mediated rejection

The pathophysiology is not well understood but the long-lived indirect antigen presentation pathway is likely to be important. CD4 T-cell activation also promotes donor-specific alloantibody production, and this causes ongoing allograft damage.

IMMUNOSUPPRESSION

Modern immunosuppression is so effective that acute rejection rates of 10–20% can be achieved in all types of solid organ transplantation. The challenge is to deliver sufficient immunosuppression to prevent rejection while minimising drug side effects. Immunosuppression also increases the risk of both infection and malignancy. This is a non-specific effect related to the total burden of immunosuppression rather than agent-specific side effects.

The mechanisms of action of current immunosuppressive drugs depend on anti-inflammatory effects and the prevention of lymphocyte activation and proliferation (***Figure 88.10***). Lymphocytes are some of the most rapidly dividing cells in the body and their activation and clonal expansion forms the immunological basis of acute allograft rejection.

Immunosuppression for transplantation has two phases: induction and maintenance. Induction therapy commonly consists of a combination of high-dose intravenous steroids and the anti-CD25 monoclonal antibody basiliximab, which blocks IL-2 receptors. Other induction agents for high-risk cases are ATG and the monoclonal antibody alemtuzumab (Campath).

The commonest maintenance immunosuppressive regimen for solid organ transplants consists of triple therapy with a calcineurin inhibitor (ciclosporin or tacrolimus), an antiproliferative agent (azathioprine or mycophenolic acid) and steroids.

Calcineurin inhibitors (ciclosporin and tacrolimus)

The calcineurin inhibitors (CNIs) are the mainstay of modern immunosuppressive regimens. CNIs prevent transcription of the IL-2 gene in T cells. As IL-2 is the main T-cell growth factor, inhibition of its production prevents T-cell proliferation.

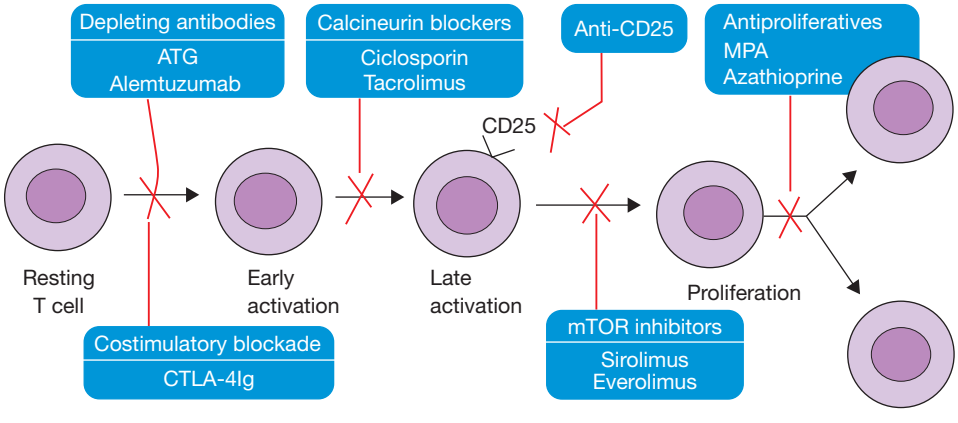

Figure 88.10 Site of action of immunosuppressive agents on T cell. ATG, antithymocyte globulin; CTLA-4Ig, cytotoxic T-lymphocyte-associated protein 4 immunoglobulin; MPA, mycophenolic acid derivatives; mTOR, mammalian target of rapamycin.

The main side effect of both ciclosporin and tacrolimus is nephrotoxicity. CNIs have a narrow therapeutic index (a small difference between the minimum effective concentration and the minimum toxic concentration). CNI dosage must therefore be guided by monitoring drug blood levels.

Antiproliferative agents (azathioprine and mycophenolic acid)

These drugs are antiproliferative agents. Their mechanism of action is to block purine nucleotide synthesis. This prevents replication of DNA and thus interferes with lymphocyte proliferation. The main side effects of both drugs are bone marrow suppression (anaemia, leukopenia, thrombocytopenia) and gastrointestinal symptoms (nausea, vomiting and diarrhoea).

Corticosteroids

These are potent anti-inflammatory agents that have wide-ranging effects on the immune system. Prolonged exposure to steroids causes numerous potential side effects, including: a Cushingoid appearance with a moon face, central obesity, abdominal striae and proximal myopathy; thin skin that bruises easily; hypertension; glucose intolerance that may lead to new-onset diabetes mellitus; osteoporosis; and peptic ulcer disease. These may be minimised by rapid reduction or withdrawal of steroids.

Mammalian target of rapamycin (mTOR) inhibitors

The mTOR inhibitors rapamycin and everolimus act by binding to and inhibiting a cytoplasmic kinase enzyme complex called mTOR. This prevents intracellular signalling from the IL-2 receptor. The downstream effect is arrest of T-cell division at the G1–S phase. The cell cycle effects of mTOR inhibitors are not limited to lymphocytes and their side-effect profile includes severe mouth ulceration, poor wound healing and lymphocele formation. This limits the use of mTOR inhibitors in the first few weeks post transplantation. However, mTOR inhibitors are not nephrotoxic and they may be used 3 months or more after transplantation as an alternative to CNIs to minimise CNI-associated renal dysfunction.

KIDNEY TRANSPLANTATION

End-stage renal disease

The incidence of end-stage renal disease (ESRD) in the UK is approximately 120 per million population and around 8000 people require renal replacement therapy annually. The leading causes of ESRD are diabetes, hypertension and chronic glomerulonephritis (***Summary box 88.1***). ESRD is largely a disease of older adults with the mean age at commencement of renal replacement therapy being 64 years.

Summary box 88.1

Common causes of ESRD

- Chronic glomerulonephritis
- Diabetic nephropathy
- Hypertension
- Renal vascular disease
- Polycystic kidney disease
- Chronic pyelonephritis
- Obstructive uropathy

Rationale for kidney transplantation

Kidney transplantation improves life expectancy and quality of life when compared with dialysis. However, only approximately one-third of patients with ESRD are fit enough to withstand transplant surgery and long-term immunosuppression. Successful transplantation frees patients from the rigors of dialysis and eliminates uraemic symptoms. Transplant kidneys produce normal levels of erythropoietin and this reverses the anaemia of chronic renal disease. Transplant patients therefore have more energy and better exercise capacity than patients on dialysis. There are also no fluid or dietary restrictions after transplantation. Importantly, for women of child-bearing age pregnancy is also possible after a successful kidney transplant. Life expectancy is higher in the transplant population with 5-year survival of >85% compared with <50% for patients on dialysis. However, these figures cannot be directly compared as there is selection bias because only relatively fit patients are offered transplantation.

Selection of patients for transplantation

Potential transplant recipients undergo a rigorous work-up process to identify major comorbidities that would preclude transplant surgery. Age per se is not a contraindication to renal transplantation and it is now common to transplant patients in their seventies as long as they have the necessary cardiovascular fitness. Uncontrolled infection and most malignancies are contraindications to transplantation. Patients with ESRD have a greatly increased risk of cardiovascular disease and require a chest radiograph, electrocardiogram (ECG) and, if indicated, an echocardiogram. Patients with a history of diabetes or ischaemic heart disease should undergo a stress echocardiogram and sometimes coronary angiography.

There are a number of technical considerations before a patient is deemed suitable for transplantation. The iliac blood vessels must be suitable for anastomosis and there must be a means of draining the transplant ureter. In patients with a history of vascular disease or deep venous thrombosis, the iliac arterial and venous system should be assessed by Doppler ultrasound scanning and possibly also MRA or CT angiography. Patients who have been anuric for a number of years may have a small non-compliant bladder and this should be assessed by urodynamics. In patients with polycystic kidney disease, the size of the native kidneys should be assessed clinically to make sure that there is sufficient room for a kidney

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.
Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the Doppler principle in 1842.

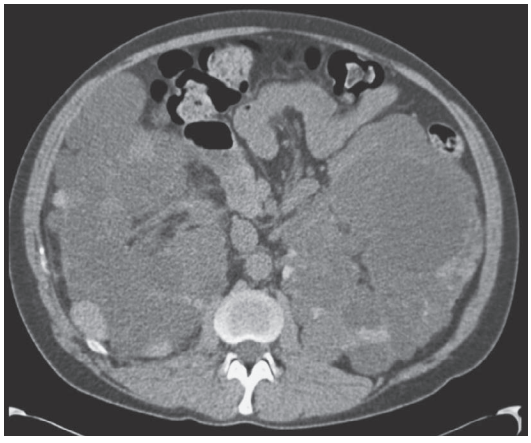

Figure 88.11 Computed tomography scan of a patient with very large polycystic kidneys that extend well into both iliac fossae. The patient requires removal of one of the polycystic kidneys to make room for a subsequent renal transplant. Nephrectomy should be performed several weeks before transplantation.

transplant in at least one iliac fossa. If there is inadequate space on both sides, then a pretransplant native nephrectomy will be necessary (*Figure 88.11*). With the exclusion of non-melanotic skin cancer, patients who have had a malignant disease should be deferred for a disease-free period of at least 2 years. Where possible patients should be listed for transplantation pre-emptively when they are within 6 months of requiring dialysis. This equates to an estimated glomerular filtration rate (eGFR) of 10–15 mL/min/1.73m^2.

RENAL TRANSPLANT SURGERY

Preparation of the donor kidney

The donor kidney must be examined and prepared on the back-table in order to check that it is suitable to be transplanted. Multiple renal arteries are present in up to 25% of kidneys and, if present, may require reconstructive bench surgery to simplify implantation. The renal arteries are end arteries, so it is important whenever possible to preserve all branches (*Figure 88.12*).

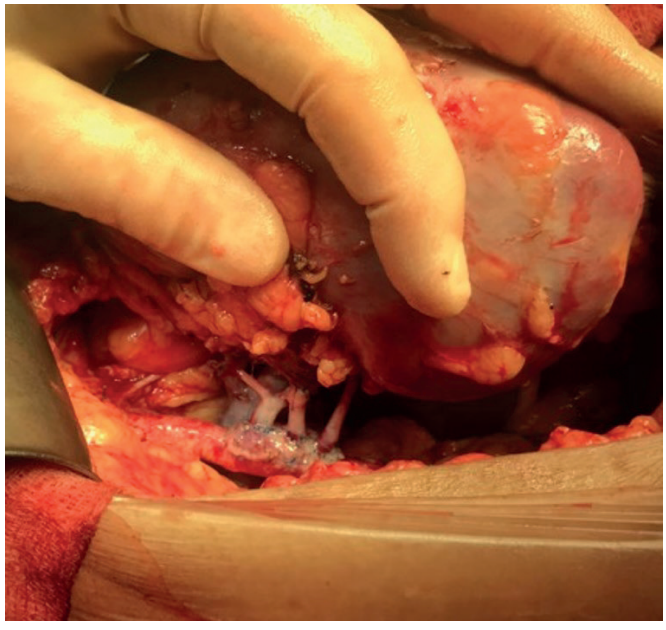

Figure 88.12 Deceased donor renal transplant with three arteries that have been reconstructed using a patch of donor aorta and anastomosed to the external iliac artery.

Renal transplant operative technique

The donor kidney is transplanted heterotopically into one of the iliac fossae via a curvilinear incision. The peritoneum should be kept intact and swept upwards to reveal the iliac vasculature. The transplant renal vein is anastomosed end to side to the external or common iliac vein. The renal artery is anastomosed either end to side to the external or common iliac artery or end to end to the divided internal iliac artery (*Figure 88.13*). The internal iliac artery is used more commonly for live donor kidneys because of the lack of an aortic patch. There are several

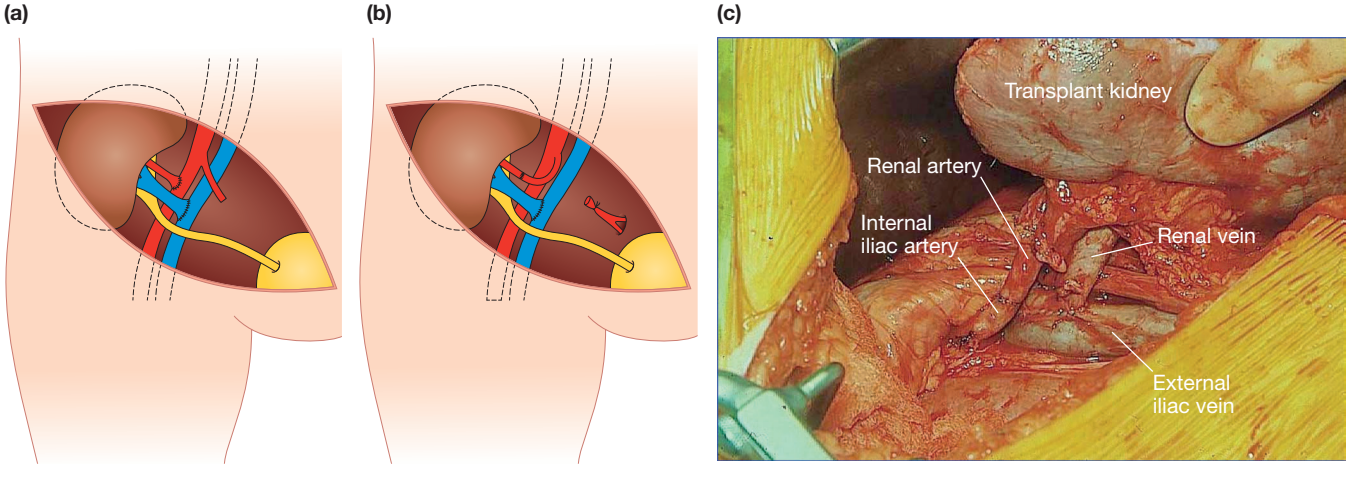

Figure 88.13 Renal allograft implantation techniques. (a) Anastomosis of the renal artery on a donor aortic patch end to side to the external iliac artery. (b) Anastomosis of the renal artery end to end to the divided internal iliac artery. (c) Operative photograph of anastomosis of the renal artery end to end to the internal iliac artery and the renal vein end to side to the external iliac vein.

techniques for anastomosing live donor kidneys with multiple arteries, but it is best to minimise the number of anastomoses by careful bench surgery. For example, equal-sized arteries can be 'trousered' to create a single ostium for anastomosis. Upper or lower polar arteries may also be anastomosed to the divided inferior epigastric artery. It is especially important to anastomose lower polar arteries as these may provide the only blood supply to the ureter. After revascularisation of the transplant kidney the ureter is anastomosed to the bladder as an extravesical onlay (the Lich–Grégoir technique) (***Figure 88.14***). It is now routine practice to place a double-J stent across the ureteric anastomosis. The stent is removed by flexible cystoscopy under local anaesthesia after a few weeks. Before closing the wound it is important to ensure that the kidney is lying in a satisfactory position without kinking of the renal blood vessels.

Dual kidney transplantation

This involves the transplantation of a pair of marginal quality kidneys from the same donor into one recipient in order to provide adequate nephron mass. Both kidneys can be placed in the same iliac fossa. This approach is used for kidneys from elderly DCD donors and so-called expanded criteria donors, which are defined by age >60 years or age >50 years with at least two of the following: hypertension; terminal creatinine >133 μmol/L; death from stroke.

Renal transplantation in children

In children with established renal failure, kidney transplantation facilitates their growth and development and markedly improves the quality of life of the child and their parents. In young children there is often a size mismatch between the donor kidney, which may be from an adult, and the recipient. In this case the kidney is transplanted intraperitoneally with anastomosis of the renal artery to the distal aorta and the renal vein to the inferior vena cava or common iliac vein.

Living donor kidney transplantation

This accounts for approximately 1000 kidney transplants annually in the UK, which is approximately one-third of the total renal transplant programme. Living donors may be related, unrelated, altruistic or part of a donor exchange scheme (for ABO blood group or HLA incompatibility). Potential live donors undergo extensive assessment that includes urine and blood screening tests, chest radiograph, ECG, echocardiography (if indicated) and CT angiography or MRA for the assessment of renal vascular anatomy. Renal function is measured by an accurate isotope GFR technique and must be above evidence-based age- and gender-specific safety thresholds for donation. Following unilateral nephrectomy, there is considerable compensation by the remaining kidney and donors are usually left with 70% of their predonation GFR. The mortality from donor nephrectomy is approximately 1:3000 and major morbidity occurs in <5%. Donation increases the risks of hypertension, renal failure and pregnancy-related complications.

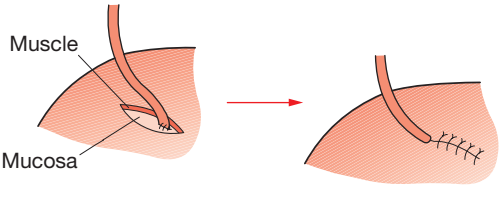

Figure 88.14 Ureteric implantation by direct anastomosis to a small cystotomy: Lich–Grégoir technique.

Minimally invasive donor nephrectomy

Laparoscopic surgery is now widely established and there are a number of techniques. After a fully laparoscopic transperitoneal dissection (***Figure 88.15***), the kidney is removed through a small retrieval incision. Hand-assisted laparoscopic nephrectomy is also used widely. A hand port is used to aid the dissection and for extraction of the kidney. This technique is easier to learn and can be safely performed by surgeons with less laparoscopic experience.

Immunosuppressive regimen for renal transplantation

Immunosuppression for renal transplantation generally comprises induction therapy with the anti-CD25 monoclonal antibody basiliximab followed by a maintenance regimen of a calcineurin inhibitor (most usually tacrolimus), an antiproliferative agent (usually mycophenolic acid) and corticosteroid (prednisolone). The anti-CD52 monoclonal antibody alemtuzumab can be used for induction instead of basiliximab for

patients at high risk of allograft rejection or as part of a steroid avoidance strategy in patients at high risk of developing diabetes post transplantation.

Early postoperative course

Accurate fluid and electrolyte balance are maintained with the help of central venous pressure monitoring. Hyperkalaemia is common in the early post-transplant period, especially in patients with DGF. This should be managed initially with intravenous glucose and insulin but early dialysis is often required. Recovery is straightforward in the majority of renal transplant patients. The bladder catheter is removed on postoperative day 5 and most patients can be discharged on day 6.

Delayed renal allograft function

DGF is defined as the need for dialysis in the first 7 days post transplant. The patient will be oliguric or anuric and the serum creatinine will fail to fall in the early postoperative period. DGF is usually the clinical consequence of acute tubular necrosis related to ischaemia–reperfusion injury. It occurs in around 30% of DBD kidneys and 60% of DCD kidneys because of the significantly longer warm ischaemic period prior to *in situ* organ cooling. In contrast, DGF occurs in <5% of live donor kidneys because of the short cold ischaemic time. An early Doppler ultrasound study should be performed in all patients with DGF to check that the graft is well vascularised. The management of DGF is supportive with haemodialysis, careful fluid balance and avoidance of CNI toxicity. Graft function usually recovers within a few days, but it may take several weeks. Primary non-function is the term used for grafts that never work. This occurs in <5% of renal transplants as a result of either vascular thrombosis or irreversible ischaemic injury leading to cortical necrosis.

Surgical complications of renal transplantation

Haemorrhage

A haematoma may develop in the transplant bed in the first few postoperative days. This is often due to bleeding from small unsecured vessels in the renal hilum that were not apparent at the time of surgery. In this situation the patient is haemodynamically stable and can be investigated by CT angiography and subsequently re-explored to remove the haematoma.

Anastomotic haemorrhage can also occur but is very rare. It presents as haemorrhagic shock associated with a fall in the haemoglobin to <50 g/L. This is a life-threatening situation and the patient should be returned to the operating theatre immediately. It may be possible to repair a defect in an arterial or venous anastomosis but transplant nephrectomy is often required.

Late anastomotic haemorrhage can also occur after some weeks or months owing to the development of a mycotic aneurysm. The commonest causative organism is donor-derived *Candida albicans*. A ruptured mycotic aneurysm requires an immediate graft nephrectomy and has a significant mortality.

Renal artery thrombosis

Although this occurs in <1% of renal transplants, the most common outcome is loss of the allograft. Most cases are due to technical complications at the arterial anastomosis. The usual presentation of renal artery thrombosis is sudden anuria and a rapid decline in renal function. The diagnosis may be missed in patients who have DGF or a normal urine output from their native kidneys. An urgent Doppler ultrasound scan will show an absence of perfusion to the graft. The patient must be returned to the operating theatre immediately to attempt thrombectomy, but most grafts will already be infarcted and transplant nephrectomy will be required.

Renal vein thrombosis

Renal vein thrombosis occurs in 1–5% of transplants. It may be due to a technical error such as kinking or torsion of the venous anastomosis, but many cases are idiopathic. The peak incidence occurs at postoperative days 3–7. The presentation is distinctive with sudden pain over the renal transplant associated with frank haematuria. In early cases with partial thrombosis, Doppler ultrasound scanning may demonstrate reversal of arterial blood flow in diastole. In an established renal vein thrombosis Doppler scanning will demonstrate marked swelling of the renal allograft, often with a significant surrounding haematoma due to rupture of the renal capsule. Re-exploration to attempt a thrombectomy is rarely successful and the vast majority of cases lead to graft loss.

Urological complications

Urological complications occur in approximately 5% of renal transplants but they rarely result in graft loss. After dissection of the ureters at organ retrieval, only the ureteric blood supply from the renal artery is preserved. In consequence, the blood supply of the distal transplant ureter can be poor.

Urinary leak

Urinary leaks can occur in any part of the urinary drainage system but are commonly due to ischaemic necrosis of the distal ureter. The peak incidence is at the time of urinary catheter removal (day 5) but leaks can be delayed for a few weeks. In early leaks clear fluid discharges through the wound or collects in the drains. Biochemical analysis will show that the fluid is urine (creatinine in the millimolar range) rather than lymph (creatinine in the micromolar range and equal to the serum level). Leaks presenting later on when the wound is fully healed present as a peritransplant fluid collection.

Initial management is bladder catheterisation and cystography to confirm the diagnosis. The anatomical site and extent of the leak can be determined by inserting a percutaneous nephrostomy and performing antegrade pyelography. It is sometimes possible to place a double-J stent across the leakage point using an antegrade approach. If there has been significant ischaemic necrosis of the distal transplant ureter the leak will not resolve and surgery will be required. There are a number of alternatives for reconstructing the urinary drainage system. If there is a sufficient length of transplant ureter after excision of the necrotic segment, the ureter can be reimplanted directly into the bladder over a new double-J stent. If the

healthy section of the transplant ureter is too short, a native-to-transplant ureteroureterostomy or ureteropyelostomy can be performed. Finally, if the ipsilateral native ureter is absent, because of a previous nephrectomy, a Boari bladder flap can be fashioned to drain the transplant kidney.

Ureteric obstruction

This can occur at any time after transplantation (days to years). Early obstruction is usually due to a technical error in the bladder anastomosis. Obstruction occurring after 3 months is invariably due to an ischaemic stricture. BK polyomavirus infection is also a cause of ureteric stricture. Patients present with renal dysfunction and investigation by ultrasound scanning reveals hydronephrosis. The initial management of choice is to place a percutaneous nephrostomy. An antegrade pyelogram can then be performed to define the site and extent of the stricture. Short strictures may be treated by interventional radiology with antegrade balloon dilatation and placement of a double-J stent across the stricture. Long, tight strictures require surgery and the options for reconstruction are the same as those for a urine leak.

Lymphocele

The incidence of significant lymphoceles (>3 cm) that cause complications and need treatment is around 5%. Small lymphoceles (<3 cm) are more common but asymptomatic and resolve spontaneously. The usual source of a lymph leak is from lymphatics that are divided during dissection of the iliac vessels. Lymph accumulates as a collection because of the extraperitoneal position of the kidney. Large lymphoceles can compress surrounding structures and, in some cases, cause renal vein thrombosis or ureteric obstruction.

All large peritransplant collections should be aspirated under ultrasound to exclude a urinary leak. Lymph is characterised by having the same biochemical profile as serum. Percutaneous drainage, sometimes on a number of occasions, leads to resolution of most lymphoceles. If this fails surgical drainage is required. This is usually performed laparoscopically and involves creating a fenestration in the wall of the lymphocele so that it drains into the peritoneal cavity.

Transplant renal artery stenosis

The incidence of transplant renal artery stenosis (TRAS) is approximately 5%. The usual presentation is refractory hypertension associated with allograft dysfunction at 3–6 months post transplant. TRAS activates the renin–angiotensin–aldosterone system and may become evident by a sudden increase in serum creatinine after prescribing an angiotensin-converting enzyme inhibitor.

Doppler scanning is suggestive of TRAS when the arterial peak systolic velocity is >250 cm/s and the waveform may have the characteristic tardus parvus (Latin for late and small) pattern. MRA or CT angiography are useful for anatomical definition. Percutaneous transluminal angioplasty with or without stenting is the preferred treatment.

Acute renal allograft dysfunction

This can be defined as a rise in serum creatinine of >10% from baseline or an absolute rise of ≥20 μmol/L. Common causes are listed in ***Summary box 88.2***. Allograft dysfunction should be investigated by urinalysis and culture to exclude urinary tract infection, CNI blood levels for drug-mediated nephrotoxicity and Doppler ultrasound scanning to check for arterial perfusion, venous drainage and hydronephrosis due to urinary obstruction. If there is uncertainty about the cause of graft dysfunction, a percutaneous needle-core transplant biopsy should be performed to establish whether allograft rejection is present.

Summary box 88.2

Causes of early graft dysfunction

Any rise in serum creatinine of >10% of baseline or ≥20 μmol/L should be considered as acute allograft dysfunction that requires investigation. Possible causes are:

- Acute rejection (antibody mediated or cell mediated)
- Calcineurin inhibitor toxicity
- Dehydration
- Urinary tract infection or pyelonephritis
- Any other source of sepsis
- Renal vein or renal artery thrombosis
- Ureteric obstruction or urine leak

Long-term allograft dysfunction

There are immunological and non-immunological causes for a progressive decline in renal allograft function over a period of months or years (***Summary box 88.3***). The commonest cause of long-term renal allograft damage and subsequent loss is chronic AMR. This is often related to inadequate compliance with immunosuppressive medication. There is no proven treatment for chronic AMR.

Non-immunological causes are also significant risk factors for chronic allograft damage. Irrespective of the cause, chronic transplant injury leads to interstitial fibrosis and tubular atrophy. Once established these changes are irreversible and will eventually lead to failure of the transplant.

The two most important factors in maintaining good long-term allograft function are meticulous adherence to immunosuppressive medication and good blood pressure control (<130/80 mmHg).

Outcomes after renal transplantation

Patient and graft survivals vary according to donor type and are presented in ***Table 88.4***. Overall, kidney transplantation is a highly successful treatment for ESRD. Living donor transplants yield better results than deceased donor transplants.

Achille Boari, nineteenth century Italian urological surgeon from Ferrara, described the technique of a bladder flap in dogs in 1894; it was first performed in a patient in 1936.

Summary box 88.3

Causes of long-term graft dysfunction

- Immunological
  - Chronic AMR
  - Acute CMR or AMR, which can occur at any time
- Non-immunological
  - Pre-existing damage in the donor kidney (especially relevant to DCD and extended criteria donor kidneys)
  - Early ischaemia–reperfusion injury
  - Chronic calcineurin nephrotoxicity
  - Ureteric or bladder outflow obstruction
  - Recurrent urinary tract infection or pyelonephritis
  - BK polyomavirus nephropathy
  - Recurrent native disease: glomerulonephritis; focal segmental glomerulosclerosis; immunoglobulin A nephropathy
  - Renal artery stenosis
  - Poorly controlled hypertension
  - Dyslipidaemia

DBD and DCD kidney transplants have comparable patient and graft survival.

Although these survival analyses are helpful, most patients want to know how long their transplant can be expected to last. This is best expressed by graft half-life ($t_{½}$) data (median graft survival). The current overall $t_{½}$ for live donor transplants is approximately 25 years and for deceased donor transplants approximately 15 years.

For all types of kidney, increasing donor age is the most important risk factor for poorer graft survival. Long cold ischaemic time (>12 hours for DCD kidneys and >24 hours for DBD kidneys) is also associated with reduced graft survival. Graft survival also decreases as the number of HLA mismatches increases.

TABLE 88.4 Patient and graft survival after renal transplantation.

Type of allograft (donor source)	5-year patient survival	10-year patient survival	5-year graft survival	10-year graft survival
Live donor	95%	90%	90%	80%
Deceased donor	90%	80%	85%	75%

Deceased donor includes both DBD and DCD results, which are comparable.

PART 13 | Transplantation

CHAPTER 89

Liver transplantation

Learning objectives

To know:
- The surgical principles of liver transplantation
- Potential future developments in liver transplantation

To understand:
- The main indications and patient selection for liver transplantation
- The complications after liver transplantation
- Living donor and paediatric liver transplantation
- The causes of liver graft dysfunction
- Liver graft preservation techniques

INDICATIONS AND PATIENT SELECTION

The indications for liver transplantation (LT) fall into four groups:

1. chronic liver disease (CLD);
2. acute liver failure (ALF);
3. metabolic liver disease (including liver-based inborn errors of metabolism);
4. primary hepatic malignancy (hepatocellular carcinoma [HCC], hepatoblastoma).

The most common indication for LT is decompensated CLD (*Table 89.1*). In adults the most common causes are alcoholic liver disease, non-alcoholic fatty liver disease (NAFLD), chronic viral hepatitis (hepatitis B virus [HBV] and hepatitis C virus [HCV]), autoimmune liver diseases (primary biliary cirrhosis, primary sclerosing cholangitis, autoimmune hepatitis and overlap syndromes) and cirrhotic metabolic liver diseases (Wilson's disease). The specific frequencies of these aetiologies depend on geographical variations. In the last two decades hepatitis-related CLD (HBV and HCV) was the most common indication for LT. However, with universal vaccination for HBV and newer treatment options for HCV and with increasing obesity in affluent countries, NAFLD is projected to become the most common indication for LT in the future. In children, who account for around 10–15% of all LTs, biliary atresia is the most common indication for transplantation. ALF requiring transplantation on an urgent basis accounts for approximately 10% of LT activity and is usually drug induced or viral (e.g. paracetamol overdose in the UK). There are a variety of non-cirrhotic metabolic diseases for which transplantation offers the prospect of cure, including urea cycle defect, oxalosis and familial hypercholesterolaemia. Primary hepatic malignancy is more common in patients with cirrhosis, especially viral-induced liver disease and NAFLD, and may be best treated by transplantation when advanced liver disease precludes liver resection because of the risk of postoperative liver failure or when the tumour is multifocal as a result of field changes in the cirrhotic liver that predispose to recurrence or further primary malignancies.

LTs are usually performed between ABO blood group-compatible donor–recipient pairs. Histocompatibility matching, as in kidney transplantation, has not been necessary in LT as the liver is considered a more immunologically privileged organ. In countries where living donor liver transplantations (LDLTs) are performed in large numbers because of a lack of deceased donor organs, there has been a recent increase in the number of ABO-incompatible LTs when there is no blood group-compatible donor available. However, there is an increased risk of infection owing to a higher immunosuppression protocol and a higher incidence of antibody-mediated rejection with this type of transplantation.

Potential candidates undergo a comprehensive multidisciplinary assessment, including hepatologists, transplant surgeons, anaesthetists, specialist nurses in LT, drug and alcohol rehabilitation services, dietician, psychologists and specialists from other clinical disciplines where indicated. Three underlying principles dictate which patients should be referred for, and potentially undergo, LT. First, the recipient should have irreversible liver disease (acute or chronic) that is expected to be fatal without transplantation. Second, the patient should have sufficient reserve to survive the operative and perioperative period. Finally, the candidate should be expected to have significant survival (>50% at 5 years) and quality of life benefit from LT.

Samuel Alexander Kinnier Wilson, 1878–1937, Professor of Neurology at King's College Hospital, London, UK. He described hepatolenticular degeneration in his gold medal winning MD dissertation of 1912 titled 'Progressive lenticular degeneration', which led the disease to be named after him as Wilson's disease.

TABLE 89.1 Conditions that are considered for liver transplantation in adults and children.

	Aetiology in adult	Aetiology in children
Acute liver failure (severe acute impairment of liver function with encephalopathy that occurs within 8 weeks of the onset of symptoms and no recognised underlying chronic liver disease)	• Drugs (paracetamol overdose) • Hepatitis A and E • Acute Wilson's disease • Autoimmune hepatitis • Acute fatty liver of pregnancy	• Drugs and toxins • Hepatitis A and E • Acute Wilson's disease
Chronic liver disease (any diseases that cause cirrhosis and its associated complications)	• Fatty liver disease: alcohol or non-alcohol related • Chronic viral hepatitis B, C, D • Autoimmune liver diseases: primary biliary cirrhosis, primary sclerosing cholangitis, overlap syndromes • Genetic haemochromatosis • Wilson's disease • α_1-antitrypsin deficiency • Secondary biliary cirrhosis	• Biliary atresia • α_1-antitrypsin deficiency • Autoimmune hepatitis • Sclerosing cholangitis • Caroli's syndrome • Wilson's disease • Cystic fibrosis • Progressive familial intrahepatic cholestasis • Alagille's syndrome • Glycogen storage disease (types 3 and 4) • Tyrosinaemia type 1 • Budd–Chiari syndrome • Any aetiology leading to hepatopulmonary syndrome or portopulmonary hypertension
Variant syndromes (metabolic liver disease with life-threatening extrahepatic complications in children)	• Intractable pruritus • Hepatopulmonary syndrome • Familial amyloidosis • Primary hypercholesterolaemia • Hepatic epithelioid haemangioendothelioma • Recurrent cholangitis • Nodular regenerative hyperplasia • Hereditary haemorrhagic telangiectasia • Glycogen storage disease • Ornithine transcarbamylase deficiency • Primary hyperoxaluria • Maple syrup urine disease • Porphyria • Amyloidosis	• Crigler–Najjar syndrome • Urea cycle defects • Hypercholesterolaemia • Organic acidaemias • Glycogen storage disease type 1 • Maple syrup urine disease • Porphyria
Liver tumours	• Hepatocellular carcinoma • Rarely – cholangiocarcinoma, neuroendocrine tumours, colorectal liver metastasis	• Unresectable hepatoblastoma (without active extrahepatic disease) • Unresectable benign liver tumours with disabling symptoms

LIVER TRANSPLANTATION FOR HEPATIC MALIGNANCY

As a general rule, malignancy in a solid organ is not an indication for transplantation. This is because of the risk of recurrence with immunosuppression post transplant; immunosuppression suppresses not only the host's immunity preventing rejection of the transplanted graft but also the host's immunity against cancer, which may cause rapid progression of disease after transplantation. However, LT is one area where a total hepatectomy in selected patients can remove the entire disease en bloc and give patients a full chance of cure. LT is widely indicated as a curative treatment for selected patients with HCC, haemangioendothelioma and hepatoblastoma. Because of its association with CLD, up to 25% of LTs in the UK are in patients with HCC. Using the size and number of HCCs on pretransplant imaging, there are a number of criteria that aim to select patients who have HCC with favourable tumour biology and hence a good outcome following LT. The two main staging criteria of HCC for the indication of LT are the Milan and the University of California San Francisco (UCSF) criteria.

With recent advances in diagnostic modalities and chemotherapeutic agents, LT has been carefully expanded to patients

Jacques Caroli, 1902–1979, Professor of Medicine, St Antoine Hospital, Paris, France, described the disease in 1958.
Daniel Alagille, 1925–2005, Eminent Professor of Paediatric Hepatology, Hôpital Bicêtre, Paris, France, first described this condition in 1969.
George Budd, 1808–1882, Professor of Medicine, King's College Hospital, London, UK, described this syndrome in 1845.
Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France after the end of the First World War, in 1918), gave his account of this condition in 1898.
John Fielding Crigler, 1919–2018, American pediatrician, described the rare inherited disorder Crigler–Najjar syndrome in 1952.
Victor Assad Najjar, 1914–2002, Lebanese–American pediatrician and microbiologist, described the rare inherited disorder Crigler–Najjar syndrome in 1952.

Summary box 89.1

Evaluation of potential recipients for LT

- Evaluation is undertaken by a multidisciplinary team, including a transplant surgeon and hepatologist
- Determine the presence of physical and mental health comorbidities
- Exclude malignancy and systemic sepsis
- Determine any contraindications
- Determine if the patient will benefit from LT with an acceptable quality of life
- Determine if the disease is sufficiently advanced to meet the minimal listing criteria for LT (e.g. UK end-stage liver disease [UKELD] score 49 or more)
- Determine the availability of family or social support and probable ability to cope psychologically with LT and comply with immunosuppression
- Optimise recipient condition before LT

with other primary or secondary malignancies of the liver. Cholangiocarcinoma (CCA) has been an uncommon indication for LT for nearly three decades. Recently there has been more interest with wider adaptation of the Mayo protocol, which involves strict patient selection, intensive pre-LT chemoradiation therapy, staging laparoscopy to assess tumour spread and then transplantation. Five-year survival has been reported in the range of 55–65% for hilar CCA in patients with primary sclerosing cholangitis (PSC), who get these cancers more commonly than *de novo* CCAs.

Summary box 89.2

LT for hepatic malignancy

- LT for HCC simultaneously treats the tumour and the underlying liver disease
- LT for HCC represents 15–50% of all transplants performed in most centres
- Milan criteria allow selection of HCC patients for LT, with improved overall and disease-free survival
- Milan criteria (one lesion ≤5 cm, or three or fewer lesions ≤3 cm each)
- UCSF criteria (one lesion ≤6.5 cm, or three or fewer lesions ≤4.5 cm each, with a total tumour diameter ≤8 cm)
- UK HCC criteria (one lesion <5 cm, or five or fewer lesions all ≤3 cm, or a single tumour >5 cm and ≤7 cm in diameter with no evidence of progression over a 6-month period)
- Tumour recurrence after LT for HCC ranges between 8% and 20% depending upon the criteria followed
- Primary malignant liver tumours constitute just over 1% of all childhood cancers
- The most common tumours that require LT in children are hepatoblastoma and HCC
- CCA, colorectal and neuroendocrine liver metastases are among the new indications for LT

LISTING FOR LIVER TRANSPLANTATION

The allocation of liver grafts to patients with end-stage liver disease is dominated by three ethical principles: equity (need), utility (usefulness) and transplant benefit. The equity model gives prioritisation for sickest first, the utility prioritises the patient with the best expected outcome from transplantation and transplant benefit prioritises the patient with the greatest difference in expected survival with and without transplantation. The last balances both equity and utility and is expected to minimise mortality and maximise survival for the overall patients listed for transplant.

TECHNIQUE OF LIVER TRANSPLANTATION

Deceased donor liver transplantation

A reverse-L or a Mercedes-Benz (transverse abdominal incision with a midline extension) incision is usually made and the diseased liver is mobilised. As a result of portal hypertension, the recipient hepatectomy (removal of damaged liver) is often the most difficult part of the operation, especially if there has been previous upper abdominal surgery. The common bile duct is divided, as are the hepatic arteries. The inferior vena cava is mobilised above and below the liver; the portal vein is clamped and divided, and the vena cava is divided above and below, allowing the recipient liver to be removed. This 'classical' technique (***Figure 89.1a***) allows quick removal of the recipient liver without the need to free the liver from the cava by tying all the short and named hepatic veins (i.e. caval 'preservation' technique). Occlusion of the vena cava and portal vein results in a reduction in cardiac output and may necessitate the use of venovenous bypass, albeit not commonly. The bypass circuit delivers blood from the inferior vena cava and/or portal vein, back to the heart via a cannula inserted into the internal jugular vein. This improves venous return to the heart and provides haemodynamic stability during the operation. The portal limb of the bypass also reduces portal hypertension and congestion of the bowel during the implantation phase and potentially can reduce blood loss.

After total hepatectomy the implantation starts by placing the liver graft in the orthotopic position. The supra- and infrahepatic caval anastomoses are the first to be performed. The liver is flushed through the portal vein with normal saline at room temperature to remove the preservative solution with the effluent draining out through the lower caval anastomosis, which is left incomplete until the flushing. The portal vein anastomosis is then completed and the graft is reperfused. The hepatic artery anastomosis can sometimes be done first to reperfuse the liver with arterial blood followed by the portal vein anastomosis. ***Figure 89.2*** shows a cirrhotic liver and the deceased donor liver after transplantation. Finally, biliary drainage is re-established usually by a duct-to-duct anastomosis

The Mercedes-Benz sign takes its name from the insignia displayed on the bonnet of a Mercedes-Benz car.

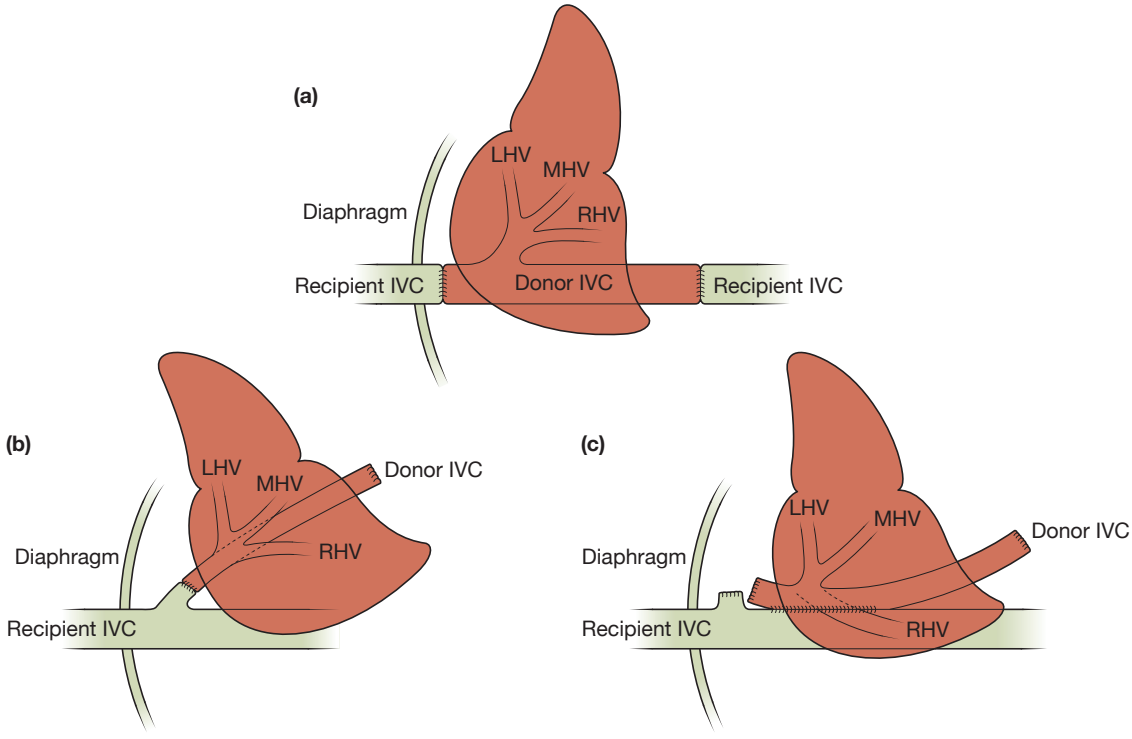

Figure 89.1 Pictorial representation of inferior vena cava (IVC) reconstruction in a deceased donor live transplantation. **(a)** A 'classical' caval replacement technique in which the recipient's retrohepatic IVC is replaced with donor IVC. **(b)** A 'piggyback' technique in which the confluence of the three hepatic veins in the recipient is used to anastomose with the top end of the donor IVC. **(c)** 'Side-to-side cavo-cavoplasty' in which the side of the donor IVC is joined with the side of the recipient IVC. LHV, left hepatic vein; MHV, middle hepatic vein; RHV, right hepatic vein.

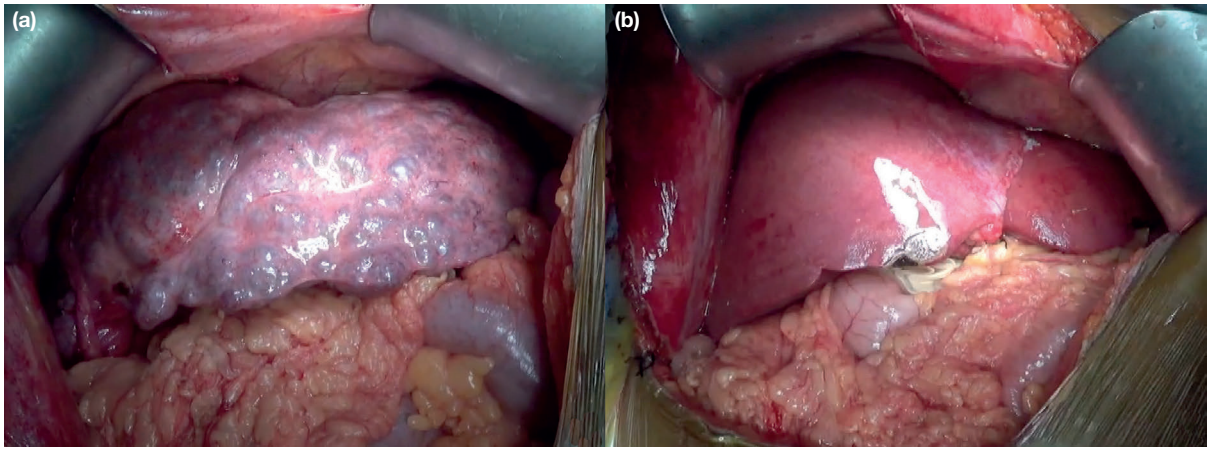

Figure 89.2 Adult deceased donor liver transplantation. **(a)** Recipient cirrhotic liver; **(b)** whole liver graft after reperfusion with the portal vein and hepatic artery.

(***Figure 89.3a***). In recipients with biliary atresia where the bile duct is absent or in those with PSC where the bile duct is diseased, the donor bile duct is reconstructed through a Roux-en-Y hepaticojejunostomy (***Figure 89.3b***).

An alternative and more commonly performed technique is the 'caval preservation' technique, which allows the recipient liver to be removed without cross-clamping the vena cava, thus avoiding venovenous bypass. The donor liver here is implanted using a 'piggyback' technique onto the confluence of the three hepatic veins in the recipient (***Figure 89.1b***) or using a side-to-side cavo-cavoplasty (joining donor and recipient cava side to side) (***Figure 89.1c***).

Optimal perioperative management is crucial to a successful outcome and presents a major challenge. These patients are often very sick preoperatively, especially those transplanted for ALF. Blood loss during and after the transplantation procedure can be very considerable, and management of coagulopathy is particularly important. Coagulation is assessed repeatedly

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

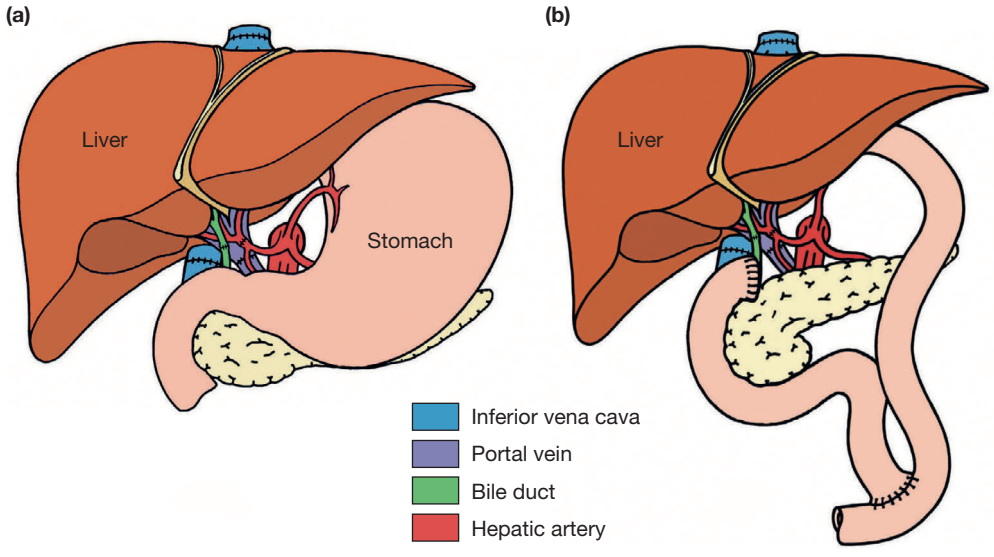

Figure 89.3 Pictorial representation of the standard deceased donor liver transplant with a 'classical' caval replacement technique. **(a)** A liver graft after completion of all anastomoses, in order of performance: (1) suprahepatic cava; (2) infrahepatic cava; (3) portal vein; (4) hepatic artery; (5) bile duct. **(b)** A Roux-en-Y reconstruction where the donor bile duct is anastomosed to the loop of jejunum. The rest of the anastomoses and order of performance are the same.

throughout the transplantation period and corrected with appropriate clotting factors, if required. Many centres routinely use point-of-care 'viscoelastic monitoring' such as thromboelastography (TEG) or rotational thromboelastometry (ROTEM) to perform dynamic assessment of coagulation.

The deceased donor liver transplant (DDLT) grafts come from either donation after brain death (DBD) donors or donation after circulatory death (DCD) donors. The latter are considered 'extended criteria' donors owing to greater ischaemia associated with donor hypoxia/death, higher risk of graft dysfunction, higher risk of vascular and biliary complications and poor long-term outcomes. Although LT has established itself as a life-saving treatment, the limited availability of deceased donor liver grafts has urged the transplant community to devise newer techniques and strategies to reduce the gap between organ demand and supply. The various options to increase organ availability are: LDLT, split and reduced-size LT, use of extended criteria donors (ECDs), auxiliary LT, domino LT and the paired-exchange programme.

Summary box 89.3

Types of LT (based on source of liver allograft)

- DDLT, which includes DBD (70–80%) and DCD (20–30%)
- LDLT – this can be adult to adult or adult to child
- Split and reduced-size LT
- ECDs
- Auxiliary LT
- Domino LT
- Paired-exchange programme

Living donor liver transplantation

In 1988, Silvano Raia in Sao Paolo, Brazil, was the first to introduce the concept of LDLT in a child. Although unsuccessful, this was followed by a report of a successful outcome in paediatric LDLT by Russell Strong in Brisbane, Australia. The expansion of LDLT to the adult population began in 1993, when the Shinshu group in Tokyo performed the first successful adult-to-adult LDLT. However, adult-to-adult LDLT is not without risks to the donor, with the global mortality risk quoted at 1 in 300–500 for adult donors. Right lobe, left lobe or left lateral segments can be used as grafts depending on the size requirement for the recipient. Right lobe grafts, which account for 60–70% of the total liver volume, are the most commonly used grafts for adult LDLT (***Figure 89.4***). The required graft volume is measured by either the graft weight to recipient weight ratio (GRWR) or the ratio of graft volume relative to the standard liver volume of the recipient (GV/SLV). An ideal GRWR must be >0.8% and/or GV/SLV >35%. The assessment of volume of the graft in the donor is measured by marking the boundaries of the liver lobe on the donor computed tomography (CT) scan manually, but this can also be done more accurately using complex three-dimensional software such as MeVis (HepaVision®, Bremen, Germany). The remnant liver mass in the donor must be kept to >30% of the whole liver, which allows for safe regeneration and prevents the risk of liver insufficiency in the donor.

LDLT is now undertaken in a number of transplant centres worldwide and is relatively common practice in some countries where deceased donation is not practised for cultural or religious reasons, notably in the Far East and South Asia. Over 90% of

Silvano Raia, b. 1930, Emeritus Professor at the Faculty of Medicine, Sao Paulo, Brazil, performed the first living donor liver transplantation in a child.
Russell Strong, contemporary, Emeritus Professor of Surgery, University of Queensland, Princess Alexandra Hospital, Australia. He successfully performed a living donor liver transplant of the left lateral segment of a Japanese mother's liver into her 18-month-old son in 1989. Both were alive and well 27 years later (2016); the recipient graduated and is practising as a physiotherapist.

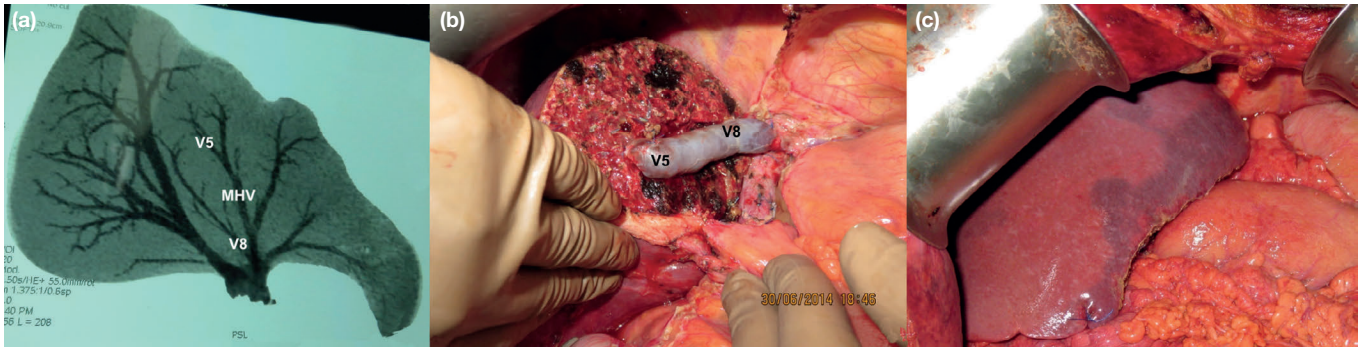

Figure 89.4 Adult right lobe living donor liver transplantation (LDLT). **(a)** Hepatic vein cuts showing the segment 5 vein (V5) and segment 8 vein (V8) draining into the middle hepatic vein (MHV). **(b)** A right lobe LDLT graft after implantation showing the reconstructed V5 and V8 using a deceased donor iliac vein graft. **(c)** A well-perfused right lobe liver graft.

transplants in the East come from LDLT, whereas in the West over 90% of all LTs are DDLT. With increasing experience and innovation, the graft and recipient survival of adult-to-adult LDLT now compare favourably with those of DDLT.

If the recipient size is large, a right liver LDLT graft might not give an adequate GRWR. Similarly, if the donor remnant is small, it is not safe for the donation to proceed. To tackle the problem of inadequate graft size in LDLT one innovative approach is 'dual-graft liver transplantation', done mostly in Korea and rarely in other LDLT countries; this approach is to transplant the recipient with two left lobe grafts or one right lobe and one left lobe graft from two living donors. With this approach, donor safety is maintained and the recipient is transplanted with adequate graft volume. The procedure is technically very demanding and requires massive infrastructure where two donor hepatectomies and recipient LT surgery have to take place all at the same time. However, the ethical issue of putting two donors at risk simultaneously for one recipient's benefit is contentious.

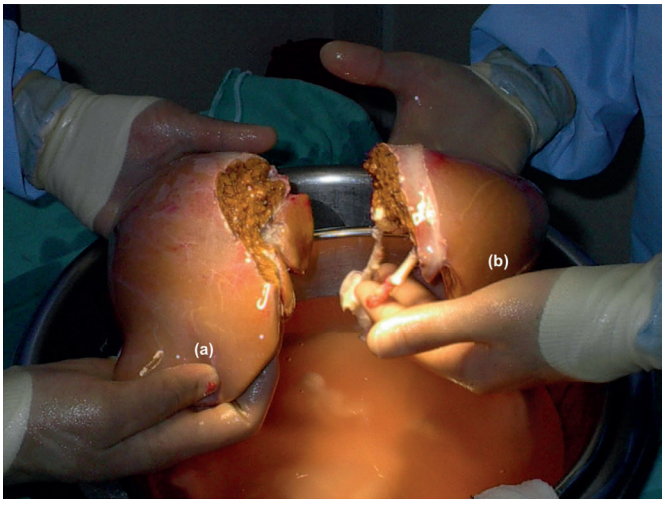

Figure 89.5 *Ex situ* splitting of a donation after brain death liver. **(a)** Extended right lobe liver graft (Couinaud's segments I and IV–VIII) prepared for implantation into an adult recipient; **(b)** left lateral segment graft (Couinaud's segments II and III) prepared for implantation into a paediatric recipient.

Split and reduced-size liver transplantation

Split LT is a valuable option for making the best use of good-quality deceased donor liver grafts, by splitting the graft into a left lateral segment (segments II and III) for a paediatric recipient and an extended right liver lobe (segments I and IV–VIII) for an adult recipient. Not so commonly, the whole liver can be split as anatomical right and left lobes, the latter being used for a larger child or a smaller adult. The splitting procedure can be done *ex situ*, where the whole organ is retrieved and split on the back-bench along the anatomical planes, so as to preserve the inflow and outflow vessels to both grafts (***Figure 89.5***). In *in situ* splitting, liver transection is performed during the donor procedure, similar to procuring a living liver donor graft. The major advantage of *in situ* splitting in contrast to *ex situ* bench splitting is that haemostasis on the cut surface can be obtained during the donor procedure with less blood loss from the cut surface during reperfusion in the recipient. *In situ* splitting also facilitates prompt transportation of the liver to transplant centres if the two split lobes are to be used in two different centres far away from each other, thereby reducing the cold ischaemic times for both organs.

Although technically demanding, split LT is a safe procedure resulting in an increased number of LTs, increased feasibility of LT in children and a reduced waitlist mortality. Short- and long-term outcomes and survival with these grafts are similar to those with whole-graft LT. Reduced-size LT is the forerunner of split LT and involves *ex vivo* resection of a full liver into an appropriate size liver to fit a small adult, with the rest of the reduced-size portion being discarded. Reduced-size LT, unlike a split technique, does not produce an additional graft. It is therefore not widely practised and is reserved for situations where a small adult or adolescent patient requires an urgent transplant and a whole liver or an extended right lobe is too large for the abdominal cavity.

Claude Couinaud, 1922–2008, French surgeon and anatomist, described the segmental anatomy of the liver in his seminal book *Le Foie: Études anatomiques et chirurgicales*.

Extended criteria donors

Using grafts from ECDs is a strategy to address organ shortage in LT. An ECD graft has been described as an organ with an increased risk of poor graft function (liver from older donors or fatty livers) and/or transmission of disease (i.e. infection or malignancy) to the recipient because of unfavourable donor characteristics (*Table 89.2*). In comparison with DBD, DCD LTs have been associated with higher rates of biliary complications and graft loss, historically limiting their use. Worldwide, there is considerable variation in the contributions that DCD makes to deceased donation overall. While some countries have no DCD programmes whatsoever (such as India, where it is illegal to procure a DCD organ), in countries like the UK and Australia DCD accounts for 20–30% of all LTs. DCD livers reduce waiting list mortality (i.e. by taking patients off the LT waiting list) and there is survival advantage in accepting a DCD offer than waiting for a 'better' DBD liver, which is more pronounced in patients with advanced liver disease. Outcomes with ECD organs can be improved with careful recipient selection and possibly with machine perfusion of the donor liver, so as to assess its function and quality, prior to transplantation.

Auxiliary liver transplantation

Auxiliary LT involves implanting a healthy liver graft placed either heterotopically or orthotopically while leaving all or part of the native liver intact. Auxiliary heterotopic LT, where the graft is implanted below the native liver, was proposed as an alternative to orthotopic LT in the early era of transplantation when recipient hepatectomy was associated with massive blood loss and transfusion requirements. But the technique was marred with failures due to the heterotopic position of the graft resulting in poor venous drainage. More recently there has been a renewed interest in auxiliary LT for ALF and certain metabolic liver diseases. To overcome the previous technical difficulties, the procedure is now performed with a partial graft placed in an orthotopic position following a recipient partial hepatectomy to create space for the graft (*Figure 89.6*). The procedure is therefore termed auxiliary partial orthotopic liver transplantation (APOLT). It is a technically

TABLE 89.2 Extended criteria donors in liver transplantation.

Type of extended criteria donor	Primary risk to the recipient
Advanced donor age	Delayed graft function
Macrovesicular steatosis	Delayed graft function
Donation after circulatory death organs	Biliary complication
Organ dysfunction at procurement: • ICU stay >7 days • Hypernatraemia >165 mmol/L • Bilirubin >51 μmol/L • Elevated liver enzymes (AST, ALT) • Vasopressor use	Delayed graft function, primary non-function
Cause of death: anoxia, cerebrovascular accident	Delayed graft function, biliary complication
Disease transmission: • Hepatitis B core antibody-positive donor • Hepatitis B surface antigen-positive donor • Hepatitis C virus-positive donor • HIV-positive donor • High-risk history (active drug abuser, etc.) • Extrahepatic malignancy	Infectious risk
Cold ischaemia time >12 hours (long storage of organ after procurement)	Delayed graft function, primary non-function

ALT, alanine aminotransferase; AST, aspartate aminotransferase; HIV, human immunodeficiency virus; ICU, intensive care unit.

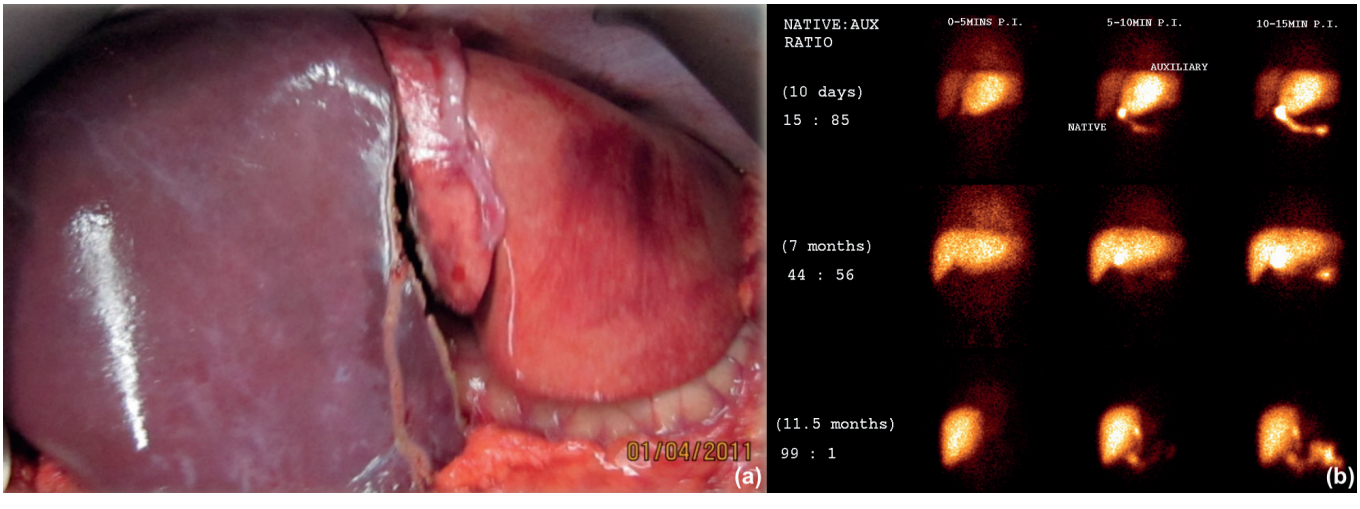

Figure 89.6 Right lobe auxiliary partial orthotopic liver transplantation (APOLT) for acute liver failure due to yellow phosphorus poisoning. **(a)** Recipient left lateral section of the liver looking pale and fatty owing to yellow phosphorus poisoning; right lobe graft from the donor implanted into the orthotopic position. **(b)** Hepatobiliary iminodiacetic acid (HIDA) scans done over the first year after transplant in a left lobe APOLT. The scans show regression of the left lobe auxiliary graft and functioning native liver.

complex procedure and has gained acceptance as a bridge to native liver regeneration in ALF. The most important benefit of APOLT is the potential for immunosuppression withdrawal when the native liver fully regenerates, although outcomes have been suboptimal in less experienced hands. In metabolic liver diseases in children, APOLT is performed with the intention of keeping part of the native liver for future gene therapy.

Domino liver transplantation

Domino LT involves transplanting a liver from a patient with metabolic disease who needs LT into a patient with end-stage liver disease with the expectation that the recipient will not develop the metabolic syndrome or the recurrent syndrome will have minimal effect. Several hereditary metabolic diseases such as familial amyloid polyneuropathy (FAP), maple syrup urine disease and familial hypercholesterolaemia are caused by aberrant or deficient protein production in the liver, and these conditions can be cured with an orthotopic LT. Although their native livers eventually caused severe systemic disease in these patients, these livers are otherwise structurally and functionally normal, and hence used as domino into those with end-stage liver failure. A typical example of domino LT is the use of a liver from a patient with FAP to a patient who is outside transplant criteria for liver malignancy. Even if they develop amyloidosis, it would take 10–20 years for the disease to become symptomatic in these recipients. If they have no recurrence of tumour and become symptomatic from FAP in the future they can be offered a retransplant without the risk of recurrence of malignancy.

Paired-exchange programmes

Liver paired exchange (LPE) allows liver donors and their intended incompatible recipients to exchange livers with another donor–recipient pair so that a compatible transplant can be performed. The advantage is that it allows the two transplant recipients to be removed from the deceased donor waiting list, thereby shortening the waiting for other patients who remain on the list, decreasing waiting list mortality. ABO blood group incompatibility, size incompatibility (small donor liver into large recipient or vice versa) or anatomical considerations (multiple arteries or bile ducts to reconstruct) are common reasons for non-acceptance of otherwise suitable donors in LDLT. In all these circumstances, donor and recipient pairs who are not optimally matched might benefit from a better match through LPE. At times, these LPEs can be initiated by a non-directed anonymous living donor (i.e. a domino paired exchange), where a person effectively donates a portion of their liver to the pool of patients on the deceased donor transplant waiting list. Compared with kidney paired exchange, LPE is inherently more complex owing to the greater morbidity and mortality risks to the donor and to the logistics involved, hence it is not widely practised.

Summary box 89.4

Strategies to overcome the shortage of livers for transplantation

- Increasing the donor pool
  - Implementing an organ donation opt-out system (introduced in the UK in Wales – December 2015; England – May 2020; Scotland – March 2021)
  - Use of marginal DBD deceased donors
  - Use of DCD deceased donors
  - Increased use of split LT
  - Increased living donor LT
  - Use of HCV-positive donor grafts
- Improve the preservation and assessment of quality of donor grafts
  - Use of machine perfusion systems (normothermic/hypothermic machine perfusion)
- Maximise post-transplant long-term survival
  - Reduce or avoid immunosuppression after LT to minimise side effects

IMMEDIATE POST-TRANSPLANT CARE

Following LT, patients are monitored in an intensive care unit (ICU) and maintained on a ventilator, usually for less than 24 hours. If haemodynamically stable and awake with good early liver graft function and renal function they are extubated. Spontaneous correction of lactic acidosis and correction of coagulopathy (falling international normalised ratio [INR]) and low serum transaminases are indicators of good early graft function. A Doppler ultrasound is also performed prior to extubation to assess the patency of blood supply to the liver. Most patients with an uncomplicated postoperative course get moved to the high-dependency unit or ward after 2 days. During the ICU stay, there is close management of fluid and electrolytes, which could be significantly abnormal as a result of the prolonged operation and massive fluid shifts. Following transfer to the transplant wards, the patient is closely monitored by the transplant surgical and medical (hepatology) team, as well as by pharmacists, nutritionists and physiotherapists. The liver and kidney function, the coagulation parameters and full blood count are monitored daily. Doppler ultrasound scans are performed at regular intervals to ensure that the blood vessels are patent and there are no other abnormalities. Dosages of immunosuppressive agents are adjusted according to blood levels and organ function during this period. Antibacterial, antiviral and antifungal prophylaxis are given to prevent infections, including those from opportunistic organisms, such as cytomegalovirus (CMV) and *Pneumocystis carinii*.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the Doppler principle in 1842.

Summary box 89.5

Factors determining graft function after LT

- Donor characteristics
  - Advanced donor age
  - DCD donors
  - Steatotic livers
  - Small graft size in LDLT ('small for size syndrome')
- Procurement-related factors
  - Warm ischaemic time
  - Type of preservation solution
  - Cold ischaemic time
- Recipient-related factor
  - High MELD or UKELD score
  - Severe portal hypertension
  - Technical factors relating to implantation
  - Haemodynamic and metabolic stability
  - Massive transfusion of blood and blood-related products
  - Immunological factors

IMMUNOSUPPRESSION FOLLOWING LIVER TRANSPLANTATION

Liver is considered to be an 'immunoregulatory' solid organ with specialised venous endothelial turnover, a high number of extramedullary haematopoietic stem cells and the ability to produce numerous immunoregulatory substances. The privileged state of liver in transplantation is highlighted by the relatively lower need for human leukocyte antigen (HLA) or blood-group matching. Compared with other organs, such as kidneys and lungs, the liver allograft has the advantage of demonstrating lower rates of acute and chronic rejection, a resistance to antibody-mediated rejection and a higher likelihood of developing spontaneous tolerance. Induction agents such as antithymocyte globulin (ATG), CD25 monoclonal antibodies (basiliximab and daclizumab) or cluster of differentiation (CD)52 monoclonal antibodies (alemtuzumab; Campath-1H), which routinely form part of kidney, pancreas and other organ transplants, are rarely used in LT. They are only considered in selected patients with a high immunological risk or renal compromise, in the latter case to delay the introduction of calcineurin inhibitors (CNIs). CNIs (tacrolimus and ciclosporin) are the mainstay of LT maintenance immunosuppression, with mycophenolate mofetil (MMF), azathioprine and corticosteroids considered as the essential adjuncts to CNIs (*Table 89.3*). Mammalian target of rapamycin inhibitors (mTORi) such as sirolimus and everolimus have established roles in patients with worsening renal function and in those with LT for HCCs and incidental cancers on explant. The side effects of prolonged immunosuppression are one of the limitations of long-term survival among LT recipients, especially those due to immunosuppression-induced metabolic syndrome, cardiovascular disease, renal impairment and malignancy. Several studies have shown that 20% of LT patients can achieve operational tolerance, whereby there is long-term survival of the allograft in the absence of immunosuppression. However, there is a need for more research to understand this better and to identify the group of patients who will benefit from withdrawal of immunosuppression.

POST-LIVER TRANSPLANT COMPLICATIONS

Primary non-function

Primary non-function (PNF) is one of the most serious and life-threatening conditions in the immediate post-transplant period. It is defined as an aggravated form of reperfusion injury resulting in irreversible graft failure without detectable

TABLE 89.3 Common immunosuppression medications after liver transplant.

Drug	Mechanism of action	Major side effects	Monitoring
Calcineurin inhibitors (tacrolimus, ciclosporin)	Inhibit T-cell signalling, prevent lymphocyte activation and block cytokine transcription	• Nephrotoxicity • Hypertension • Diabetogenic (tacrolimus) • Gingival hypertrophy/hirsutism (ciclosporin) • Increased susceptibility to infection	Blood trough levels
Mycophenolate mofetil	Inhibits T-cell and B-cell proliferation	• Leukopenia • Increased susceptibility to infection and cancers	No monitoring
Azathioprine	Purine analogue, impedes DNA and RNA synthesis	Bone marrow suppression with cytopenias, pancreatitis	No monitoring
Corticosteroids	• Decrease cytokine production • Decrease lymphocyte activation and proliferation • Decrease antibody production • Decrease phagocytosis and release of proteolytic enzymes	Steroid excess (Cushing's syndrome)	No monitoring
mTORi (sirolimus/everolimus)	Mammalian target of rapamycin inhibitor	Impaired wound healing, hyperlipidaemia, proteinuria, hepatic artery thrombosis	Blood trough levels

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.

technical or immunological problems. The reported incidence is 4–8% and this is the most common indication for retransplantation after LT. It is almost always a problem associated with DDLT, but can present in LDLT as well.

Haemorrhage

Portal hypertension and coagulopathy of CLD are important causes of bleeding that are unique to LT procedures. A study of more than 12 000 LTs showed 12.5% needing re-explorations during the same hospitalisation, of which 68% were for bleeding. Meticulous haemostasis during the transplantation operation is important in order to minimise the risk of early haemorrhage. Excessive haemorrhage is also common if the graft has sustained a severe reperfusion injury or if a marginal graft is used and the early graft function is poor. *Ex situ* split LT can also have a high blood loss from the cut surface of the liver. This is not the case in *in situ* split LT and LDLT partial grafts where haemostasis is secured during the donor operation.

It is standard practice to place two large drains behind the right and left lobes of the liver to monitor for bleeding and bile leak. It may be necessary, occasionally, to pack the peritransplant area for 24–48 hours to achieve adequate haemostasis when there is diffuse oozing despite correction of coagulopathy. Evacuation of an extensive perihepatic haematoma may be required to avoid secondary infection.

Vascular complications

Hepatic artery thrombosis (HAT) is one of the most dreaded complications after LT, and may occur spontaneously or as a result of acute rejection; it is more common in children and in adults with PSC. The incidence of HAT has been reported to be in the range of 1–10% after LT. Anatomical variant grafts such as split, reduced and LDLT grafts have a higher risk of HAT when compared with whole-organ LT. Early HAT (within 4 weeks of LT) may present as a rise in serum transaminase levels, unexplained fever or bile leak. The risk factors for early HAT are not only related to technical factors such as vessel kinking, stenotic anastomosis and intimal dissection, but also to other factors such as elderly donors with calcified vessels, a hypercoagulable state in the recipient and rejection episodes. Doppler ultrasound or CT angiography is used to confirm the diagnosis, and urgent retransplantation is usually required. Endovascular interventions and thrombolysis are rarely successful. The UK super-urgent liver scheme allows listing of those patients who develop early HAT, up to 21 days after transplantation. Late HAT (after 4 weeks of LT) usually has an insidious course and can present as asymptomatic elevation of liver enzymes, bile duct strictures or liver abscess. The bile ducts suffer the most ischaemic insult as they primarily depend on arterial blood supply with no portal venous blood supply. Retransplantation is usually reserved for those with severe biliary complications.

Portal vein thrombosis and stenosis are rare and can present with features of portal hypertension. The management usually involves endovascular interventions such as balloon dilatation or stent insertion, surgical bypass or retransplantation. Late portal vein thrombosis/stenosis manifests as portal hypertension without graft dysfunction. Most can be managed conservatively without risk of graft loss.

Hepatic venous outflow obstruction often presents with increasing ascitic fluid losses over the postoperative period. A cavogram with hepatic vein pressure studies should be undertaken to confirm the diagnosis, and insertion of vascular stents, surgical correction or retransplantation may be required to treat the problem.

Biliary complications

The biliary complications usually present as bile leak, biliary anastomotic stricture (AS), biliary non-anastomotic stricture (NAS), bile duct sludge/stone/casts, biloma and duct loss (ductopenia) in patients with chronic rejection. Biliary complications following LT can be caused by the vulnerable vascular supply to the biliary tree (supplied by hepatic artery alone), the biliary epithelium being more liable to ischaemic injury than hepatocytes, suboptimal preservation of the peribiliary plexus

Summary box 89.6

Complications after LT

Early complications (within 6 months)

- Graft
  - Primary non-function
  - Delayed graft function
- Surgical
  - Bleeding
  - Hepatic artery thrombosis
  - Portal vein thrombosis
  - Hepatic venous outflow obstruction
  - Bile leak
  - Biliary anastomotic stricture
- Medical
  - Infections (bacterial, viral, fungal)
  - Rejections
  - Acute kidney injury

Late complications (after 6 months)

- Graft
  - Ischaemic cholangiopathy (non-anastomotic biliary strictures)
- Surgical
  - Vascular stenosis (hepatic artery, portal vein or hepatic vein)
  - Late HAT
  - Biliary AS
  - Incisional hernia
- Medical
  - Infections (bacterial, viral, fungal)
  - Rejections/chronic rejection leading to graft failure
  - Renal impairment
  - Disease recurrence
  - Cardiovascular disease
  - Metabolic and bone diseases
  - Malignancy

during organ procurement and storage and ischaemia–reperfusion injury. The incidence of biliary complications is higher in LDLT and other anatomical variant grafts than in whole-graft LT. This is because of the small size of the ducts, multiple duct anastomoses and also cut surface leaks. Due to the morbidity involved with biliary complications, bile duct anastomosis is considered the Achilles' heel of LT. The management of bile leaks usually involves bile duct reconstruction with Roux-en-Y hepaticojejunostomy in the immediate post-transplant period or endoscopic decompression of the bile duct and percutaneous drain insertion. For AS, the management involves endoscopic dilatation, stent insertion or surgical revision. The NAS or ischaemic-type biliary lesions (ITBL) are the most severe form of biliary strictures, where there is widespread desquamation of biliary epithelial cells with formation of biliary casts, multiple segmental stenosis and a picture similar to PSC. This can happen within a few weeks, months or years after transplantation and the incidence is 25–30% with DCD grafts but is less common in DBD grafts. The management will include imaging to rule out HAT or stenosis, dilatation of dominant strictures, ursodeoxycholic acid to increase bile flow and lower the lithogenicity and antibiotic maintenance therapy to prevent recurrent episodes of cholangitis. Eventually most patients will require retransplantation.

CAUSES OF ALLOGRAFT DYSFUNCTION

Liver graft dysfunction can happen any time after transplantation; if not identified early and treated promptly, it can lead to graft loss. The most common presentation is an asymptomatic elevation of liver enzyme levels. Early after LT, acute cellular rejection is the most common cause of graft dysfunction and is usually treated by increasing the dose of immunosuppression, which includes pulsed-steroid therapy for 3 days or more depending on the degree of rejection. The other common reasons for graft dysfunction are the vascular complications, bile leak or bile duct obstruction, post-transplant infections and drug toxicity. Even if rejection is suspected, it is important to rule out any vascular or biliary complications by performing a Doppler ultrasound scan and, if there is any doubt, a contrast-enhanced CT scan. Liver biopsy is usually performed through a percutaneous route, but a coagulopathic patient might need transjugular liver biopsy.

LT patients are followed up more frequently in the first 3 months after transplant, as this is the time when presentation with graft-related issues is most common and also when monitoring and optimisation of immunosuppression are crucial. The follow-up protocol varies between LT centres, but mostly includes once a week for the first 6 weeks after transplant and then once a fortnight for another 6 weeks, before reducing the frequency of appointment. Late graft dysfunction is usually due to acute/chronic rejection, vascular issues such as hepatic artery stenosis or venous outflow obstruction, biliary obstruction, recurrence of primary disease such as hepatitis C (rare nowadays owing to viral clearance prior to transplant), autoimmune diseases or NAFLD, and other opportunistic infections such as CMV or herpes simplex hepatitis.

DISEASE RECURRENCE AFTER LIVER TRANSPLANTATION

Disease recurrence after LT has increased over the past decade, as many more patients are living more than 15–20 years with their liver graft. Disease recurrence after LT can be divided into four main groups: (i) malignant disease, (ii) viral disease, (iii) autoimmune diseases such as primary biliary cholangitis (PBC) and PSC, and (iv) lifestyle-related diseases such as NAFLD and alcoholic liver disease. The severity of recurrence varies from mild to the development of progressive allograft failure.

Despite strict morphological criteria in selecting patients with HCC for LT, tumour recurrence still occurs in 8–20% of cases, being associated with a median survival of 7–16 months after recurrence. The risk factors for tumour recurrence are larger tumour burden (beyond the Milan criteria), poor tumour biology, microvascular invasion, higher AFP levels, viral aetiology and obesity in the recipient, percutaneous biopsy of the tumour leading to spillage of cells, longer waiting time to transplant, higher donor age, DCD transplants and higher burden of immunosuppression in the post-transplant period. HBV recurrence has been reported in 10% of patients after LT. However, new combinations of post-LT prophylaxis, including hepatitis B immunoglobulin and nucleos(t)ide analogues such as lamivudine, have reduced the recurrence rates and are part of most LT guidelines. HCV recurrence post LT leads to accelerated liver disease and cirrhosis, with reduced graft and patient survival. Factors associated with increased HCV risk or severity of recurrence after LT include older age, immunosuppression, HCV genotype 1 and high viral load at LT. The introduction of protease inhibitors in 2011 and direct-acting antiviral agents in 2013 has led to the reduction both of HCV complications requiring LT and of the consequences of recurrent HCV infection after LT. Autoimmune diseases commonly recur after LT and may need retransplantation. This usually happens when corticosteroids are withdrawn, but patients usually respond rapidly to the reintroduction of steroids with no adverse long-term impact. PBC and PSC can recur in 20% of patients at 5 years, some of which can be *de novo* secondary disease. Resumption of alcohol use post LT leads to recurrent ALD and has an overall poor outcome. NAFLD can recur in patients with metabolic syndrome who continue with poor dietary habits post LT, leading to fibrosis in the graft and eventually needing retransplantation. Prothrombotic conditions such as Budd–Chiari syndrome can recur in the transplanted liver, requiring retransplantation, but with dismal outcomes.

Summary box 89.7

Diseases that recur after LT

- Chronic hepatitis B and C
- PBC
- PSC
- Autoimmune hepatitis
- Alcoholic liver disease (recurrence alcohol consumption)
- NAFLD
- Budd–Chiari syndrome
- Malignant tumours (HCC, hepatoblastoma)

OUTCOMES AFTER LIVER TRANSPLANTATION

The outcomes after LT depend on the underlying liver disease; the best results are seen in patients with CLD. Patients undergoing transplantation as a result of ALF have a higher mortality in the early post-transplantation period because of multiorgan failure, but those who make a satisfactory recovery have very good long-term liver allograft survival. In the UK, unadjusted 1-, 5- and 10-year patient survival for adult patients receiving their first elective transplant is 94%, 84% and 72%, respectively. For super-urgent transplant, the survival is less: 90%, 82% and 70%, respectively (NHSBT Annual Report September 2020). Conversely, patients transplanted for tumour have a very good early outcome but ultimately fare less well because of recurrent malignancy. As with other solid organ transplants, chronic immunosuppression has its effect on the LT recipient with increased risk of infections, metabolic syndrome and cancers. The common causes of death in post-LT recipients after 3 years of transplant are mostly non-transplant related, such as malignancy or cardiovascular disease, and are less due to chronic rejection and recurrent primary liver disease.

PAEDIATRIC LIVER TRANSPLANTATION

Paediatric LT has now been carried out for more than three decades and enjoys excellent success with good long-term outcomes. Split LT and LDLT have contributed to reduced waiting times in these children with improved outcomes (***Figure 89.7***). Contraindications to LT in children are uncommon, and usually include: (i) non-resectable extrahepatic malignant tumour; (ii) concomitant end-stage organ failure that cannot be corrected by a combined transplant; (iii) uncontrolled sepsis; and (iv) irreversible neurological damage. Left lateral segment grafts usually suffice for small children, but larger children will need left lobe or right lobe grafts. The left lateral segment graft donor operation involves removal of around 20–25% of the liver; this is associated with a low and acceptable risk of donor complications. Monosegment grafts (transplanting isolated liver segments such as segment II or segment III for an infant) for small children (less than 5 kg) is a norm in experienced centres and can solve the problem of 'large for size' grafts in this age group.

CHALLENGES AND POTENTIAL FUTURE DEVELOPMENTS IN LIVER TRANSPLANTATION

Donor shortage is the key issue in LT. The biggest challenge ahead for the LT community will be to implement strategies that will overcome donor organ shortage, but at the same time maximise the long-term outcomes of the grafts transplanted. Reducing the waiting list mortality will involve bridging the gap between the demand and availability. Optimising the organ quality using newer technologies such as machine perfusion and 'growing livers in the lab' are exciting prospects that could overcome the chronic organ shortage.

Machine perfusion

With the advances and improvements in outcomes in LT over the last four decades, there has been a focus on expanding deceased donor organs. Static cold storage (SCS) remains the standard-of-care preservation method in LT. This is achieved by cooling the liver to 4°C with preservation solution; this decreases cellular energy consumption by reducing the metabolic demand of the tissue. However, when these SCS organs are reperfused, there is a higher ischaemia–reperfusion injury owing to efflux of accumulated metabolic products formed during cold storage, resulting in a profound inflammatory immune response and causing damage to the hepatocytes and cholangiocytes, thereby leading to poor short- and long-term outcomes. One of the ways of reducing ischaemia–reperfusion injury is to perfuse the liver with cold solution (hypothermic machine perfusion; HMP) or warm blood (normothermic

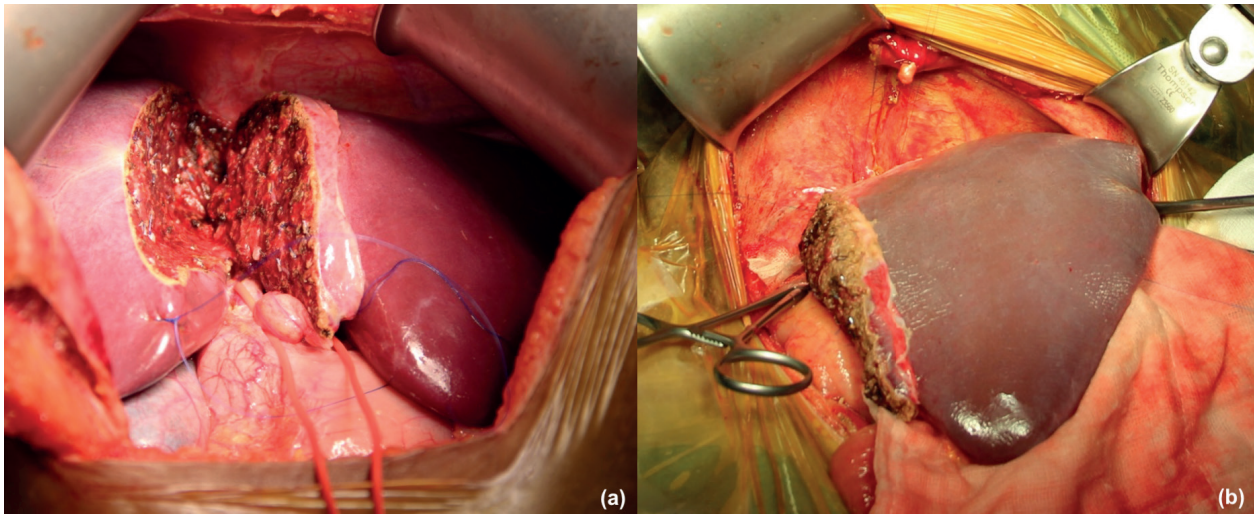

Figure 89.7 Paediatric living donor liver transplantation. **(a)** Donor left lateral segmentectomy where the parenchymal transection is completed and the graft is ready to be taken out; **(b)** the left lateral segment graft implanted into a paediatric recipient.

machine perfusion; NMP) with the aim of maintaining a healthy endothelium, replenishing adenosine triphosphate (ATP) and thereby improving quality. This allows the organs to be preserved for a longer period prior to transplantation, thereby addressing the logistics of LT. Further studies will be needed to explore the ideal perfusion method with the aim of improving longer term outcomes and avoiding biliary complications such as ischaemic cholangiopathy and to study viability markers to identify livers that will not function in the recipient, allowing liver-directed therapeutic interventions on the machine. In other exciting technology – *in situ* normothermic regional perfusion (NRP) – the blood supply to the abdominal organs after death is restored using extracorporeal circulation for a limited period before organ recovery. This leads to superior liver outcomes in DCD livers compared with conventional organ recovery, and may be an answer to the problem of ischaemic cholangiopathy.

Liver support devices

ALF has a high mortality in the range of 50–80%. Extracorporeal liver support systems have the potential to provide temporary support to bridge patients with ALF to LT or spontaneous recovery.

Artificial liver support devices function as 'dialysis' machines, which filter and adsorb toxic substances such as bilirubin, bile acids, metabolites of aromatic amino acids, medium-chain fatty acids and cytokines without significant loss of albumin from the circulation. Some examples of commonly available artificial liver support systems are the Molecular Adsorbent Recirculating System (MARS®; Gambro, Stockholm, Sweden) and Hepa Wash® (Hepa Wash GmbH, Munich, Germany). Biological liver support uses whole animal or human liver, and the liver support–detoxification is achieved by portal and/or artery perfusion. Some examples of commonly available biological liver support systems are the Extracorporeal Liver Assist Device (ELAD®; Vital Therapies Inc., San Diego, CA, USA) and the HepatAssist® system (Alliqua Inc., Langhorne, PA, USA).

Summary box 89.8

Definitions

- Acute liver failure: complex multisystem illness that evolves quickly after a catastrophic insult to the liver, leading to coagulopathy and encephalopathy; based on onset of encephalopathy – hyperacute (within 7 days), acute (8–28 days), subacute (>28 days)
- Allograft: an organ or tissue transplanted from one individual to another
- Chronic liver disease: progressive deterioration of liver functions for more than 6 months, with inflammation, destruction and regeneration of liver parenchyma, leading to fibrosis and cirrhosis
- Heterotopic graft: a graft placed in a site different from that where the organ is normally located
- HLA: human leukocyte antigen, the main trigger to graft rejection
- MELD score: model for end-stage liver disease score; predicts prognosis in patients with chronic liver disease and is used to allocate liver for transplant
- NAFLD: non-alcoholic fatty liver disease; associated with metabolic syndrome (obesity, hyperlipidaemia and diabetes mellitus). Some patients develop non-alcoholic steatohepatitis (NASH), which leads to fibrosis and cirrhosis
- Orthotopic graft: a graft placed in its normal anatomical site
- UKELD score: United Kingdom model for end-stage liver disease score; predicts survival of patients listed for LT in the UK

PART 13 | Transplantation

CHAPTER 90

Pancreas transplantation

Learning objectives

To understand:

- The indications and patient selection for solid organ pancreas transplant
- The different types of pancreas transplant and the respective surgical techniques
- The principles of immunosuppression
- The common surgical and long-term complications of solid organ pancreas transplant and their principles of management

To appreciate:

- The principles of pancreas retrieval and preservation

INTRODUCTION

Current World Health Organization estimates are that about 9% of the global population have diabetes. This translates to over 600 000 000 people living with diabetes, with a significant proportion of these patients requiring insulin: approximately 10% of this population has type 1 diabetes. The aims of pancreas transplantation are to restore normoglycaemia, with freedom from insulin therapy, and to limit the progression of complications associated with diabetes. Pancreas transplantation is most commonly (but not exclusively) performed in individuals with type 1 diabetes with end-stage renal disease. In certain diabetic patients without renal insufficiency, pancreas transplantation alone can be performed to avert life-threatening complications of hypoglycaemia and to prevent the progression of diabetic complications. Unlike cardiac, lung and liver transplant, pancreas transplantation is not an immediately life-saving procedure, although it significantly improves not only quality of life but also life expectancy. Despite successful outcomes in the majority of patients following transplant, particularly for combined kidney–pancreas transplant, there is significant morbidity and mortality associated with the procedure. These factors, including the complications of long-term immunosuppression, must be carefully weighed against any potential benefit prior to patient listing. Current data indicate that more than 42 000 pancreas transplants have been performed worldwide, with the majority having been in the USA.

BACKGROUND AND INDICATIONS

History

Kelly, Lillehei and colleagues performed the first successful pancreas transplant in a human at the University of Minnesota, USA, in 1966. Initial results were poor, with high mortality associated with sepsis, rejection and other complications, but over the subsequent 30 years there was a steady increase in the numbers of pancreas transplants and an improvement in outcomes. Important factors in this improvement were changes in surgical techniques and the introduction of the immunosuppressive agent ciclosporin in the mid-1980s: this reduced both the need for steroids and the incidence of rejection. By 1996 patient survival and pancreas graft survival were 91% and 72% at 1 year and 84% and 62% at 3 years, respectively. The introduction of tacrolimus and mycophenolate mofetil as maintenance immunosuppression and the use of T-cell-depleting agents such as rabbit antithymocyte globulin (ATG) and alemtuzumab in the 1990s and 2000s resulted in further reductions in cellular rejection rates and improved graft survival. Continued refinement of surgical technique, organ preservation and postoperative care have led to steady improvements in outcomes of all types of pancreas transplant.

Types of solid organ pancreas transplant

1. **Simultaneous pancreas–kidney transplant (SPK)**. Both organs come from the same deceased donor. This is the commonest type of pancreas transplant and is indicated in patients with chronic renal failure (on or close to requiring dialysis) secondary to diabetes.
2. **Pancreas transplant alone (PTA)**. Primarily for patients with type 1 diabetes who have repeated episodes of hypoglycaemia associated with unawareness (i.e. patients develop hypoglycaemic coma without warning). This is a life-threatening situation and such patients are

William D Kelly, 1922–2006, led the surgical team at University of Minnesota, Minneapolis, MN, USA, that performed the first pancreas transplant.
Clarence W Lillehei, 1918–1999, part of the surgical team at University of Minnesota, Minneapolis, MN, USA, that performed the first pancreas transplant, subsequently went on to pioneer open heart surgery.

often unable to live independently or carry out normal employment.

3 **Pancreas-after-kidney transplant (PAK)**. Deceased donor pancreas transplantation is performed after a previous kidney transplant, from either a living or deceased donor.

4 **Simultaneous deceased donor pancreas and live donor kidney transplant**. This option may shorten waiting times but is logistically very challenging and rarely performed.

Transplantation of the islets of Langerhans (islet cell transplant) is an alternative to pancreas transplant alone for patients with hypoglycaemic unawareness. This is not a solid organ transplant and therefore not detailed in this chapter, but a brief description follows. After pancreas retrieval, islets are isolated, prepared and delivered into the portal vein (PV) of the recipient, usually via a percutaneous transhepatic radiologically guided procedure. Early results demonstrated that the presence of functioning islets appeared to protect against refractory hypoglycaemia and improve glycaemic control but with a low incidence of insulin independence. However, success rates have improved in the last decade with some series showing 50% of patients remaining insulin independent at 5 years. Immunosuppression is required for islet transplantation and the associated long-term risks need to be balanced with the treatment benefits.

Indications

The indications for pancreas transplant can be split into those for patients with concomitant renal failure and those without. SPK is the most frequently performed procedure for patients with type 1 diabetes and renal failure due to diabetic nephropathy. There is a small population of patients with type 1 diabetes with renal failure due to primary renal disease or non-diabetic causes and they are also included in this group. The organs are almost exclusively from the same deceased donor, although there are rare examples of organs from living donors (LDs); however, LD pancreas transplantation has not been widely accepted and carries significant risk to the donor.

In patients with type 1 diabetes and the option of an LD kidney the possibilities are to undergo an LD kidney transplantation followed by either a PAK or an SPK. The decision is not clear-cut: although pancreas graft survival was historically superior in SPK, PAK results have improved over recent years and the outcomes of the two procedures are now similar. If the patient presents late and has already accrued time on dialysis, the high morbidity and mortality associated with dialysis (30% mortality at 5 years) renders LD kidney transplantation followed by PAK somewhat more desirable. The policy regarding SPK or LD kidney transplantation followed by PAK is dependent on many factors, particularly the expected waiting time for an SPK.

SPK indications as defined by the NHS Blood and Transplant Pancreatic Advisory Group (NHSBT PAG) include type 1 diabetes with end-stage renal failure requiring dialysis or dialysis predicted within 6 months (glomerular filtration rate [GFR] <20 mL/min). Patients with type 1 diabetes without renal failure but with life-threatening hypoglycaemic unawareness are potential candidates of solid organ PTA or islet transplantation. The annual mortality rate of patients with insulin-induced hypoglycaemic unawareness is estimated to be between 3% and 6% – a major risk for this group of typically young patients. In patients with early diabetic nephropathy the risk of repeated acute kidney injury (AKI) needs to be considered prior to PTA to minimise the chance of accelerating renal failure, and a baseline GFR of 80–100 mL/min/1.73m^2 means the patient is unlikely to need a kidney transplant.

Patients with type 2 diabetes can also be considered for SPK, although after careful selection: many obese patients with type 2 diabetes are better managed with diet and/or bariatric surgery. Suitable candidates are non-morbidly obese patients, typically with insulin requirements of less than <1 unit/kg body weight in 24 hours (to exclude patients with insulin resistance). When selected in this way, the results of SPK in these patients are similar to those in patients with type 1 diabetes.

Patient selection

Once the indication for pancreas transplantation is satisfied the patient needs a comprehensive assessment of cardiovascular and surgical fitness. An anaesthetic review, echocardiogram and assessment of inducible cardiac ischaemia using dynamic imaging such as a myocardial perfusion scan or stress echocardiogram should be performed. If cardiac assessment demonstrates occult ischaemic heart disease (IHD) then angiography and revascularisation via angioplasty or bypass surgery may be needed prior to wait-listing. Patients with diabetic nephropathy usually have other manifestations of secondary diabetic complications, including sensory neuropathy, retinopathy, gastropathy, peripheral vascular disease, foot ulcers and autonomic neuropathy leading to postural hypotension. These complications should be sought and discussed prior to listing as they can have an impact on whether a pancreas transplant is appropriate and may alter the surgical strategy. For example, the significant anticoagulation required post transplant can lead to retinal haemorrhage; in a patient with severe retinopathy, this can lead to a deterioration in vision and even blindness. Patients with severe gastropathy may require a feeding jejunostomy at the time of transplant surgery, as gastropathy and bowel dysfunction are frequently exacerbated by surgery, which can lead to vomiting, difficulties absorbing immunosuppressants and malnutrition. The overall risks of this major surgery and immunosuppression in a patient with advanced diabetic complications have to be balanced with the likely benefits in severely overweight patients: most transplant centres have a body mass index (BMI) cut-off (e.g. <32 kg/m^2).

Paul Langerhans, 1847–1888, German pathologist, physiologist and biologist credited with the discovery of the 'islets of Langerhans', the cells that secrete insulin in the pancreas.

Summary box 90.1

Types of transplant and patient selection

- There are three main types of solid organ pancreas transplant: SPK; PTA; PAK
- The most common indication for pancreas transplant is type 1 diabetes with diabetic nephropathy
- Hypoglycaemic unawareness and life-limiting complications from insulin therapy are indications for pancreas transplant alone
- A comprehensive preoperative assessment of surgical fitness and occult cardiac disease is essential prior to wait-listing

ORGAN DONATION AND PRESERVATION

Organ retrieval

Pancreas organ retrieval is standardised in the UK and is carried out by dedicated abdominal organ retrieval teams. Donation after brain death (DBD) donors constitute 75% of all pancreas donors with donation after circulatory death (DCD) donors making up 25%. The pancreas can be retrieved either alone or en bloc with the liver. If the liver and pancreas are retrieved en bloc the retrieval surgeon separates the organs, ensuring that there is 10 mm of PV and an adequate length of splenic artery (SA) and superior mesenteric artery (SMA) for reconstruction. The bifurcation of the iliac vessels is sent with the pancreas to facilitate a vascular Y-graft construction (***Figure 90.1***), creating a single arterial inflow. Only around 50% of pancreases that are retrieved with the intention of transplantation are actually transplanted; this is a much higher discard rate than occurs in other abdominal organs and is for a number of reasons. The condition of the pancreas is frequently suboptimal owing to fatty infiltration or fibrosis, features that are associated with a poorer outcome. Also, injury to the pancreas during retrieval is much more common than in other organs: it is easily damaged and the consequences of even a relatively minor parenchymal injury can be severe, with postoperative leakage of exocrine secretions. Acceptance criteria for pancreases varies between centres and is usually related to donor age, BMI, alcohol intake and lifestyle factors. Other adverse donor and retrieval features that impact acceptance rates include: a prolonged agonal phase in DCD donors, evidence of hepatic or pancreatic ischaemic injury (raised transaminases, amylase and lipase) and complex vascular anatomy.

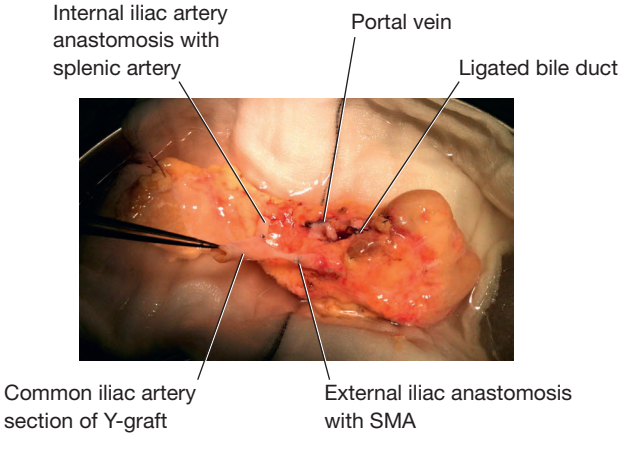

Figure 90.1 The inferior border of the donor pancreas prepared for implantation demonstrating a completed vascular reconstruction. The surgical forceps are holding the cut end of the donor common iliac artery and the completed anastomoses between the donor external iliac artery and the superior mesenteric artery (SMA) and the donor interior iliac artery with the splenic artery are demonstrated (blue vascular suture).

Organ preservation

Static cold storage (SCS) has remained the gold standard preservation method for the pancreas graft since the first transplantation was performed in 1966. SCS is the most common preservation method for organs after retrieval because of its simplicity, relative effectiveness for many organs and low cost. Hypothermic preservation is based on the principle that cooling an organ reduces the metabolic rate and the demand for adenosine triphosphate (ATP). The pancreas is extremely sensitive to both warm and cold ischaemia, which has a significant impact on preservation. Once retrieved from the donor, the pancreas is inspected for any damage and for adequacy of perfusion and then submerged in preservation solution within an organ bag and placed in an icebox for transport to the transplant centre. Unlike other organs the pancreas is not flushed following retrieval in order to minimise endothelial damage and (supposedly) to reduce the risk of early graft pancreatitis and thrombosis. Early pancreas transplants suffered from a significant thrombosis rate of up to 25%. For this reason, in 1986 Belzer and Southard set out to redefine the needs of pancreas preservation by developing a new preservation solution. This new solution – University of Wisconsin (UW) solution – was first successfully applied in experimental pancreas transplantation; this study was published by Wahlberg, who was a member of the Wisconsin group. The colloid constituent, hydroxyethyl starch (HES), was particularly important in the pancreas, especially in suboptimal organs and those with longer cold ischaemia times. Translation to clinical use of the UW solution led to a significant improvement in the results of pancreas transplantation and a marked reduction in pancreatitis and thrombosis of the grafts.

There have been studies in experimental pancreas preservation using hypothermic machine perfusion; in these studies the organ is continuously pumped with a cooled solution, but this has yet to translate into clinical practice, although recent results are promising. Normothermic machine perfusion of pancreases has been performed on animal and discarded human organs but led to organ injury, possibly because of

Folkert O Belzer, 1930–1995, pioneering transplant surgeon who was Chairman of the Department of Surgery, University of Wisconsin, USA, along with Jan Wahlberg (Uppsala, Sweden) and Rutger Ploeg (Leiden, the Netherlands) developed University of Wisconsin solution.

James H Southard, contemporary, Emeritus Professor, Department of Surgery, University of Wisconsin, USA, co-inventor of the University of Wisconsin solution with Belzer.

high concentrations of autolytic enzymes (amylase and lipase). Normothermic regional perfusion is a technique in which, following cessation of circulation in a DCD organ donor, the donor blood is warmed, oxygenated and then pumped back around the abdominal organs. This appears to be beneficial in the context of the liver, but has yet to show convincing data in pancreas transplantation – the numbers studied are small and the technique is still in its infancy.

Summary box 90.2

Organ donation and preservation

- The majority of pancreas transplants (75%) are from DBD donors
- The pancreas is the most frequently damaged organ during retrieval, which can impact on clinical outcomes
- SCS remains the gold standard of preservation, although research into machine perfusion is gaining momentum

SURGICAL TECHNIQUES

Preparation for transplant

Once the organ has been inspected and is deemed suitable for transplant it needs to be prepared for implantation. This is a crucial step and meticulous attention to detail and a systematic approach are vital to minimise bleeding and complications after reperfusion. The pancreas is retrieved with the spleen attached, a length of duodenum and the cut ends of the SMA, SA and PV (***Figure 90.2***). The splenic vessels are ligated and the spleen removed; the duodenum is shortened, stapled and the staple lines buried with a suture. Excess fat and omentum are removed, and the cut end of the inferior mesenteric vein ligated. An arterial 'Y-graft' is usually fashioned between the SMA and SA of the pancreas using donor iliac vessels, so that the end of the common iliac artery (CIA) can be used for a single arterial anastomosis (***Figure 90.1***).

Transplantation procedure

Pancreas transplant can be performed as an intraperitoneal or extraperitoneal procedure and the exocrine drainage of the pancreas can be managed by connection to the small intestine or urinary bladder (***Figure 90.3***). The majority of surgeons favour an intraperitoneal approach as the peritoneal cavity has an excellent capacity for containing and reabsorbing fluid generated as a result of reperfusion pancreatitis. The steps of the surgical procedure are as follows. A midline laparotomy is performed and the retroperitoneum is exposed. The inferior vena cava (IVC) and CIA are dissected and controlled. In the enteric drainage procedure (donor duodenum anastomosed to recipient jejunum) the organ is positioned with the head of the pancreas towards the liver and the tail towards the pelvis. However, for bladder drainage (donor duodenum anastomosed to recipient urinary bladder) the organ is positioned with the head facing towards the pelvis and tail towards the liver. A side-biting vascular clamp is used to partially occlude the IVC and the PV is anastomosed end to side to the IVC. Whether performing a single arterial anastomosis or separate SMA and SA anastomoses, the right CIA is most frequently used. Heparin is administered prior to clamping the CIA and the arterial anastomosis is performed. The organ is reperfused and haemostasis is ensured before performing the duodenal anastomosis (this renders the organ less mobile and more difficult to access). For enteric drainage, the jejunum is identified as close as convenient to the duodenojejunal flexure and anastomosed side to side to the duodenum in two layers. This can be performed by passing the duodenum through a window in the colonic mesentery, using a Roux-en-Y technique or with the two sections of bowel lying adjacent underneath the colon (***Figure 90.3***). The Roux-en-Y technique creates a blind-ending loop of bowel; if severe complications develop and the pancreas needs to be removed, then separation from the main enteric flow is straightforward and the need for a defunctioning stoma is avoided. In the bladder drainage technique, the anastomosis to the bladder is also performed in two layers and a urinary catheter is kept in place for 7–10 days to reduce the chance of anastomotic leak.

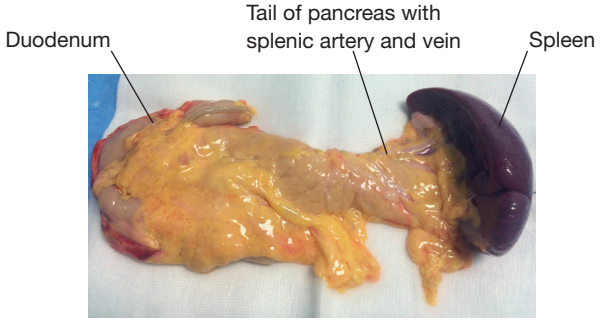

Figure 90.2 A healthy donor pancreas prior to preparation for surgical implantation. The pancreas is lying in its anatomical position with the head of the pancreas beneath omental fat encircled by the duodenum and the tail within the hilum of the spleen.

Enteric conversion

Bladder drainage of the exocrine secretions is associated with complications that may require conversion to enteric drainage. Enteric conversion is performed in patients to eliminate these complications of bladder drainage (see ***Postoperative management, Complications***). It is usually delayed until 1 year post transplant but can be performed sooner if indicated. A lower midline laparotomy is performed and the urinary bladder is filled and the transplant duodenum is identified. The transplant duodenum is disconnected from the bladder and the bladder is closed in two layers. An adjacent section of small bowel is identified and a longitudinal enterotomy is performed on the antimesenteric border; the anastomosis to the duodenum is completed in two layers. Surgical drains are placed adjacent to the anastomoses and a urinary catheter is usually kept in place for 14 days.

César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland. Described the Roux-en-Y loop in 1908.

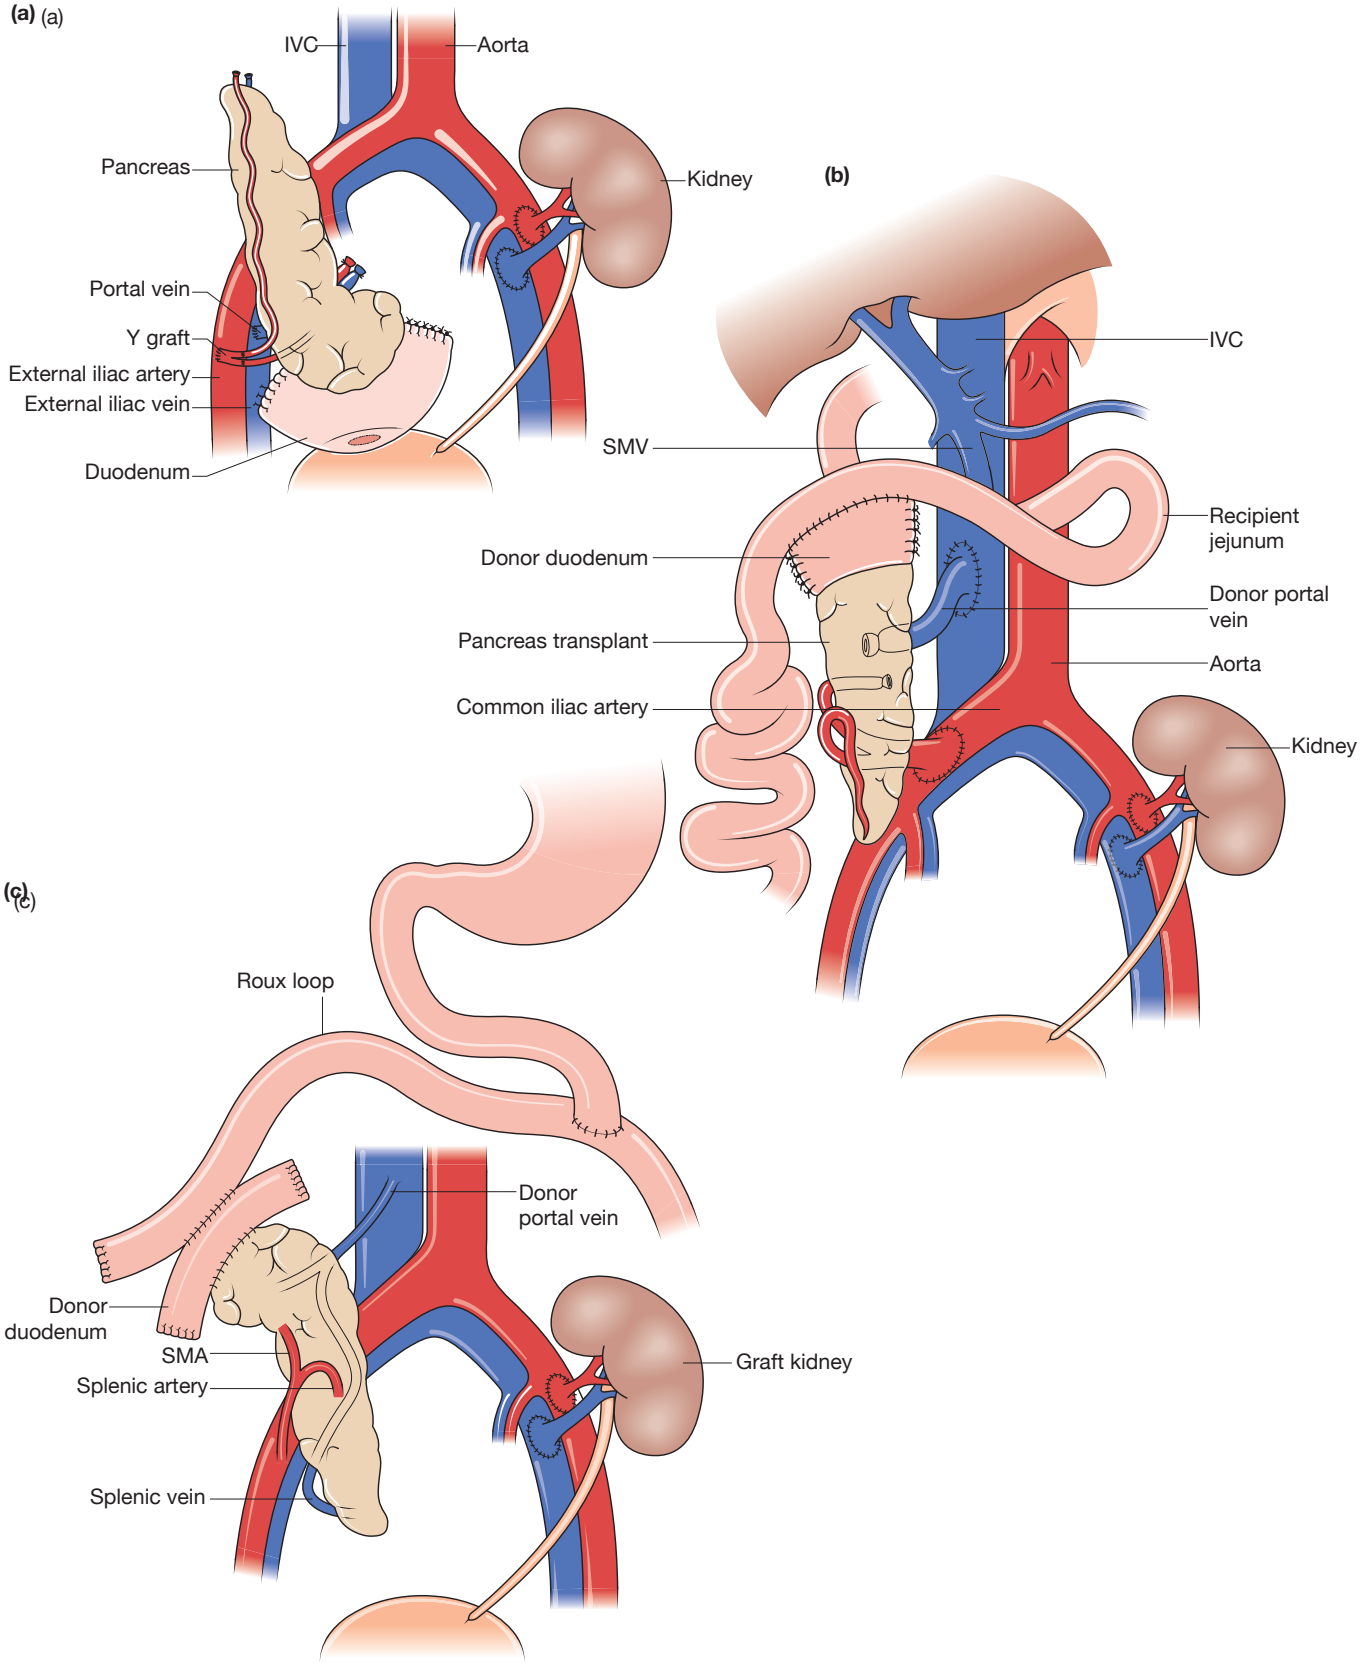

Figure 90.3 Illustration of the organ positions in a simultaneous kidney–pancreas transplant and the options for management of the exocrine secretions. **(a)** Transplanted pancreas positioned head-down with the duodenum anastomosed to the urinary bladder. **(b)** Transplanted pancreas positioned head-up with the duodenum anastomosed to the jejunum. **(c)** The donor duodenum anastomosed to the Roux limb of the Roux-en-Y construction. IVC, inferior vena cava; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

Summary box 90.3

Surgical techniques

- Careful inspection and preparation of the pancreas is essential and involves the construction of a Y-graft between donor iliac vessels and the SA and SMA to aid arterial anastomosis
- The pancreas is usually transplanted intraperitoneally with the PV anastomosed to the IVC and the Y-graft anastomosed to the CIA
- Drainage of enteric secretions is performed by anastomosis to the bowel, although bladder drainage can also be performed

POSTOPERATIVE MANAGEMENT

Anticoagulation

To minimise the risk of graft thrombosis in the early postoperative period anticoagulation is indicated for all patients. Every centre has its specific protocol: the exact details are less important than the balance between adequate anticoagulation to minimise thrombosis and over-anticoagulation leading to bleeding and the need for further surgery. Intravenous unfractionated heparin, dextran or epoprostenol are examples of preparations used; monitoring of their effect can be achieved by measuring prothrombin time (PT) and/or thromboelastography (TEG). TEG is a real-time bedside test that gives a numerical value for overall coagulation. The heparin dose or infusion rate of therapy can be amended according to the TEG or PT results. TEG has an advantage over PT as the result is immediate and analysis incorporates the entire clotting cascade and platelet function. Patients usually require 24–48 hours of high-dependency care (high-dependency unit or intensive care unit) and close blood glucose monitoring is essential. Insulin secreted by the transplant pancreas drains directly into the IVC and straight into the systemic circulation without passing through the liver, thereby avoiding first-pass metabolism. This is unlike normal physiology where insulin drains via the portal vein through the liver. As a result of high systemic insulin levels the patient may require intravenous glucose supplementation to maintain blood glucose levels. This phenomenon usually accommodates within 48 hours. If blood glucose levels rise above 8 mmol/L, then cross-sectional imaging with arterial phase contrast is usually performed to assess for thrombosis. The presence of a small volume of thrombus in the distal ligated end of the SMA is considered normal. However, thrombus propagating from the stump into the SMA, SA thrombus or PV thrombus should be treated with full anticoagulation. The indication for surgery is limited to complete thrombosis of the arterial inflow or PV; thrombectomy usually fails, resulting in graft pancreatectomy.

Complications

Major abdominal surgery carries a number of general risks which are well detailed elsewhere; for the sake of brevity, they will not be discussed here. Pancreas transplant patients are assessed preoperatively to rule out significant cardiac disease and to ensure that they are suitable for major surgery. Despite this, longstanding diabetes means that complications are common and potentially serious. Intraoperative complications such as bleeding following reperfusion can lead to the need for blood transfusion and inotropic support. Up to one in three patients require further surgery postoperatively. This may be due to reperfusion pancreatitis or bleeding. Reperfusion pancreatitis (a manifestation of ischaemia–reperfusion-related injury) can result in an amylase-rich transudate around the pancreas and in the abdominal cavity. Drainage may be necessary to aid recovery: in patients with an ongoing inflammatory state clinicians have a low threshold to return to the operating theatre for washout and debridement of peripancreatic necrosis. Thrombosis affects up to 8% of patients and this may result in early graft loss or β-cell dysfunction. Anastomotic leaks, particularly from the duodenum, are rare but difficult to manage; they can be controlled with direct drainage, such as a Foley catheter within the duodenum. However, such complications may necessitate surgical revision or, in extreme cases, graft pancreatectomy.

Bladder-drained pancreases can cause cystitis from pancreatic enzyme secretion and electrolyte disturbance, acidosis and dehydration from the loss of bicarbonate. Up to 50% of patients with bladder-drained pancreas transplants require enteric conversion (where the transplant duodenum is surgically detached from the bladder and reconnected to the small bowel) within the first year following transplant. This usually follows recurrent hospital admissions for acidosis and is performed to mitigate the risk of acute kidney injury. Also, the indication for conversion may be driven by patient choice because of symptoms from chemical cystitis, urinary tract infection (UTI) and the need for high-dose oral sodium bicarbonate. Late complications of pancreas transplantation include pseudoaneurysm formation, which may result from fungal infection or a vascular anastomosis, and highlights the importance of culturing the preservation fluid at the time of transplant and treating any cultured microorganisms.

A full list of complications following pancreas transplantation is given in *Table 90.1*

IMMUNOSUPPRESSION AND FOLLOW-UP

Long-term monitoring

Blood glucose monitoring is reassuring for the patient but, once glucose levels are raised as a result of graft rejection, it is usually too late to reverse. Haemoglobin A1c (HbA1c) levels are an independent predictor of long-term graft function and oral glucose tolerance testing can also be used to assess organ dysfunction and aid management. Fasting C-peptide and insulin levels can also give an idea of pancreatic function. Cellular rejection is difficult to diagnose owing to the absence of a biomarker: in patients who have undergone SPK, serum creatinine can be used as a surrogate marker and renal biopsy

Frederic Eugene Basil Foley, 1891–1966, urologist, Ancker Hospital, St Paul, MN, USA.

TABLE 90.1 Complications following pancreas transplantation.

Generic complications	Enteric drainage	Bladder drainage
• Bleeding • Reperfusion pancreatitis • Thrombosis • Paralytic ileus • Rejection • Infection – e.g. CMV, candida • Retinal haemorrhage and worsening of vision • Limb ischaemia	• Anastomotic leak • Stoma formation • Exacerbation of gastropathy and malnutrition	• Loss of sodium bicarbonate and acidosis/ extracellular volume depletion • Chemical cystitis • Urethritis • Bladder leak • Reflux pancreatitis • Recurrent UTIs • Bladder stones[a] • Urethral strictures[b] • Urethral irritation[b] • Epididymitis[b] • Prostatitis and prostatic abscess[b]

CMV, cytomegalovirus.
[a]Linked to duration of transplant.
[b]Documented complications but very rare.

performed, although discordant rejection of kidney and pancreas is a well-recognised event. However, if the pancreas rejects but not the kidney, the diagnosis is much more difficult and relies on cross-sectional imaging (to exclude vascular complications) and a high level of clinical suspicion. In PTA, the exocrine secretions can be managed by anastomosis with the urinary bladder, which means that urinary amylase can be measured sequentially and used as a biomarker of pancreatic function and a surrogate for rejection. A reduction in levels of urinary amylase may indicate rejection. Cystoscopic duodenal biopsy can be performed but the histology is often difficult to interpret and the presence of lymphocytes may not necessarily indicate rejection. Computed tomography angiography may show peripancreatic inflammation, which would be consistent with rejection and be an indication for rescue therapy.

Outcomes

There are no randomised controlled trials that compare the outcome of SPK transplantation with kidney transplantation alone, so best practice has mostly been determined from registry analyses and single-centre experiences. The major limitation of comparing SPK with deceased donor kidney transplantation is the inherent selection bias that patients who are suitable for SPK are fit enough to undergo major abdominal surgery and those undergoing deceased donor kidney transplant may not be. However, registry analyses show a clear survival benefit of SPK compared with deceased donor transplant. Adjusted 10-year patient survival rates were 67% for SPK recipients, 65% for LD kidney recipients and 46% for deceased donor kidney recipients. In the UK, 1- and 5-year pancreas graft survival for patients undergoing their first SPK is 90% and 81%, respectively. Patient survival is 98% and 89% at 1 and 5 years, respectively. PTA has the poorest long-term survival because of high rates of early thrombosis and cellular rejection but provides exogenous insulin production to treat the complications detailed above. For pancreas alone transplants the outcomes are still inferior with 1- and 5-year pancreas graft survival of 82% and 54%, respectively. In the USA, the data are similar with 5-year pancreas graft survival currently 73% for SPK, 65% for PAK and 53% for PTA; 5-year patient survival rates are 93% for SPK, 91% for PAK and 78% for PTA recipients, respectively.

Immunosuppression

Immunosuppression is split into induction (immediate post transplant) and maintenance (long term) therapy. Induction therapies include non-depleting antilymphocyte antibodies that cause T-cell inactivation, such as basiliximab, which blocks the interleukin-2 receptor and inhibits T-cell expansion. T-cell-depleting antibodies have largely replaced non-depleting therapies as a more effective way of suppressing lymphocytes. These include polyclonal ATG and the monoclonal antibody alemtuzumab (Sanofi). The use of T-cell-depleting antibody therapy has reduced rejection levels but without a corresponding effect on graft or patient survival. Alemtuzumab is easier to administer and is associated with lower rates of viral infection than ATG, so is preferred by some transplant units. Maintenance immunosuppression has evolved from triple therapy with ciclosporin, azathioprine and steroid to current practice with tacrolimus and mycophenolate mofetil. Steroid-free regimes are aimed at minimising insulin resistance and wound infection and are favoured by some centres. Comparison of ciclosporin with tacrolimus in combination with mycophenolate mofetil (MMF) and steroid, plus induction with ATG, in the EUROSPK 001 trial showed a reduction in the rates of severe rejection, with lower rates of pancreas graft loss at 3 years in the tacrolimus combination group.

Summary box 90.4

Immunosuppression and follow-up

- Pancreas rejection is challenging to diagnose and once glucose levels rise it is usually too late to reverse
- Outcomes from SPK and LD kidney transplant are similar and both options offer a survival advantage compared with deceased donor transplant
- Induction therapy with lymphocyte-depleting antibodies (alemtuzumab, ATG) has reduced rejection rates without changing graft and patient survival

FUTURE WORK

The major limiting factor in pancreas transplantation is greater morbidity compared with kidney transplantation alone. This is largely a function of the immediate reperfusion pancreatitis that is a common sequel to implantation. A second limitation is the very poor utilisation of donor organs: in the UK, only 25% of organs that are offered are actually transplanted. The risk profile of the organ donor population is increasing (largely because of age) and this increases the need to develop a means of preservation and organ assessment that gives clinicians the confidence that organs are suitable for transplant.

The development of novel preservation methods, such as machine perfusion, has been successful in other organs, but there has been no such advance in pancreas transplantation – this is largely a function of the relatively small numbers of patients undergoing this procedure. New methods of graft surveillance to detect rejection or other complications at a much earlier stage are also needed. International collaboration and multicentre clinical trials are needed to advance practice. If it were possible to reduce the morbidity and improve the survival of pancreas transplants to the same level as kidney transplants, the indications for this procedure would expand, possibly allowing patients to benefit before developing kidney failure.

ACKNOWLEDGEMENT

Our sincere thanks to Mr James Gilbert for supplying the photographic images.

CHAPTER 91

Intestinal and multivisceral transplantation

Learning objectives

To understand:

- The indications for intestinal transplantation
- The assessment process for intestinal transplantation
- The different transplant types
- Both the medical and surgical complications associated with intestinal transplantation
- The outcomes associated with intestinal transplantation

BACKGROUND

Intestinal and multivisceral transplantation can be a life-saving therapy for patients with complications from the treatment of intestinal failure. Indications for this highly specialised type of transplant are broadening to include acute vascular catastrophes and some otherwise irresectable intra-abdominal tumours (e.g. desmoids and pseudomyxoma peritonei). Since the first successful multivisceral transplant in the late 1980s, more than 4000 transplants have taken place worldwide and outcomes continue to improve. Intestinal transplantation is the most challenging area of abdominal transplantation, with higher rates of complications than other transplant groups. These complications include rejection, sepsis, post-transplant lymphoproliferative disease (PTLD) and graft-versus-host disease (GVHD).

Graft and patient outcomes for isolated intestinal transplants are close to those for long-term parenteral nutrition (PN). The role of intestinal transplantation may be changing with earlier referral to try to avoid the complications of long-term PN, including intestinal failure-associated liver disease (IFALD).

INTRODUCTION

The first reported intestine-containing transplant in humans was performed in 1966, when a short segment of duodenum was included in a pancreas transplant. This was followed by attempts to transplant more substantial amounts of intestine, but these did not result in long-term survival. It was not until 1988 that the first 'successful' intestine-containing transplant was reported.

At this time intestinal transplants were a rarity but with increasing experience (both surgical and immunological) outcomes have improved, making intestinal transplantation a relatively routine procedure.

Changes in immunosuppression regimes (depleting antibodies and tacrolimus) have improved rates of rejection, a complication that is difficult to control and can be life-threatening.

In 1996 the International Intestinal Transplant Registry was established and reported a total of 180 transplants performed in 25 centres worldwide. By 2019 this number was over 4100, with almost double the number of active centres. The majority of transplants have been performed in the USA and Europe, with the most prolific units performing over 10 adult transplants per year.

With improvements in the management of paediatric intestinal failure the number of multivisceral and intestinal transplants in this group has fallen.

INDICATIONS FOR TRANSPLANTATION

Complications from PN for irreversible intestinal failure are the most well-established indications for intestinal transplantation (***Table 91.1***). Short bowel syndrome (SBS) is the most frequent cause for the need for PN. The aetiologies of SBS vary between the adult and paediatric population.

The most common causes for SBS in the paediatric population are volvulus, gastroschisis, necrotising enterocolitis and intestinal dysmotility or pseudo-obstruction. The last two result in functional SBS.

The most common causes for SBS in adults result from bowel resections owing to mesenteric ischaemia, inflammatory bowel disease (most commonly Crohn's disease), benign tumour resection and dysmotility or pseudo-obstruction.

Until recently, intestinal transplantation was only considered for patients with complications of PN, including loss of vascular access, recurrent life-threatening line infections (especially fungal infections) and IFALD. Increasingly patients are being transplanted for quality-of-life indications, although this remains controversial.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

TABLE 91.1 Current indications for intestinal transplantation in the UK.

1. Life-threatening complications of parenteral nutrition a. Progressive IFALD or non-IFALD • Assessed by biochemistry and biopsy • Combined intestinal and liver transplant is best considered in the presence of advanced liver disease (portal hypertension or advanced fibrosis)
b. Severe sepsis • More than one life-threatening episode of catheter-related sepsis for which no remediable cause can be identified • Endocarditis or other metastatic infection
c. Limited central venous access • Venous access limited to three major conventional sites in adults (above and below the diaphragm) and two major conventional sites above the diaphragm in children • Conventional central venous sites are defined as internal jugular, subclavian and femoral veins
2. Very poor quality of life thought likely to be correctable by transplantation
3. Surgery to remove a large proportion of the abdominal viscera considered untenable without associated multivisceral transplantation (e.g. extensive desmoid disease, extensive critical mesenteric arterial disease)
4. Localised malignancy considered amenable to curative resection requiring extensive evisceration (e.g. localised neuroendocrine tumours). Particular caution should be exercised in this group and patients should be discussed in a multidisciplinary multicentre forum (e.g. National Adult Small Intestinal Transplant [NASIT] forum)
5. Where the transplantation procedure is expected to preclude the possibility of future intestinal transplantation (e.g. loss of venous access or further human leukocyte antigen sensitisation)
6. Where the need for subsequent intestinal transplantation is considered likely and the risk of death is increased by excluding the intestine from the graft *Examples include predictable problems related to administering immunosuppression (e.g. line sepsis), or continuing severe intestinal disease such as diabetic visceral neuropathy, or ultra-short bowel syndrome, which may cause fluid, electrolyte and acid–base balance problems that would damage an existing or planned renal graft*
7. Transplantation of additional organs for feasibility reasons a. Renal transplantation b. Adults and children with corrected GFR of <45 mL/min/m^2 are evaluated for the possibility of simultaneous renal transplantation

GFR, glomerular filtration rate; IFALD, intestinal failure-associated liver disease.
Adapted from NHS Blood and Transplant (https://www.odt.nhs.uk/transplantation/small-bowel/).

If the indication for transplant is IFALD, the degree of liver impairment influences the organs required at transplant. Mild to moderate liver fibrosis may allow an isolated intestinal transplant to be undertaken. This results in improved patient outcomes, better organ utilisation and reversal of liver fibrosis with discontinuation of PN. Severe liver fibrosis or cirrhosis will necessitate a liver-containing graft.

Indications for intestinal transplantation continue to change and now include to facilitate the resection of some tumours (desmoids and pseudomyxoma peritonei). In this situation, without intestinal transplantation, extensive evisceration would render the patient dependent on PN. Hepatic cirrhosis with extensive portomesenteric thrombosis may make isolated liver transplantation technically impossible, so multivisceral transplantation may be considered for some individuals.

Acute widespread splanchnic ischaemia (arterial and venous) is a rare but growing indication for super-urgent intestinal and multivisceral transplantation as well as other acute abdominal catastrophes.

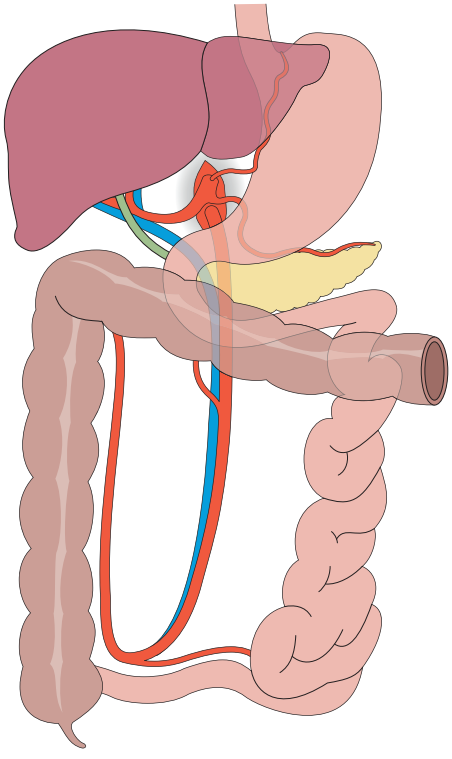
ASSESSMENT FOR TRANSPLANTATION

Assessment for a multivisceral/intestinal transplant requires a multidisciplinary approach, including:

- transplant surgeons;
- intestinal failure physicians;
- transplant anaesthetists;
- hepatologists;
- psychiatrists and/or psychologists;
- radiologists;
- infectious disease physicians;
- transplant specialist nurses;
- dieticians.

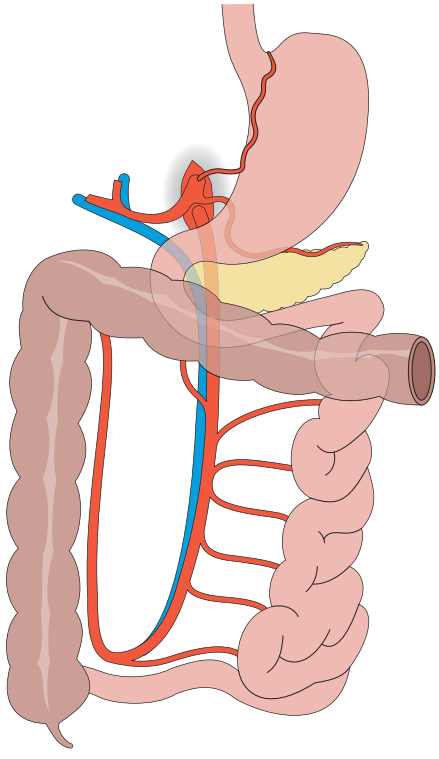
Assessment of venous access and the degree of liver fibrosis is critical. Patients on PN for a substantial time or who have ultra-short gut are at high risk of developing IFALD. They will need a liver biopsy as part of the assessment process. Detailed venous mapping is essential in all candidates.

Appropriate assessment of the cardiovascular and respiratory systems is necessary. Upper and lower gastrointestinal endoscopies may be necessary.



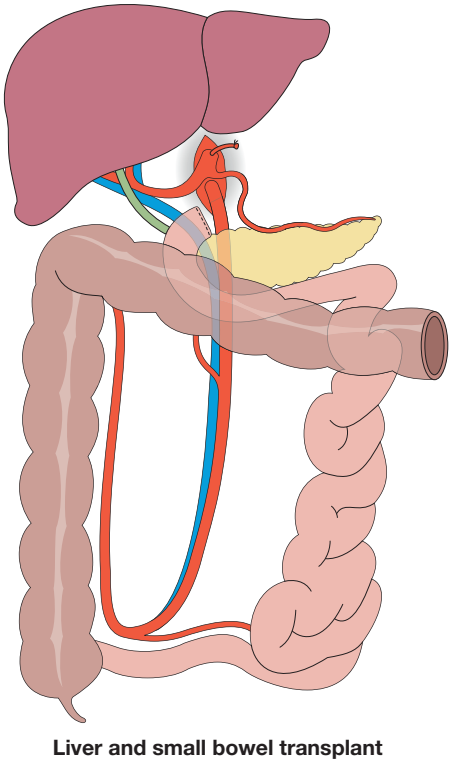
Cross-sectional imaging of the abdomen to assess the abdominal anatomy is central to operative planning.

Significant renal impairment may result in the need to consider inclusion of a kidney at the time of transplant.

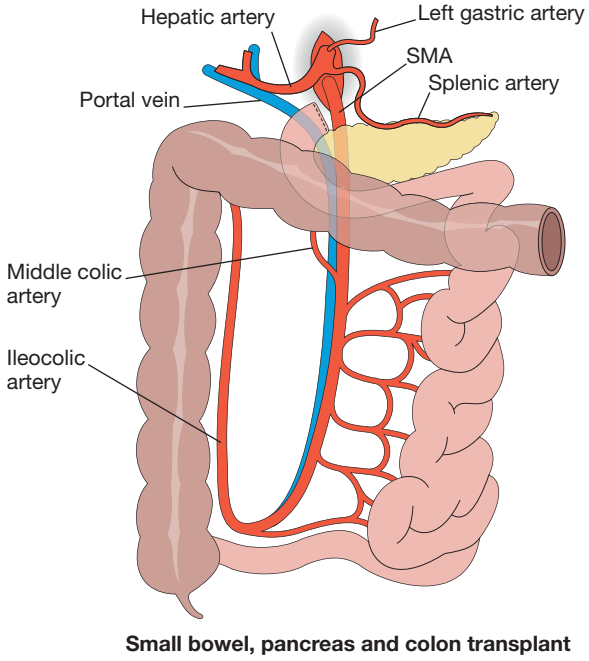


Patients should have anaesthetic and psychiatric assessment and dietetic review.

TYPES OF TRANSPLANT



Multivisceral or intestinal transplant covers a number of different 'cluster' transplants, as shown in ***Table 91.2*** and ***Figure 91.1***.



Full multivisceral transplant

Modified multivisceral transplant

Liver and small bowel transplant

Small bowel, pancreas and colon transplant

Figure 91.1 Types of intestinal transplant. SMA, superior mesenteric artery.

TABLE 91.2 'Cluster' transplants.

Transplant	Organs included	Extent of resection	Proximal enteric anastomosis
Small intestinal and colon transplant	Small intestine and colon (with/without pancreas)	Small intestine and part of colon	Duodenum or proximal jejunum
Modified multivisceral transplant	Stomach, pancreas, small intestine and colon	Stomach, pancreas, spleen, small intestine and part of colon	Proximal stomach or oesophagus
Liver and small bowel transplant	Liver, pancreas, small intestine and colon	Liver, small intestine and part of colon	Duodenum or proximal jejunum
Multivisceral transplant	Liver, stomach, pancreas, small intestine and colon	Liver, stomach, pancreas, spleen, small intestine and part of colon	Proximal stomach or oesophagus

PREOPERATIVE PLANNING

The decision regarding the type of transplant to be performed is dependent on a variety of patient factors. Intraoperative flexibility is necessary and may change the type of transplant undertaken.

A robust plan for adequate venous access is necessary and may require pretransplant venous reconstruction by the interventional radiology team or surgical reconstruction.

If substantial intraoperative blood loss is predicted, selective arterial embolisation may be considered. Commonly this will involve the superior mesenteric artery and coeliac axis, but more selective embolisation can be undertaken if preservation of the stomach or the pancreaticoduodenal complex is planned.

THE TRANSPLANT

Multivisceral/intestinal transplants are almost invariably performed with organs donated from deceased brain dead donors. A small number of living donor intestinal transplants have been performed.

In intestinal and multivisceral transplant procedures the donor and recipient operations occur simultaneously; this is not the case for liver and kidney transplantation. This is to minimise cold ischaemia time (the intestine is intolerant of ischaemia and ideally cold ischaemia times of less than 6 hours are required).

The recipient operation is often complex and technically challenging. Portal hypertension, extensive adhesions and distorted anatomy all result in these patients having surgically hostile abdomens, making the explant challenging. Substantial blood loss and transfusion may result in severe coagulopathy. Preoperative embolisation can reduce blood loss significantly. The extent of the explant is dependent on what transplant is required, a full multivisceral being the most extreme (*Figure 91.2*).

At retrieval the organs are retrieved en bloc (*Figure 91.3*), with the vascular inflow coming from the coeliac axis and superior mesenteric artery (SMA) and the venous outflow from either the portal vein (in a non-liver-containing graft) or the vena cava when a liver is implanted. This technique was first described by Starzl in the 1990s.

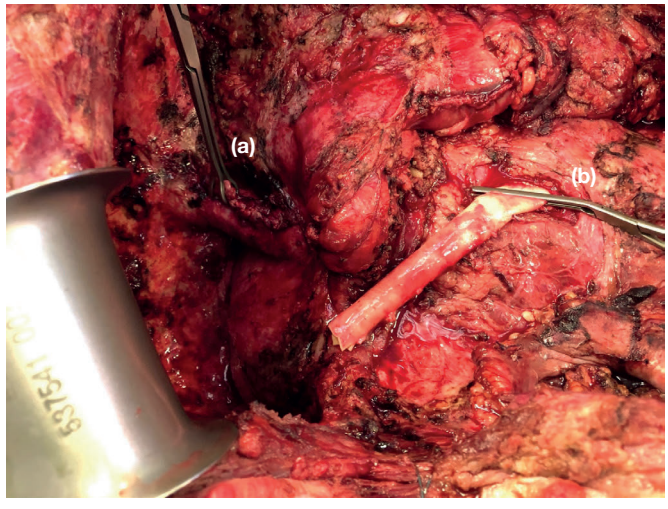


Figure 91.2 Intraoperative picture following exenteration. (a) Clamp on the retrohepatic cava in preparation for caval anastomosis (venous outflow for the multivisceral graft). (b) Clamp on the donor thoracic aorta anastomosed to the infrarenal aorta of the recipient (arterial inflow to the multivisceral graft).

Figure 91.3 Intraoperative picture following exenteration. Multivisceral graft (stomach, small bowel, pancreas and liver) immediately prior to implantation. The graft is preserved using University of Wisconsin solution.

Thomas Earl Starzl, 1926–2017, Distinguished Professor of Surgery, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA. Referred to as 'the father of modern transplantation'. He was awarded the USA's highest honour for scientific achievement, the Medal of Science, in 2005.

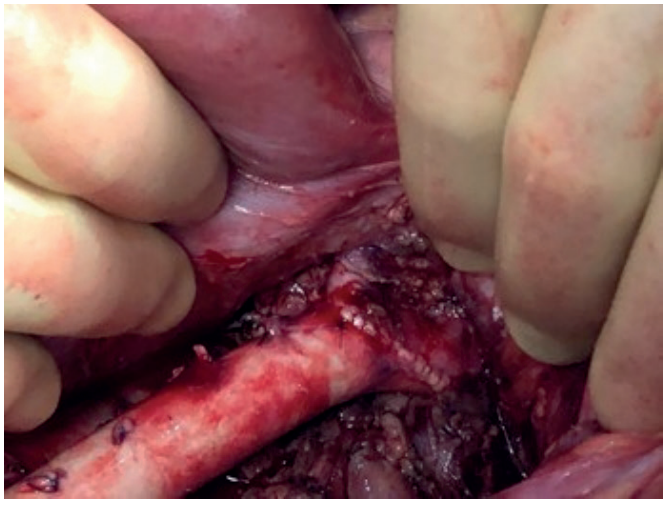

Figure 91.4 Intraoperative picture following exenteration. A Carrel patch (donor superior mesenteric artery and coeliac artery) onto an aortic conduit constituting the arterial inflow to the multivisceral block.

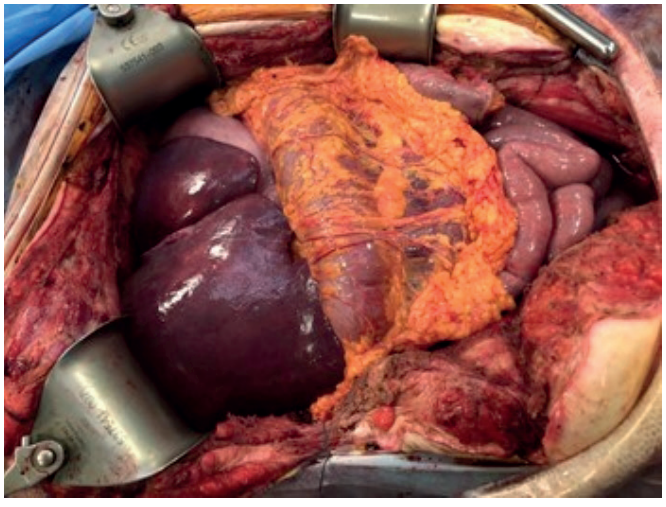

Figure 91.5 Intraoperative picture following exenteration. Intraoperative photograph of a multivisceral block (stomach, liver, small bowel, pancreas and colon) following reperfusion.

Arterial inflow to the graft is usually achieved from the infrarenal aorta. Commonly a section of donor thoracic aorta is used as an arterial conduit, onto which the donor aortic patch containing SMA and coeliac artery is anastomosed (***Figure 91.4***). In intestine-only grafts (not including the pancreas) the inflow is the SMA, which is either anastomosed directly to the aorta (as a Carrel patch) or the recipient SMA or a conduit can be fashioned from donor iliac vessels.

When undertaking a liver-containing graft, venous outflow from the whole graft is via the hepatic veins and inferior vena cava (IVC). For non-liver-containing grafts the venous outflow is via the portal vein. This can be drained either systematically via the IVC or into the portal circulation.

Following reperfusion of the graft (***Figure 91.5***) the enteric anastomoses are performed. This requires a proximal enteric anastomosis and a distal stoma or anastomosis. In some circumstances (modified multivisceral transplant) a biliary anastomosis may be required.

The proximal bowel anastomosis may be either oesophagogastric, oesophagojejunal, gastrogastric, gastrojejunal or jejunojejunal. If an oesophagogastric or gastrogastric anastomosis is performed, then a pyloroplasty is necessary (the block lacking vagal innervation).

An end stoma is the simplest option distally, but, where safe, a primary distal anastomosis can be considered. In most circumstances a covering ileostomy is performed. This allows ready access to the graft for endoscopic surveillance.

ABDOMINAL CLOSURE

One of the most challenging parts of a multivisceral/intestinal transplant is achieving abdominal closure. Multiple previous laparotomies and enterocutaneous fistulae can result in a rigid abdominal wall and loss of the abdominal domain owing to extensive bowel resections. Many techniques to achieve primary closure under these circumstances have been developed. These include preoperative tissue expansion, the use of biological meshes and plastic surgery techniques (e.g. vascularised pedicle flaps).

Transplantation allows novel techniques to be used, including transplantation of part or all of the abdominal wall from a donor. The rectus sheath from the donor can be used as a non-vascularised sheet of fascia. Prior to implantation the muscle and fat are removed from the rectus abdominis graft, leaving the fascial and peritoneal components. This can then be used as a biological 'mesh'. Unlike other biological mesh it vascularises rapidly. Skin coverage is achieved by mobilisation of the recipient's skin and subcutaneous tissues, although rarely a skin graft is needed.

Vascularised abdominal wall grafts can also be used where the anterior abdominal wall with its over lying subcutaneous fat and skin is transplanted using the inferior epigastric arteries and veins as the vascular inflow and outflow.

POST-TRANSPLANT COMPLICATIONS

With the complexity of multivisceral/intestinal transplantation complications are common (***Table 91.3***).

Early postoperative

Many patients considered for multivisceral/intestinal transplantation have underlying prothrombotic tendencies. A defined prothrombotic disease may be characterised but a history of multiple previous thrombotic episodes without a specific diagnosis necessitates a need for anticoagulation after transplantation. Balancing the risks of bleeding and thrombosis after transplant is challenging.

Enteric anastomotic leaks can occur after transplantation, most commonly if an oesophagogastric anastomosis is

Alexis Carrel, 1873–1944, French surgeon, received the Nobel Prize in Physiology or Medicine in 1912 for developing a method of suturing blood vessels.

TABLE 91.3 Early and late complications in multivisceral/intestinal transplantation.

	Surgical	Medical
Early	• Vascular (thrombosis, bleeding, secondary haemorrhage, mycotic aneurysm) • Enteric leak (anastomotic or non-anastomotic) • Abdominal collections (chylous, pancreatic, infected) • Pancreatitis (graft or native) • Stomal complications	• Renal impairment • Drug related (PRES, TMA, pancreatitis) • Infections (viral, bacterial, fungal) • GVHD • PTLD • Acute cellular rejection
Late	• Thrombosis • Mycotic aneurysm • Hernias • Stomal complications	• Renal impairment • Acute cellular rejection • Chronic rejection • PTLD • Immunosuppression-related malignancy

GVHD, graft-versus-host disease; PRES, posterior reversible encephalopathy syndrome; PTLD, post-transplant lymphoproliferative disease; TMA, thrombotic microangiopathy.

undertaken. Given that the enteric anastomoses are performed on previously ischaemic bowel, often under circumstances where inotrope requirements are substantial, the rate of anastomotic leaks is surprisingly low.

When an enteric leak does occur, the immunosuppressed state of the patient can result in an atypical presentation. Therefore, a high index of suspicion is needed should a patient fail to progress as expected postoperatively.

Proximal enteric anastomotic leaks, especially involving the oesophagus, are the most challenging to deal with. Oesophagogastric anastomotic leaks have a significant morbidity and mortality in the general population and are even more challenging to manage in an immunosuppressed patient. The use of an EndoVac® has improved management of these patients. A vacuum (vac) sponge fixed to a nasogastric tube is placed endoscopically in the cavity at the site of the leak. This controls the leak and facilitates healing without operative intervention.

Intra-abdominal collections are common and should be treated by aggressive radiological drainage where possible. These collections may be chylous and may require nutritional modifications, either PN or (if the patient is enterally fed) a medium-chain triglyceride diet should be adopted.

Immunosuppression and rejection

The rate of acute cellular rejection for intestinal grafts is higher than for any other abdominal organ. This is reflected in the magnitude of immunosuppression required. As with other solid organ transplants acute cellular rejection is most common in the first few months after transplantation, although it can occur at any time.

Multivisceral/intestinal transplant immunosuppression regimens commonly utilise an induction agent, usually a lymphocyte-depleting antibody such as antithymocyte globulin (ATG) or alemtuzumab. Paediatric regimens commonly use non-depleting antibody induction. Maintenance immunosuppression comprises a calcineurin inhibitor (most commonly tacrolimus), an antimetabolite (mycophenolate or azathioprine) and prednisolone. In addition, some programmes supplement this with early addition of an mTOR (mammalian target of rapamycin) inhibitor (sirolimus or everolimus).

Acute cellular rejection is usually initially manifested in the terminal ileum. Rarely other organs (liver/pancreas) may be affected without intestinal rejection.

Rejection most commonly presents with increased stoma output or diarrhoea, sometimes with an associated fever. Severe (exfoliative) acute cellular rejection with loss of intestinal mucosa results in rapid bacterial translocation and sepsis. In any intestinal transplant recipient presenting with sepsis or septic shock, a diagnosis of rejection needs to be considered.

Endoscopic assessment and biopsy of the graft are required for the diagnosis and assessment of the severity of acute cellular rejection. Graft surveillance in a protocolised manner is performed in some programmes; others respond to symptoms suggestive of rejection (i.e. an increase in stoma output).

At endoscopy, rejection can range from mild, with some erythema of the mucosa, to moderate, with some ulceration, to severe, with confluent loss of mucosa. At biopsy, salient features of rejection are an inflammatory infiltrate in the lamina propria, crypt loss and ulceration and an increase in apoptotic bodies in the base of the crypts.

Rejection is treated primarily with high-dose intravenous pulsed steroids. If the rejection is steroid resistant then further lymphocyte depletion may be needed with either ATG or alemtuzumab.

Infectious complications

Infection is the leading cause of death in multivisceral/intestinal transplant recipients. This is as a consequence of the degree of immunosuppression and also the potential for bacterial translocation across the graft mucosa. Opportunistic infections, common to all solid organ transplant recipients, such as cytomegalovirus (CMV), *Pneumocystis jirovecii* (PJP), adenovirus, Epstein–Barr virus (EBV) and fungal infections, are all more common following intestinal transplantation. Appropriate prophylaxis with antiviral (valganciclovir or aciclovir), antifungal (fluconazole) and anti-PJP (co-trimoxazole) agents is critical.

Infective enteritis is common among transplant recipients and can mimic rejection, thus it is important to send stool for culture and viral polymerase chain reaction when a patient presents with a high-output stoma or diarrhoea. Rejection triggered by infection is possible and a high index of suspicion and early repeat endoscopy are important if clinical improvement does not occur.

Michael Anthony Epstein, b. 1921, Professor of Pathology, University of Bristol, Bristol, UK.
Yvonne Barr, 1931–2016, virologist who emigrated to Australia. Epstein and Barr discovered this virus in 1964.

Long-term complications

PTLD is a potential complication of immunosuppression for any patient after transplant. The incidence in intestinal transplant recipients is higher than for other solid organ transplant recipients – up to 17% in some series. This is likely to be due to both the level of immunosuppression and the amount of lymphoid tissue associated with an intestinal-containing graft. PTLD should be considered if there is a persistent positive EBV viraemia or B symptoms such as night sweats, unexplained fevers and weight loss. If diagnosed with PTLD the first-line treatment is usually with rituximab and immunosuppression reduction. This has to be done with great caution in multivisceral/intestinal transplant recipients because of the risk of rejection and the consequences thereof.

The extent of lymphoid tissue associated with the multivisceral/intestinal graft increases the risk of GVHD. Outcomes from GVHD in this patient group can be very poor. The most common presenting symptoms of GVHD are a rash, fever and bone marrow suppression. Optimal management of GVHD is unclear and proposed strategies include both enhancement and also reduction of immunosuppression. Management is guided by the level of peripheral T-cell chimerism. There is an increasing trend towards withdrawing immunosuppression initially to rebalance the equilibrium between the host and donor immune systems. Bone marrow involvement and ultimately failure is almost universally fatal.

Deterioration in renal function is common to all solid organ transplant groups but is most marked following multivisceral/intestinal transplantation. The cause of this is multifactorial but is likely to include contributions from the physiological insult of surgery, the use of nephrotoxic medication (e.g. tacrolimus) and fluid losses associated with the stoma. It is imperative to maintain good hydration postoperatively and home intravenous fluids may be needed initially post discharge. Immunosuppression modifications including conversion from calcineurin inhibitor-based protocols to mTOR inhibitors may prevent further deterioration of renal function. These interventions need to be undertaken with caution as they may precipitate an episode of acute cellular rejection.

OUTCOMES

Graft and patient outcomes vary depending on the type of transplant undertaken with survival post-multivisceral transplant being markedly poorer than isolated small intestinal transplant. As with many transplant groups, outcomes are improving over time and the outcomes in the last published Intestinal Transplant Registry report in 2015 showed continued improvement in both 1- and 5-year patient survival. In 2019 the overall 1-year patient survival for intestinal-only grafts was >80% and for liver-containing grafts was >70%. A decade ago the 1-year patient survival for *all* intestinal transplant recipients (intestine only and multivisceral grafts) was 70%. Five-year survival rates have also improved and the long-term results of intestinal-only transplants are now comparable to those of long-term PN. Intestinal transplantation may have progressed to the stage at which it may be offered to patients on PN to improve their quality of life rather than just for those with life-threatening complications of PN.

SUMMARY

Multivisceral and intestinal transplantation remains a complex and uncommon treatment, however it can be life-saving. The risks are high but with improvements in surgical techniques, especially the introduction of preoperative embolisation, the intraoperative risks have improved. With this and a better understanding of how to manage the varied and complex postoperative complications, outcomes continue to improve.

Intestinal transplantation for patients on PN was previously reserved for those with life-threatening complications of this treatment. Outcomes have improved such that, in certain circumstances, it can now be offered to improve quality of life.

With time, improvement in patient management may allow intestinal transplantation to fulfil the same role for patients on PN as kidney transplantation currently offers those on dialysis: to improve both quality and length of life.

The need for liver-containing grafts will always remain for those who require a liver transplant but are unable to have a single-organ transplant for anatomical reasons. With improvements in liver functional assessment and increasing awareness of the possibility of earlier intestinal transplantation, it may be possible to reduce and hopefully eliminate the need for liver transplantation for IFALD. The benefits for the individual in terms of improved survival and also the population with better organ utilisation are substantial.

The main cause of death in multivisceral and intestinal transplant recipients remains sepsis. This is frequently associated with a preceding episode of severe acute cellular rejection and so further developments in immunosuppression regimens will be necessary to continue to improve patient outcomes.

PART 13 | Transplantation

CHAPTER 92

Heart and lung transplantation

Learning objectives

To recognise and understand:

- The indications and contraindications to transplantation of the heart and lungs
- The selection of recipients
- Heart and lung donation
- The technique for heart and lung transplantation
- Early postoperative complications
- Long-term outcomes

HEART TRANSPLANTATION

The incidence of heart failure is increasing as the population ages and coronary artery disease, hypertension and obesity rise. Current medical therapy, including resynchronisation pacemakers and implantable defibrillators, is effective in improving symptoms and survival but many will develop end-stage disease for which heart transplantation remains the gold standard surgical treatment.

Experimental procedures by Demikhov in the 1940s and the xenotransplantation of a chimpanzee heart into a patient with intracardiac thrombus by Hardy in 1964 led Lower and Shumway at Stanford University, CA, USA, to demonstrate that the circulation could be maintained entirely by an orthotopically transplanted heart. The first clinical heart transplant was undertaken in 1967 by the South African Christian Barnard, but mortality remained very high until the advent of modern immunosuppressants.

Heterotopic heart transplantation, in which a donor heart is transplanted as a biological biventricular assist with the native heart remaining in place, was first used clinically in 1974 but is now seldom used as long-term survival is poor.

Recipient selection

The primary indication for transplantation is prolonged advanced heart failure despite optimal medical management, often typified by repeated admissions or acute deterioration. The decision to transplant must take into account the patient's ability to withstand surgery and adhere to long-term treatment.

The most frequent indications for heart transplantation in adults are dilated and ischaemic cardiomyopathy. An increasing number of patients with adult congenital heart disease (ACHD) are now considered but need more complex surgery (abnormal anatomy, previous operations) and may have elevated pulmonary vascular resistance and immune sensitisation. There are higher early mortality results after transplantation although the long-term outcome in survivors is excellent.

Patients should be within the 'transplant window', being robust enough to survive the operation but their condition and prognosis should warrant the risks involved. As advanced failure can increase risk through the dysfunction of other organs (e.g. cardiorenal syndrome, liver dysfunction) reversible issues that can resolve with the improved cardiac output that transplantation will bring must be identified.

Elevated pulmonary vascular resistance (>5 Wood units and a transpulmonary gradient >15 mmHg) is associated with an increased risk of right ventricular failure and mortality after heart transplantation; if irreversible despite vasodilators, this resistance is a contraindication.

Age and previous cardiac surgery do not preclude transplantation and neither does diabetes if controlled with an absence of microvascular complications. A body mass index (BMI) >30 kg/m^2 has been associated with a worse outcome and weight loss is required before listing. Active infection is an absolute contraindication. Patients with chronic infections

---

Vladimir Demikhov, 1916–1998, Russian pioneer of organ transplantation, performed heart and heart–lung transplantation in animals between 1940 and 1950.
James Hardy, 1918–2003, performed the world's first lung transplant in 1963, undertook the world's first heart transplant attempt when he transplanted the heart of a chimpanzee into a dying patient in 1964.
Richard Lower, 1929–2008, American pioneer of heart transplantation who, with Shumway, developed many of the techniques required, including the use of hypothermia and the orthotopic technique in Stanford, CA, USA. Instrumental in the use of ciclosporin and in developing techniques of myocardial biopsy to monitor rejection.
Norman Shumway, 1923–2006, American pioneer of heart transplantation who, with Lower, developed many of the techniques required, including the use of hypothermia and the orthotopic technique in Stanford, CA, USA. Performed his first human heart transplant in 1968.
Christiaan Barnard, 1922–2001, performed the world's first successful heart transplant in 1967 after studying the techniques used by Lower and Shumway.

should have these eradicated by appropriate antimicrobial and surgical therapy. Malignancy, other than localised non-melanoma skin cancer, precludes transplantation but patients who have achieved sustained remission following cancer therapy may become candidates.

The presence of circulating antibodies against the allograft (allosensitisation) owing to pregnancy, blood transfusion, previous transplantation and the use of ventricular assist devices (VADs) is associated with worse outcomes and candidates are likely to have an extended waiting time to find a compatible donor. Screening for anti-human leukocyte antigen (HLA) antibodies is routine for all heart transplantation candidates.

Psychosocial factors such as substance abuse (including tobacco, alcohol) is a relative contraindication. Relapse of smoking has been associated with a poor outcome after cardiac transplantation.

Summary box 92.1

Criteria for heart transplantation

1. Impaired left ventricular systolic function
2. New York Heart Association III (e.g. patient cannot climb one flight of stairs without symptoms)
3. Receiving optimal medical therapy (maximum tolerated doses of β-adrenergic antagonists, angiotensin-converting enzyme inhibitors, aldosterone antagonists)
4. Resynchronisation pacing or implantable defibrillator device inserted (if indicated)
5. Evidence of a poor prognosis, e.g.
   a. Exercise testing (O_2 max <12 mL/kg/min if on β-blockade)
   b. Elevated B-type natriuretic peptide serum levels
   c. Calculated Seattle Heart Failure score indicating >20% 1-year mortality

Summary box 92.2

Factors considered in heart allocation

- Biological matching
  - Blood group compatibility
  - Appropriate size matching (accounting for recipient sex and pulmonary hypertension)
  - Need to avoid specific donor HLA antigens in sensitised recipients
- Clinical need
  - Severity of heart failure
  - Prognosis
- Logistic factors influencing ischaemia time
  - Distance of donor from the recipient centre
  - Prior surgery in the recipient (multiple sternotomies)
  - Surgical complexity (e.g. prior VAD, ACHD)
- Fairness
  - Time on the waiting list

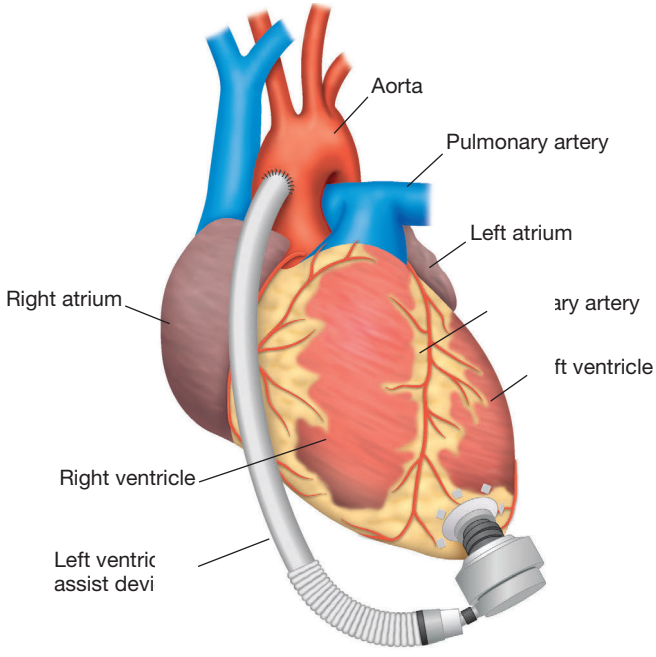

Figure 92.1 Typical implantable left ventricular assist device that takes blood from the apex of the left ventricle and passes it through a rotor to a graft anastomosed to the aorta. A driveline crosses the skin to a controller and battery pack providing electrical power.

Ventricular assist devices

VADs have had a significant impact. They may be used as a bridge to transplantation, a bridge to recovery (where the device is explanted if the patient's cardiac function improves) or as long-term durable destination therapy.

The first total artificial heart implant was performed by Cooley in Houston, Texas, USA, in 1969 with the patient subsequently undergoing heart transplantation 48 hours later. In 1966, DeBakey utilised a left VAD in a patient unable to wean from cardiopulmonary bypass after valve surgery.

Current generation devices use continuous non-pulsatile flow technology, which permits small device size, has the rotor as the only moving part and uses electrical rather than the more bulky pneumatic power delivery (***Figure 92.1***).

Patients can now remain on device support for years if necessary, although complications from anticoagulation (stroke, device thrombosis, gastrointestinal bleeding), right ventricular failure, aortic valve regurgitation and driveline infection are common; hospital readmission is frequent. Early mortality is akin to heart transplantation but long-term survival is inferior with 50% survival at 5 years.

Given the shortage of suitable donor organs, VAD implantation is an increasingly common approach for those deteriorating on the waiting list to gain time for a suitable donor heart to be become available. Future technology improvements are

Denton Cooley, 1920–2016, American surgeon, performed the first implantation of a total artificial heart and made major contributions to all aspects of cardiac surgery.

Michael DeBakey, 1908–2008, American cardiovascular surgeon, undertook the first surgery to implant an external ventricular assist device for heart failure and developed a classification of aortic dissection.

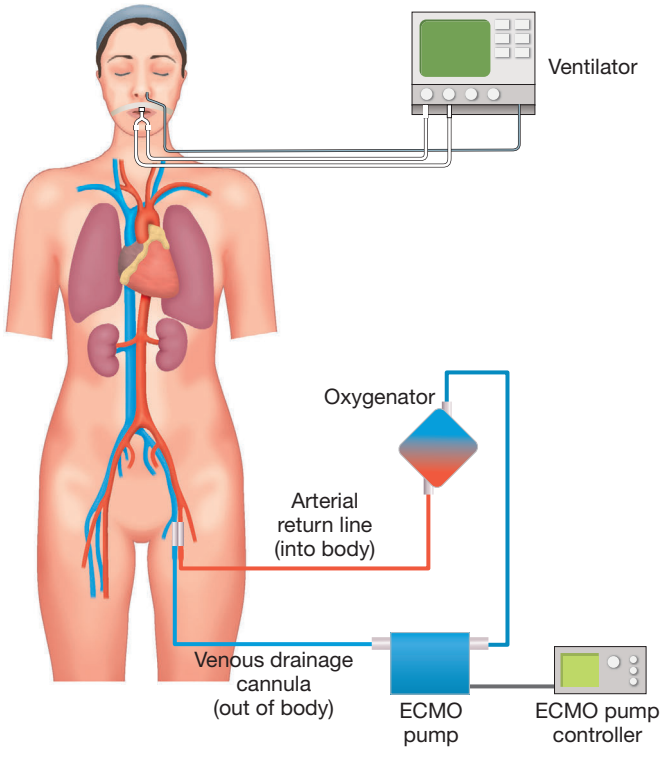

Figure 92.2 Extracorporeal membrane oxygenation (ECMO), which can be used for cardiorespiratory support before or after heart and lung transplantation. Blood is drained from the right atrium via the femoral vein, oxygenated and pumped back to the arterial circulation. In a variation where respiratory and not circulatory support is needed (venovenous ECMO) oxygenated blood is returned to the right atrium via the other femoral vein or jugular vein.

focused on increased biocompatibility, artificially generated pulsatility and avoidance of drivelines.

Among patients admitted in cardiogenic shock, venoarterial extracorporeal membrane oxygenation (ECMO) can be used to restore perfusion rapidly via the peripheral femoral artery and vein cannulation and permit urgent heart transplantation to be carried out within days, although the results are inferior (*Figure 92.2*).

Summary box 92.3

Complications associated with VADs

- Anticoagulation
  - Bleeding – gastrointestinal tract, intracerebral, subarachnoid, extradural
- Thrombosis
  - Pump obstruction
- Device failure
- Infection
  - Driveline, systemic sepsis
- Structural
  - Aortic regurgitation, tricuspid regurgitation
- Right ventricular failure
- Higher risks at transplantation
  - Adhesions, infection, vasoplegia

Donor selection and organ preservation

At the time of heart procurement from brainstem dead (donation after brainstem death [DBD]) donors, the heart must be arrested and explanted prior to transportation. There follows a period of ischaemia until the heart is reperfused in the recipient. Allograft ischaemic time is a strong risk factor for post-transplant mortality, especially when it exceeds 3–4 hours, so every effort must be made to keep this time period as short as possible. At retrieval cardioplegic solutions that inhibit the Na^+/K^+ ATPase cell membrane pump or lead to cellular depolarisation and diastolic cardiac arrest are infused into the aortic root to rapidly arrest and uniformly cool the heart.

Continuous heart perfusion is an alternative but more expensive and complex method of preservation. This is typified by the widely used Transmedics Organ Care System (*Figure 92.3*). Rather than being stored in an arrested and hypothermic state, the heart is kept warm and beating. It can be managed with inotropes and monitored through lactate assays, permitting longer transport times. Trials have shown that 30-day post-transplant survival is similar to standard preservation. There is some evidence to suggest that machine perfusion reduces mortality in higher risk donors and recipients and opens the potential for organ modification and improvement. Other systems that utilise cold oxygenated continuous perfusion of a still heart are under investigation.

To expand the current donor pool hearts may be retrieved from patients suffering circulatory arrest (donation after circulatory death [DCD]) after the withdrawal of life-sustaining care and proclamation of death (*Figure 92.3*). The heart is then rapidly retrieved and reperfused in an organ care system before transport and transplantation. Clinical results appear equivalent to conventional donation and this has been a major advance.

Heart retrieval

After exposing the heart by median sternotomy and opening the pericardium the organ is thoroughly inspected for contractility and coronary artery disease. Heparin is administered (300 U/kg) and a cannula placed into the aorta. The venae cavae are then occluded, the aorta cross-clamped and cardioplegia administered to arrest and cool the heart. The inferior vena cava (IVC) is vented.

When the lungs are retrieved the pulmonary artery will also have been cannulated and the left atrial appendage incised.

Cardiectomy is then carried out by dividing the superior vena cava (SVC), removing the cross-clamp and dividing the aorta and pulmonary artery at the bifurcation. The inferior vena caval incision is completed and the heart lifted to expose the inferior wall of the left atrium, which is then circumferentially incised to explant the heart. The interatrial septum is inspected to rule out a patent foramen ovale and all valves are carefully examined.

The heart is then placed in a bag filled with cardioplegia solution at 4°C. Two additional sterile bags are wrapped around it. These bags are then placed in a sterile container and then in a cooler for transport.

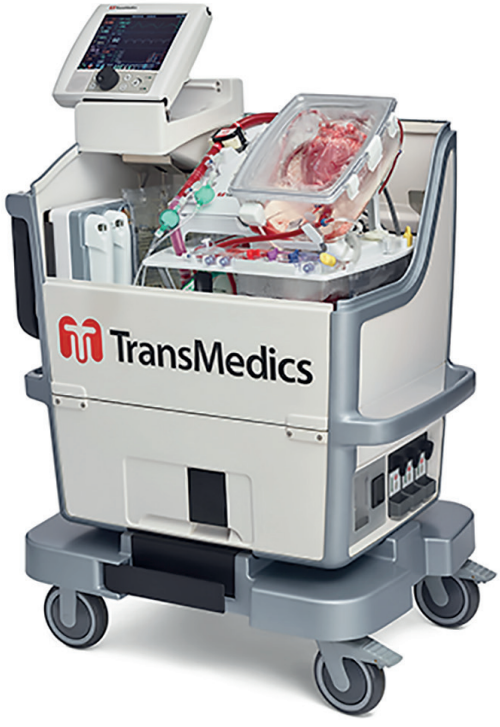

Figure 92.3 An organ care system that allows retrieved hearts to be perfused with warm oxygenated blood and remain beating during transportation to the recipient hospital. Devices can shorten ischaemic time and may be beneficial in higher risk patients. They have facilitated highly successful donor circulatory arrest heart donation to expand the donor pool.

Operative technique

Coordination between the retrieval team and the implanting team is of paramount importance to minimise ischaemic time and the duration of cardiopulmonary bypass.

A median sternotomy incision is performed and the aorta, SVC and IVC are encircled. After heparin administration the ascending aorta, SVC and IVC are all cannulated in sequence to establish cardiopulmonary bypass. Blood is drained from the cavae into a reservoir, then oxygenated, cooled to 32°C and returned via a roller pump to the ascending aorta to perfuse the body while the heart is excised and the transplant performed (*Figure 92.4*). Carbon dioxide is insufflated into the pericardial cavity to reduce the risk of air embolism.

When the donor heart arrives in the operating theatre, the recipient aorta is cross-clamped and the heart excised by dividing the SVC, IVC, aorta and pulmonary artery. The left atrium is incised, leaving a cuff of atrium into which the four pulmonary veins drain.

After administering a dose of cardioplegia to the donor heart, the left atrial cuff is anastomosed, followed by the pulmonary artery, aorta and both cavae. Donor and recipient vessels are trimmed to obtain a perfect match in terms of length and width.

A vent is placed in the ascending aorta for de-airing and the cross-clamp is removed, allowing reperfusion of the heart (*Figure 92.5*). Steroids are usually administered to reduce rejection.

Sinus rhythm is usually restored but temporary pacing wires are sutured to the heart for heart rate control. After a period of reperfusion (20 minutes for each hour of ischaemic time) to allow myocardial recovery, the new heart can be separated from cardiopulmonary bypass gradually, until it has taken over the circulation. Nitric oxide is useful at this stage to reduce pulmonary vascular resistance and protect the right ventricle from dysfunction. Isoprenaline is commonly infused.

A transoesophageal echocardiogram can help to assess biventricular function and valvular competence.

Outcomes and complications

Survival has dramatically improved with advances in immunosuppression and perioperative care, with 1-year post-transplant survival of over 90% and a median post-transplant survival of

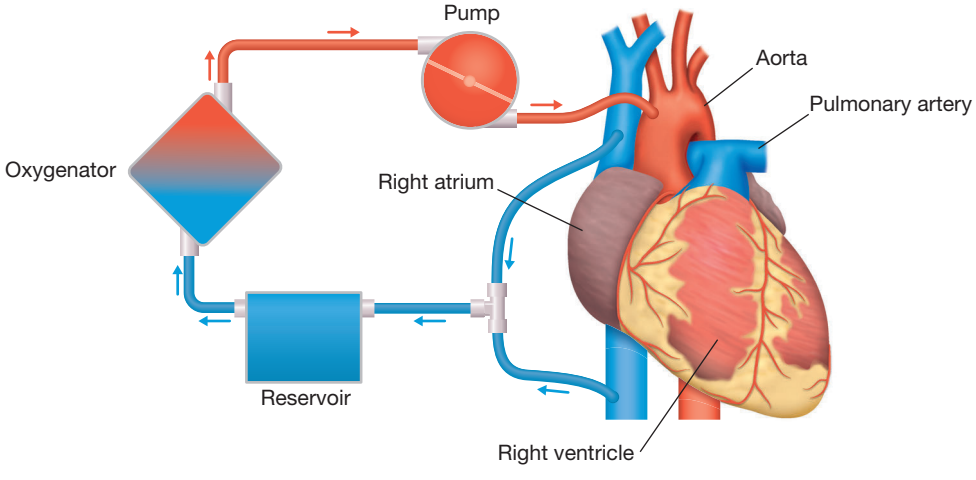

Figure 92.4 Cardiopulmonary bypass is used in heart transplantation and sometimes in lung transplantation. Blood is drained from cannulae in the superior and inferior venae cavae to a reservoir, then oxygenated in a membrane oxygenator before return to the ascending aorta via a roller or centrifugal pump. The patient can have their circulation maintained with oxygenated blood while the heart or lungs are explanted during transplantation.

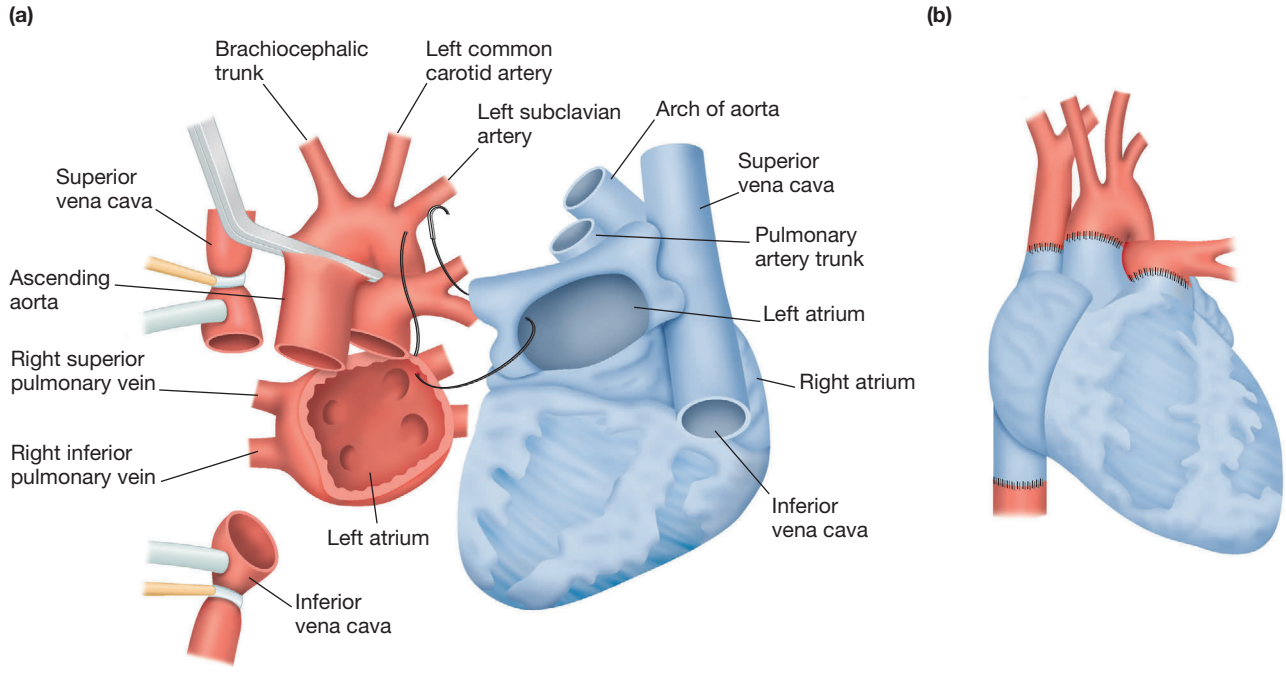

Figure 92.5 Cardiac transplantation. **(a)** A left atrial cuff is fashioned, into which the four pulmonary veins drain. This is anastomosed to a cuff of left atrium on the donor heart followed by anastomosis of the pulmonary artery, aorta and both venae cavae to complete the implant **(b)**.

approximately 12 years anticipated. Early mortality is 5–10% at 30 days but often higher in those who have a VAD implanted as the device must be explanted with the recipient's heart, increasing the complexity of surgery owing to adhesions and vasoplegia from long-term non-pulsatile flow or infection often being encountered.

After surgery most patients do not require rehospitalisation and functional status is good, with many returning to work and having a greatly improved health-related quality of life. Denervation of the heart is an unavoidable consequence of transplantation but, despite this, baseline cardiac function is preserved and increases in cardiac output are mediated by circulating catecholamines and stretch receptors responding to increased venous return with exercise.

Early after transplantation, the main causes of mortality include primary graft dysfunction, rejection and infection. Long-term survival is dictated by the development of chronic allograft vasculopathy (CAV) and immunosuppression-related malignancy, diabetes, infection and renal dysfunction.

Primary graft dysfunction occurs soon after implantation in around 10% of cases and is the leading cause of death. Low cardiac output and uni- or biventricular failure secondary to ischaemia–reperfusion injury occurs and is associated with older donor or recipient age, female-to-male donation, prolonged ischaemic time (>240 minutes) and donor-to-recipient size mismatch. Escalating inotropic support is needed, sometimes culminating in the institution of ECMO for circulatory support until the recovery of heart function.

Isolated acute right ventricular failure may occur secondary to prolonged ischaemic time, elevated pulmonary vascular resistance, volume overload or donor size mismatch. The use of inotropes and nitric oxide and the optimisation of volume and mechanical support may be required.

Three types of rejection can occur after heart transplantation: hyperacute rejection, acute cellular rejection and antibody-mediated rejection. Hyperacute rejection occurs intraoperatively immediately after reperfusion. Cross-matching of blood type and panel reactive antibodies has rendered this very unlikely.

Lifelong immunosuppression is required, balancing prevention of rejection but avoiding the adverse effects of malignancy, infection, renal dysfunction, hypertension, diabetes and hyperlipidaemia. Most patients are prescribed triple therapy, consisting of a calcineurin inhibitor (e.g. ciclosporin, tacrolimus), an antimetabolite (e.g. azathioprine) and a tapering dose of steroids. Induction therapy with antithymocyte globulin or interleukin-2 receptor antagonists (basiliximab) is sometimes used but this may increase the risk of infection and malignancy with no survival benefit.

The risk of acute rejection is highest in the first 6 months and a regime of routine surveillance cardiac biopsies obtained from the right ventricle via a bioptome inserted through the internal jugular vein are carried out. Alternatives to biopsy have been explored, especially the modalities of cardiac imaging, but they have been associated with low accuracy. Gene expression profiling of blood mononuclear cells is under investigation and may be promising in the future. Free DNA of donor origin in the recipient's blood has also been tested as a means to predict rejection in the transplanted heart.

Acute cellular rejection is a T-cell reaction to the donor's HLA molecules that occurs in 20–40% of patients, most commonly during the first 12 months. It is classified based on the severity of lymphocytic infiltrates and myocyte damage and is treated with high-dose corticosteroids. With modern immunosuppression and the low risk of late cellular rejection, biopsies are often ceased after 3 years.

Antibody-mediated rejection is seen in 10–20% of patients and has a mortality rate of 8%. Donor antigens and recipient antibodies form an antigen–antibody membrane attack complex that leads to endothelial injury. The diagnosis of antibody-mediated rejection is confirmed by the presence of circulating donor-specific antibodies (DSAs) with evidence of complement activation. This is treated with intravenous immunoglobulin, plasmapheresis, antilymphocyte antibodies and high-dose steroids.

CAV is a frequent long-term complication of heart transplantation and the leading cause of late mortality. It has an incidence of 30% at 5 years with a complex pathogenesis involving immunological factors and ischaemia–reperfusion all implicated. Diffuse thickening of coronary arterial intima occurs, often affecting the entire length of the epicardial vessels and typically extending to the microvasculature. As the heart is denervated recipients do not experience ischaemic chest pain. By the time the patient presents with declining left ventricular function and heart failure, the prognosis is poor. CAV surveillance by serial coronary angiography often combined with intravascular ultrasound can reliably detect intimal changes early to allow for treatment modification or consideration of retransplantation.

Future perspectives

Contemporary immunosuppressive therapies and modern surgical and perioperative techniques have all contributed to improved outcomes. The principal innovations being investigated for the future are aimed at increasing donor availability and improving the long-term survival.

Xenotransplantation has been extensively investigated with the use of transgenic pig hearts. In 1964, Hardy performed a xenotransplant using a chimpanzee heart that beat for 90 minutes before failing, and in 1984 infant Stephanie Fae Beauclair (often referred to as Baby Fae) famously lived for 21 days after receiving a baboon heart. Gene-editing techniques that allow modification of antigen expression are among the biggest technological breakthroughs to support the resurgence of xenotransplantation. Knockout pigs that lack swine leukocyte antigens to reduce organ immunogenicity have led to pig-to-primate allograft survival of up to 945 days. Despite the technical and scientific challenges the first contemporary pig-to-human transplant was undertaken in 2022 at the University of Maryland, USA, with good early clinical xenograft function using a pig heart with 10 genetic modifications, including four knockouts (three responsible for rapid antibody-mediated rejection of pig organ and one to prevent excessive growth) and six human genes added to increase the likelihood of acceptance. Rejection in the medium and long term and the hazard of infection transmission with porcine retroviruses remain of concern.

The problems faced by xenotransplantation could be overcome by organ engineering. Decellularised extracellular matrix scaffolds of hearts can be created by removing cellular tissue then repopulating with autologous cardiac cells. Automatic contractility has been demonstrated.

In addition to finding new sources of donor organs, improvement of long-term survival remains a priority. New agents to provide better immunosuppression with less rejection and a more favourable side-effect profile remain under investigation. The induction of tolerance of the recipient immune system to donor antigens has promise and T-cell co-stimulation blockade, mixed chimerism (recipient bone marrow engraftment with donor bone marrow cells) and regulatory T-cell infusions are being studied. Personalisation of current immunosuppressants to individual patients may allow for adjustments based on molecular diagnostic techniques to increase efficacy and reduce side effects.

LUNG TRANSPLANTATION

Pulmonary transplantation has made significant advances since the first human lung transplant performed by James Hardy in 1963 in Mississippi, USA. Mortality and morbidity remain high, in part because lungs remain exposed to the environment through the airway.

For patients with end-stage pulmonary disease, lung transplantation can significantly improve both survival and quality of life. Approximately 80% of lung transplants are bilateral, with single-lung transplants and living related lobar transplants undertaken less often. Long-term outcomes for all recipient pathologies are superior with bilateral lung transplantation. Single-lung transplantation cannot be used in diseases where infection may remain in the other lung, such as in cystic fibrosis (CF) or bronchiectasis.

Recipient selection

Candidates have advanced lung disease with shortened life expectancy and poor quality of life owing to breathlessness and oxygen dependency. The most common indications are chronic obstructive pulmonary disease (COPD), CF, pulmonary arterial hypertension (PAH) and interstitial lung disease (ILD). Organ allocation schemes recognise the last as associated with rapid decline and poor prognosis. Their prioritisation has led to shorter waiting times and a 20–40% reduction in death on the waiting list. The lung allocation score (LAS) is a useful tool to select those most in need of a particular donor lung. Risks are calculated using a set of 17 patient-related variables,

Summary box 92.4

Pulmonary diseases and type of transplant

- Cystic fibrosis
  - Bilateral and living related (or cadaveric lobar transplants in small highly selected recipients in experienced centres)
- Interstitial (fibrotic) lung disease
  - Bilateral or single (but associated with poorer long-term survival)
- Emphysema/COPD
  - Bilateral or single (but associated with poorer long-term survival)
- Pulmonary hypertension
  - Bilateral (or rarely combined heart–lung transplantation especially if associated with congenital heart disease)

including age, BMI, underlying diagnosis group, presence of pulmonary hypertension and the 6-minute walk distance.

In deteriorating patients more conventional treatments can be used in some groups before transplant assessment. In COPD endoscopic lung volume reduction is increasingly recognised as a treatment option. Transmembrane conductance regulator modulators have improved outcomes for patients with CF with a reduction in exacerbation frequency and an improvement in quality of life and prognosis. This has resulted in a recent fall in transplantation for CF.

In idiopathic pulmonary fibrosis, antifibrotic drugs (e.g. nintedanib, pirfenidone) have slowed the rate of functional decline, but the clinical course remains progressive and unpredictable.

Although age should not be considered a contraindication to transplantation it is associated with comorbid conditions that may need to be taken into account. It is unusual to transplant patients over 70 years of age.

Previous surgery, such as lobectomy, lung volume reduction or pleurodesis, is not a contraindication to lung transplantation, although inevitably it makes the transplantation operation more challenging with a greater risk of bleeding, phrenic nerve injury, chylothorax and renal dysfunction. A pneumothorax occurring in a waiting-list patient can be managed as required as the choice of intervention is unlikely to affect future acceptance.

Untreatable major organ dysfunction, severe atherosclerosis, bleeding diathesis, high or low BMI, severe osteoporosis and chronic infection are all contraindications. In particular, infection with *Burkholderia cenocepacia*, *Burkholderia gladioli* and *Mycobacterium abscessus* can be associated with very poor post-transplant outcomes. For patients infected with hepatitis B and/or C, surgery can occur provided cirrhosis or portal hypertension are absent. Controlled human immunodeficiency virus (HIV) disease with undetectable HIV RNA, and compliance with antiretroviral therapy, allows transplantation to occur.

For those with a history of malignancy a low predicted risk of recurrence and a 5-year period of remission are required.

With regard to coronary artery disease, percutaneous coronary intervention may be undertaken ahead of transplantation or coronary artery bypass grafting when lung transplantation occurs. The degree of coronary artery disease deemed acceptable will vary but good results have been achieved.

In rapidly deteriorating patients who are otherwise excellent candidates a bridge to lung transplantation may be undertaken using ECMO support. This permits ongoing rehabilitation while awaiting a suitable organ and is preferable to ventilation, which is usually a contraindication to pulmonary transplantation as physiotherapy is more difficult, deconditioning likely and the onset of pneumonia and barotrauma more common. Venovenous ECMO can be used in patients with severe hypoxia whereas venoarterial ECMO is used for patients with both hypoxia and haemodynamic instability or pulmonary hypertension. Instituting ECMO, however, is associated with serious and potentially fatal complications, such as bleeding, infection and thromboembolism. Recent series have shown that outcomes from bridging to transplantation can be similar to those transplanted electively despite being far sicker.

Donor selection and organ preservation

More than 80% of potential lung grafts are declined because of concerns over donor history, chest trauma, pneumonia or aspiration. Ideally lung donors should demonstrate standard criteria but in reality only 20% of donors actually meet these values. Those outside of the standard criteria are called extended criteria donors. Experience has shown that these organs can be safely transplanted without detrimental effects on survival or longer term outcome. When oxygenation of donor lungs falls below the standard criterion of 300 mmHg aggressive donor management with alveolar recruitment, ventilatory optimisation, bronchoscopy and diuretics can lead to improvements.

Additionally the opiate abuse epidemic in the USA has led to a significant rise in the number of organ donors but with a concomitant increase in hepatitis C infection. Antiviral therapies, however, may enable widespread use of such donors in hepatitis C-negative recipients.

Summary box 92.5

Standard criteria lung donors

- Investigations
  - Clear chest radiograph
  - Negative Gram stain of bronchial secretions or purulent secretions
  - Arterial oxygen tension >300 mmHg (inspired oxygen fraction of 100% and positive end-expiratory pressure 5 cmH_2O)
- History
  - Age <55 years
  - Smoking <20 pack-years
  - No chest trauma
  - No aspiration
  - No pneumonia

Outcomes are adversely affected by a donor smoking history of an increasing number of pack-years. Recipients of donor lungs from smokers have a higher 3-year mortality and prolonged hospital stay after adjusting for age and oxygenation but this is not a consistent finding and there remains an overall survival benefit to using lungs from heavy smoking donors to reduce waiting-list mortality.

Lungs from older donors (>55 years) can be safely used to 70 years old and short-term outcomes of older donors are similar in well-selected cases. A history of cancer in the donor does not automatically preclude lung donation. Those with a history of skin cancer, as well as certain low-grade central nervous system tumours, can be used with minimal risk.

Lung retrieval

Flexible bronchoscopy is first performed to clear mucopurulent secretions or aspiration. After median sternotomy and exposure of the lungs in each pleural space, detailed inspection is carried out for masses, consolidation or contusion. Uniform

lung inflation must be observed with resolution of any areas of atelectasis. Lung compliance is also assessed by observing lung deflation when disconnected from the ventilator.

Heparin is administered and the main pulmonary artery cannulated. Prostaglandin E (500 μg) is then injected to induce pulmonary vasodilatation and 3 litres of a cold pulmoplegia preservative infusion is initiated. The left atrial appendage is incised to vent the effluent while the lungs are also topically cooled with saline. Lung ventilation continues during flushing to improve fluid distribution and prevent atelectasis.

The pulmonary artery is then divided proximal to the bifurcation and the left atrium is incised to create a cuff of left atrium on each side, into which the two pulmonary veins drain. Division of the pulmonary ligament on each side allows the lungs to be removed after inflating them to 25 mmHg and stapling the trachea, the lungs remaining inflated for transportation.

A 500-mL retrograde pulmoplegia infusion is carried out into each pulmonary vein to augment preservation and flush out clots from the vasculature.

The lungs are then placed into a bag containing pulmoplegia and double-bagged for transport within an ice-packed cooler.

Lungs are more resistant to warm and cold ischaemic times and safe transplantation can be undertaken with preservation times of 6–12 hours.

As in heart transplantation the use of DCD donors has expanded the donor pool. After the declaration of death the lungs are rapidly retrieved. Lungs are resistant to the effects of warm ischaemia much more so than the heart and outcomes are equal to those obtained with DBD donors. The avoidance of the catecholamine storm and associated inflammation associated with brain death may be particularly advantageous in these cases.

The technique for DCD lung retrieval is somewhat different. Five minutes after the declaration of death, bronchoscopy is performed and the lungs inflated. After rapid chest entry the pulmonary artery is quickly cannulated, the left atrial appendage is incised and pulmoplegia is started. The lungs are quickly inspected for abnormalities and topical hypothermia is accomplished with ice slush to limit the warm ischaemic time.

Most donors involve controlled withdrawal of treatment (Maastricht 3) but uncontrolled DCD (Maastricht 2) donation where failed resuscitation from unexpected cardiac arrest with a declaration of death is followed by heparinisation, the insertion of chest drains with *in situ* cooling of the lungs and consent for donation and organ retrieval has been shown to be efficacious in Spain. The use of *ex vivo* lung perfusion (EVLP) is recommended to allow for assessment.

Ex vivo lung perfusion

This technique involves placing donor lungs into a machine at the recipient centre; the lungs are ventilated and perfused with an electrolyte and protein solution for 2–4 hours, sometimes longer. This permits the reconditioning and evaluation of lungs that may not appear to be useable for transplantation in the first instance. Treatments may be administered that can optimise graft function, such as antibiotics, steroids and immunomodulatory drugs, and biomarkers for poor outcomes can be detected. EVLP may be used for logistic reasons to reduce ischaemic time and in the future it may permit *ex vivo* therapeutic interventions such as gene therapy. By using perfusates with an optimised colloid osmotic pressure, pulmonary oedema can be reduced, thereby improving gas exchange. The lungs can be monitored on the device for the development of changes in compliance, airway pressure, pulmonary vascular resistance and perfusate oxygenation. Bronchoscopy can be performed to resolve areas of atelectasis (***Figures 92.6 and 92.7***).

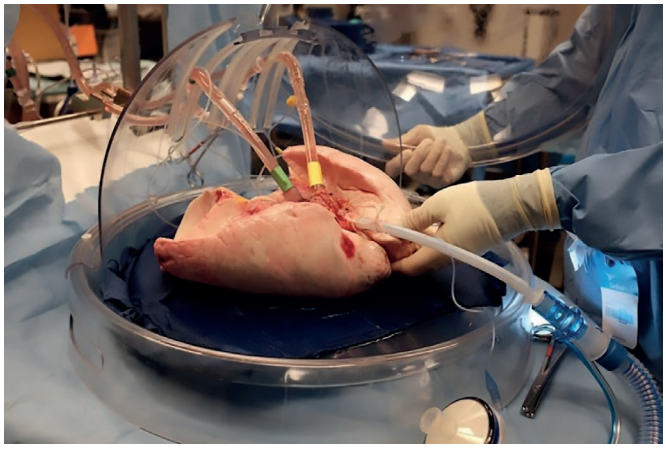

Figure 92.6 *Ex vivo* lung perfusion. The lungs have been explanted from the donor but may be borderline for acceptance for transplantation. Perfusion, bronchoscopy and ventilation in the system can recondition lungs to a useable state to permit the transplant to proceed.

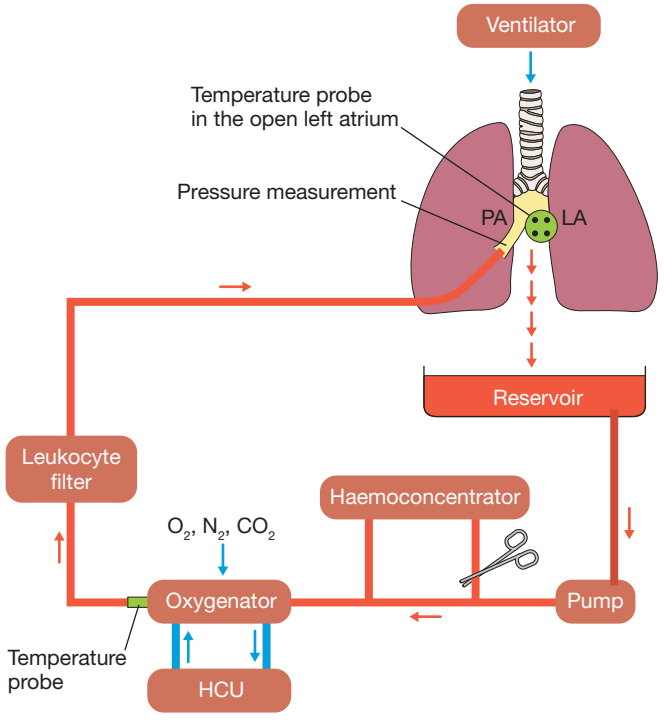

Figure 92.7 Schematic of a typical *ex vivo* lung perfusion circuit. HCU, heater–cooler unit; LA, left atrium; PA, pulmonary artery.

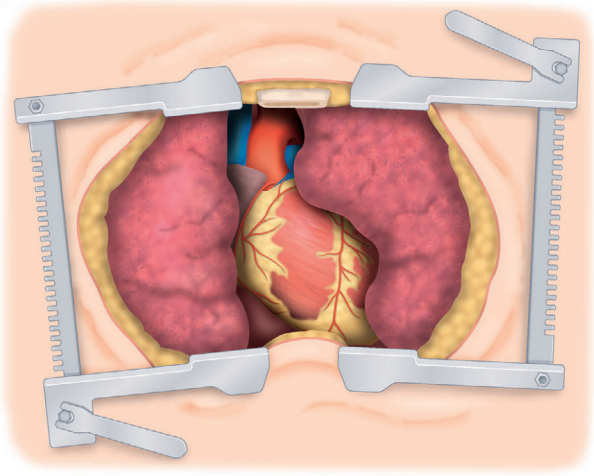

Figure 92.8 The clamshell thoracotomy commonly used for bilateral lung transplantation. Bilateral anterior thoracotomies through the fourth or fifth intercostal space are connected by division of the sternum. This facilitates excellent visualisation of the thorax

With this technique, lungs can be evaluated for function and quality between donation and transplantation with 35–97% of initially unacceptable lungs being used successfully with 5-year mortality rates equivalent to those of conventional transplantation, although some studies have suggested an increase in postoperative ECMO requirements and longer intensive care unit stays.

A different EVLP system that involves a portable organ preservation system taken to the donor hospital rather than the recipient hospital has also been shown to have favourable safety and efficacy.

Trials have been completed in which EVLP was used in standard criteria donors to assess whether this would lead to improved outcomes but no benefit was demonstrated.

Operative technique

The decision as to whether to use extracorporeal support during the transplant in the form of cardiopulmonary bypass or ECMO during bilateral lung transplantation varies with institutional experience, intraoperative stability and patient selection. Cannulation can be achieved either within the thorax or peripherally via the femoral vessels.

A clamshell thoracotomy incision (***Figure 92.8***) through the fourth or fifth intercostal space is often favoured with division of the sternum, but the procedure may also be performed using separate bilateral sternum-sparing anterior thoracotomies or via median sternotomy.

After opening both pleurae the pericardium is opened in preparation for central cannulation and to aid with hilar dissection and retraction of the heart. There are often significant adhesions in the pleural spaces that need dissection, although care not to injure the phrenic or vagus nerves should be exercised.

If an elective decision is made for cardiopulmonary bypass or ECMO, heparin is administered and aortic/femoral artery cannulation is performed for oxygenated blood return with right atrial (direct or via the femoral vein) cannulation for venous drainage. Extracorporeal support is generally avoided where possible owing to increased bleeding and an association with ischaemia–reperfusion injury.

After releasing the inferior pulmonary ligament, hilar dissection is carried out and pneumonectomy performed by division of the bronchus, pulmonary artery and both pulmonary veins. A large Satinsky clamp is placed across the left atrium and the individual pulmonary veins are opened and connected, creating a recipient cuff for anastomosis.

Recipient lung bronchial secretions are sent for microbiology and the hilum is prepared by circumferentially opening the pericardium to mobilise the left atrium and pulmonary artery. Mediastinal lymph nodes may need excision to facilitate the transplant. Bronchial arteries are ligated to prevent significant bleeding. Denudation of the recipient bronchus should be avoided to limit local ischaemia at the site of the anastomosis. The pleural space is then liberally irrigated with antibiotic or aseptic solutions.

The donor lungs are prepared for implantation by obtaining bronchial cultures for microbiology and dissecting the bronchus, pulmonary arteries and the left atrial cuff, into which the two pulmonary veins drain. Importantly the donor bronchus should be cut short just one or two rings from the bifurcation into the upper and lower lobe bronchi to minimise ischaemia at the anastomosis.

The implantation is then conducted by sequentially creating anastomoses between the bronchus, the left atrial cuff of the donor lung and the left atrium of the recipient and the pulmonary artery (***Figure 92.9***). Prior to reperfusion, 500 mg of intravenous methylprednisolone is administered.

The pulmonary artery clamp is removed slowly to lessen reperfusion injury and blood is permitted to escape from the left atrial suture line to de-air the vasculature before the left atrial clamp is opened.

After a period of ventilation on a low inspired oxygen concentration to reduce oxygen free radical release, the patient is ventilated and weaned from cardiopulmonary bypass or

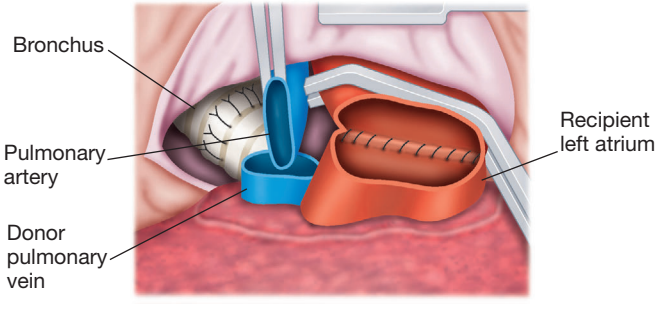

Figure 92.9 Hilum of the lung during lung transplantation. A left atrial cuff is fashioned into which the donor pulmonary veins drain. This is anastomosed to the left atrium of the recipient. The bronchus has been anastomosed already and the pulmonary artery is to be connected next.

Victor Satinsky, 1912–1997, American cardiovascular surgeon and co-creator of coronary bypass surgery.

ECMO if this has been used. Intraoperative echocardiography is used to check de-airing and the patency of the vascular anastomoses.

There has been a growing trend in the use of living related lobar lung transplantation for small recipients, especially in restrictive lung disease with low intrathoracic lung volume with two relatives each undergoing lower lobectomy. Results in a limited number of centres have been good but must be balanced against the risk of complications or death in the two donors.

Alternatively larger donor lungs can be reduced in size through multiple wedge resections and right middle lobectomy. With this technique, variable outcomes have been reported when using oversized donor lungs with donor–recipient size mismatch.

Outcomes and complications

Current median survival after pulmonary transplantation is 6.2 years. In recipients who survive the first year the median survival is 8.3 years and this is associated with a significant improvement in quality of life.

The main cause of postoperative mortality is primary graft dysfunction in which florid pulmonary oedema occurs with diffuse alveolar damage resulting from ischaemia–reperfusion injury. In survivors this is also associated with later dysfunction of the graft in the form of bronchiolitis obliterans syndrome (BOS). The pathogenesis is highly complex and involves acute-phase cytokines that are involved in inflammation that are upregulated or augmented in response to ischaemia or reperfusion and donor-specific characteristics such as infection, transfusion, barotrauma or smoking.

Summary box 92.6

Complications of lung transplantation

- Primary graft dysfunction
- Bleeding
- Parenchymal and pleural infection
- Bronchial anastomotic dehiscence or stenosis
- Vascular anastomotic stenosis or kinking
- Rejection – acute or chronic (chronic lung allograft dysfunction [CLAD])
- Infection – bacterial, viral or fungal – donor or recipient acquired
- Phrenic nerve palsy
- Gastro-oesophageal reflux

Summary box 92.7

Immunosuppression after heart and/or lung transplantation

- Induction (if used)
  - Antithymocyte globulin/interleukin-2 receptor antagonists (basiliximab)
- Maintenance
  - Ciclosporin, azathioprine, methylprednisolone

Primary graft dysfunction is treated with optimised ventilation, nitric oxide to improve ventilation–perfusion mismatch and diuresis. Support with ECMO is highly beneficial to allow for lung protective ventilation with eventual weaning when the lung injury recovers.

Infections are the second highest cause of mortality within 30 days. Most centres use broad-spectrum antibiotics in the postoperative period based on bronchoalveolar lavage specimens from both the donor and recipient lungs. Using donor lungs from hepatitis B core-positive donors is feasible with a low risk of transmission.

Rejection commonly occurs after lung transplantation. Immunosuppression is used postoperatively to prevent acute rejection as well as CLAD by inhibiting T- and B-cell proliferation and activation. Agents similar to those used after heart transplantation are commonly utilised but generally greater immunosuppression is needed compared with other organs because of the increased susceptibility of the lungs to rejection, and this significantly increases the risks of drug toxicity such as renal failure, diabetes and hypertension. Induction therapy may be given as in heart transplants but is not universally applied and side effects such as major infection and malignancies limit its use despite evidence of a survival benefit.

Acute cellular rejection occurs in around 30% of patients in the first year and is characterised by an acute decline in pulmonary graft function without any other cause. Diagnosis is confirmed histologically using scheduled transbronchial biopsies and is based on the presence of perivascular and interstitial mononuclear cell infiltrates. Pulsed high-dose steroid therapy is the mainstay of treatment with modified or augmented immunosuppression in resistant cases.

Antibody-mediated rejection is a separate entity in which DSAs directed towards donor HLA are present with neutrophil margination, arteritis and evidence of complement activation (C4d) present on histology. Treatment strategies focus on using plasmapheresis to deplete circulating DSAs, intravenous immunoglobulin and rituximab. Despite this a poor outcome is expected with a 1-year survival of less than 50%.

CLAD (which includes BOS) limits long-term survival after lung transplantation and has a prevalence of 50% at 5 years. It leads to a significant fall in lung function and treatment options are limited but may include extracorporeal photopheresis combined with augmented immunosuppressive regimens and total lymphoid irradiation. Pirfenidone is being investigated as a possible option. In advanced CLAD, retransplantation can be considered.

Gastro-oesophageal reflux disease is very common after pulmonary transplantation and has a strong association with the development of CLAD. Intraoperative vagal nerve injury, loss of cough reflex, impaired mucociliary clearance and immunosuppression-related gastroparesis may all be implicated. Early fundoplication has been suggested as an option.

The bronchial anastomosis is a common site of complications with dehiscence occurring from local ischaemia or infection and stenosis occurring longer term in 5% of cases. Reoperation to cover a defect with an intercostal muscle flap or endobronchial stent insertion for narrowed anastomoses is effective.

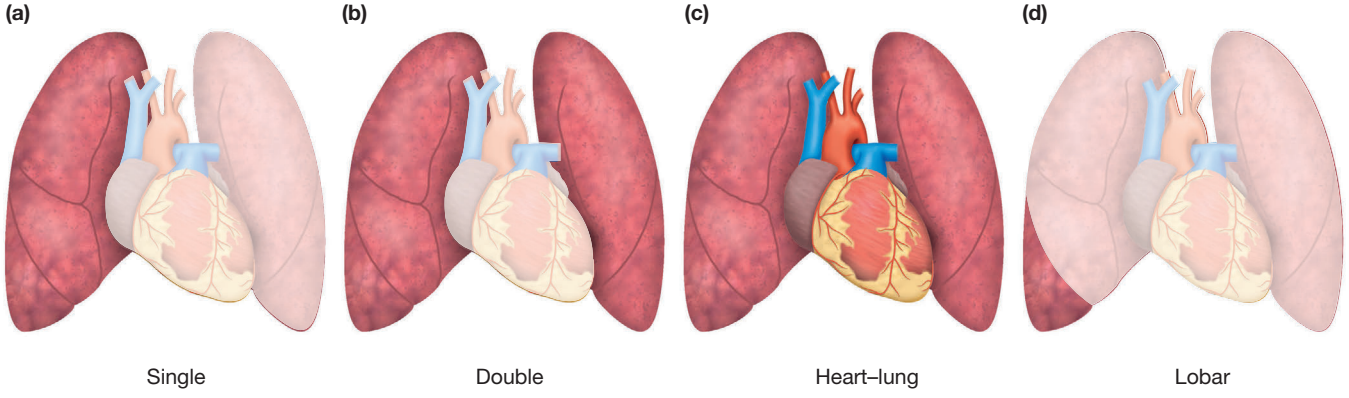

Figure 92.10 Types of lung transplant. Heart–lung combined transplantation is now rarely performed and is reserved mainly for congenital heart disease associated with pulmonary hypertension. Bilateral lung transplantation is the commonest option and accounts for 80% of pulmonary transplants performed. Single-lung transplantation can be used in cases where retention of the other lung will not pose a risk from infection, such as fibrotic lung disease or emphysema. Using this option in cystic fibrosis, for example, would be contraindicated. Single-lung transplantation is associated with inferior survival. Lobar transplantation is rarely performed but in experienced centres can provide good results in highly selected patients. In living related donation relatives would donate a lower lobe but risk complications.

Heart–lung transplantation

Combined heart–lung transplantation is an excellent treatment for PAH (***Figure 92.10***). However resolution of right ventricular dysfunction has been observed consistently after bilateral lung transplantation, making it the favoured option in the vast majority of patients, Currently, the main indication is in congenital heart disease with pulmonary hypertension. Early post-transplant survival remains lower than after lung transplantation. After a peak of activity in the late 1980s, the number of procedures has steadily declined to less than 100 per annum. Organ allocation systems are weighted towards directing hearts and lungs separately to urgently listed patients, making combined heart–lung donor blocks a rarity for these patients.

Future perspectives

Bioengineered artificial lung technology using recipient cells grown onto a decellularised lung scaffold is under development and will avoid an immune response; however, it remains a long way from clinical reality. Success would permit lung transplantation without the need for immunosuppression, waiting lists or rejection.

Artificial lungs, mimicking the success of VADs in heart transplantation, remain elusive. The physical volume of membrane oxygenators is too great for implantation within the thorax and devices are not durable, lasting weeks rather than months or years. Membranes are thrombogenic and high levels of anticoagulation would be required.

SUMMARY

As the population ages and coronary artery disease, hypertension and obesity increase in prevalence the incidence of heart failure continues to rise. Current medical therapy is effective in improving symptoms and survival but many continue to develop end-stage syndromes. The most critical issue is the growing number of patients on the waiting list and the relatively static donor pool. VADs have emerged as a strategy to bridge patients to cardiac transplantation if they are deteriorating or as durable destination therapy. However complications such as stroke, pump thrombosis and poorer long-term survival remain a challenge. Cardiac transplantation remains the gold standard for the treatment of end-stage heart failure and is associated with excellent outcomes for patients, but it is limited by chronic rejection and the side effects of immunosuppression.

Lung donor availability and increased waiting-list mortality are major challenges in pulmonary transplantation, but extended criteria donors can be safely used with good results. The use of DCD lungs and organs reconditioned with *ex vivo* lung perfusion has further expanded the donor pool, the latter technique showing promise for therapeutic interventions in due course.

Bridging patients with ECMO rather than ventilation to lung transplantation is successful for those most in need and new allocation systems have been implemented that have led to decreased waiting list mortality, especially in those with fibrotic ILD.

Overcoming primary graft dysfunction in the early postoperative period and chronic lung allograft dysfunction in the longer term are the main targets of ongoing research to improve outcomes for lung transplant recipients.
